[189] A.P. Davis, Director, to F.E. Weymouth, Acting Director, Reclamation Service, April 21, 1923; and Memorandum, From: Project Manager, To: Chief Engineer, April 28, 1923. Folder 303, Box 919, Entry 7, RG 115, NARA Denver.

[190] W.T. Young, President, Hudspeth County Conservation and Reclamation District No. 1, To the Honorable, The Secretary of the Interior, August 16, 1923; and W.T. Young, President, Hudspeth County

EBID and EP #1 were wary about the addition of these downstream lands to the project. Their concerns were similar to those articulated by Davis, that the project water supply would prove insufficient to irrigate land down to Ft. Quitman. EP #1 manager Roland Harwell, although like Davis sympathetic to Hudspeth landowners, consequently declined to accept the district's petition citing the need for "the consent of the Secretary of the Interior."[191]

Lawson, however, believed that efforts could be made to improve the water available to lands downstream without incorporating those lands into the project. Having received a forwarded copy of Harwell's reply to Young, the Rio Grande project manager observed in his own letter to the EP #1 manager that "recovered water from the Juarez and El Paso valleys below the International Dam [which turned water released from Elephant Butte into Mexico] if properly collected, would probably supply irrigation demands for the area now in cultivation in the Fort Hancock district." Additionally, given that current "methods employed by the Fort Hancock area in obtaining their water supply are entirely inadequate and wasteful," Lawson favored those area landowners undertaking "such construction work as will place them in a position to receive the beneficial use of such water as is available in the Rio Grande at the upper end of the area." Such an effort would leverage "the recently constructed intake works near Fabens for the [Rio Grande Project's] Tornillo Main Canal, which intake has the advantage of full river control," and would provide "for the collection of the lower project's recovered water and the delivery of this supply undiminished by river losses and unauthorized diversion to the Fort Hancock area." The Rio Grande Project manager also favored continuation of the delivery of such water to Hudspeth-area landowners on an annual contract basis "with the particular understanding that the quantity furnished is on a surplus basis and subject to prior project demands."[192]

Lawson had made substantially the same suggestions in a memorandum to Reclamation Chief Engineer F.E. Weymouth back in August 1923, and in October, Weymouth furnished his endorsement. At the same time, the chief engineer noted the need for the approval of EBID and EP #1, and advised against a proposed plan for downstream landowners to pay for the canal

extension itself and thereby obtain an ownership interest and a legal claim to its use. Weymouth expressly cautioned that "no water can be turn out of the Elephant Butte Storage for its [Hudspeth's] benefit."[193]

Reclamation Commissioner D.W. Davis approved of the plan in November, and after obtaining an assurance that it could enter into a temporary contract for "such waste water as would be available at the end of the Tornillo Canal," HCCRD #1 agreed to the proposal. Financed through a bond issue of $750,000, the district subsequently built a main canal with distribution laterals as well as a deep-well pump drainage system that was later replaced by an open drain system. In August 1924, Hudspeth executed a temporary contract which provided for the diversion of water from the river below the Rio Grande Project, as Fiock later reported, "through several private or community ditch headings which existed before the organization and development as a District."[194]

With the completion of the extension of Tornillo Canal, HCCRD #1 entered into a Warren Act contract with Reclamation in December 1924. Passed by Congress in 1911, the Warren Act authorized Reclamation to contract for impoundment, storage, or conveyance of non-project irrigation water in federal facilities, when excess waste was available. The Hudspeth district's Warren Act contract permitted the district to purchase waste or other excess water available at the end of the Tornillo Canal, the last major project irrigation structure, but it did not expressly guarantee any quantity of water to the district. According to Fiock, the canal was to supply those lands between Fabens and Ft. Quitman with "such waste, return flow and developed water as was considered might be available at the lower end of the project." It further defined the water delivered as "secondary and inferior to the right to use water for any purposed on the lands of the Rio Grande Federal Irrigation Project." In executing the contract, HCCRD #1 "relinquish[ed] any and all right, title, interest, and claim to any and all waters of the Rio Grande, except…as provided" by the contract. Both EBID and EP #1 acquiesced to the canal's construction, and paid for its construction. The two project districts viewed the arrangement with downstream

landowners as not only defraying their own project expenses, but also ensuring "beneficial use of such water [i.e., available waste, return flow, and developed water] at the end of the project.[195]

Starting with the 1925 irrigation season, water was delivered to land in Hudspeth County through the Tornillo Canal. The water supplied, however, remained inadequate. Both the Tornillo Canal and the Hudspeth district's own main canal lacked the capacity to deliver all the water required for irrigable lands downstream of the project. Moreover, the amount of water within the Tornillo Canal available for diversion was limited to that which passed through unused by the Rio Grande Project above. HCCRD #1 had to supplement its supply by diverting directly from the Rio Grande below the end of the Tornillo Canal. This water, although not part of the supply to be delivered when available pursuant to the Warren Act contract, nonetheless consisted of project drainage water (from drains emptying below Tornillo Canal) and surplus water in the river that had not been diverted into the Tornillo Canal yet had passed through the project. The latter occurred typically when the water in the river exceeded the capacity of the Tornillo Canal at its heading.[196]

That any water was available to Hudspeth County lands through Tornillo Canal was the result of project operations intended to supply the Tornillo district of the Rio Grande Project with water of sufficient quality (as noted in Opinion II above). This district was the last unit of the project, the furthest downstream. According to Fiock, a "50-50 mixture of upper valley irrigation water and the drain water discharging immediately above Fabens" was necessary to dilute the alkali in the water reaching this area, so Reclamation endeavored "to carry enough of the reservoir released water on through to Fabens" so that it could be "mixed with the drain water discharging immediately above Fabens." This, consequently,

> produced a total discharge at Fabens about equal to the capacity of the Tornillo Canal, or more than twice the amount necessary for the irrigation requirements of the Tornillo area alone, thus making available water for delivery to the heading of the Hudspeth District Canal at the terminus of the Tornillo Canal.

Moreover, when the amount of water – "a mixture of drain and upper valley irrigation water" – reaching Fabens exceeded "the capacity or requirements of the Tornillo Canal…[it] has been allowed to go on down the river." This was particularly true during the fall, winter, and early spring irrigations, which required "as much of the upper valley irrigation water supply reaching Fabens in order to accomplish the dilution of drain water." "[A] large part of the mixed water"

thus went "to waste" below the project and became available to lands downstream, between Fabens and Ft. Quitman.[197]

In the negotiations leading to the 1929 temporary compact, the water received by Hudspeth County lands was a focus of discussion. Various parties maintained that this water had to be considered in drafting a compact that would equitably apportion the waters of the Rio Grande above Ft Quitman. Major Richard Burges, an El Paso attorney who represented EP #1, HCCRD #1, and the City of El Paso, established the geographic boundaries for the commission's consideration at the first compact commission meeting in October 1924. Burges was deeply interested in a compact as lands in both El Paso and Hudspeth counties depended upon Rio Grande water. As no representative for Texas had yet been selected, he attended the meeting with Texas Governor Pat Neff's blessing. Burges stressed to the Colorado and New Mexico commissioners, Delph Carpenter and Julian O. Seth, respectively, that "the problem of the Rio Grande, as it affects the state of Texas," principally concerned "the El Paso Valley, which includes the irrigable lands in El Paso County and Hudspeth County." This was a point of view that Carpenter heartily accepted and Seth was willing to entertain once a Texas commissioner was formally appointed.[198]

Burges reiterated this stance in December 1928 after T.H. McGregor had been appointed the commissioner for Texas. Serving as special counsel, he delivered at McGregor's request Texas's opening statement, and in that statement, he made clear that Texas claimed not only "its rights under the federal Rio Grande Project" but also waters for some 20,000 acres between the project and Fort Quitman that was "under successful cultivation today by irrigation" – land in Hudspeth County.[199]

For Colorado, excess water beyond the project, the water for Hudspeth that Burges identified, was objectionable. Provided the state secured its own water project for San Luis Valley, however, that water could be tolerated. Corlett, for instance, complained that the "return water" received by Hudspeth lands "would some three or four times supply all of the water that was conceded to Mexico" yet was denied Colorado. Colorado's engineering advisor R.I. Meeker, supported Corlett's contention in his presentation to the commission, noting "that there are large wastes passing the lower end of the Rio Grande Project at Fort Quitman," and among the beneficiaries

Burges Papers, Proceedings of Rio Grande Compact Conference Held Dec. 19-20-21, 1928 at Santa Fe, N.M., Box 2F471, RGCCR, 1924-1941, 1970, UTA.

of this water was land in Hudspeth County. Nevertheless, in calculating an equitable quantity for Texas that made possible development of Colorado's San Luis Valley, Meeker included the water received by land downstream of the project along with the water demands of lands within the Rio Grande Project and the obligations to Mexico under the 1906 treaty, even though the water diverted by Hudspeth landowners was "junior in every respect."[200]

Harwell likewise sought to condition the rights of landowners downstream of the project before the commission, although he did not dismiss the fact that those in Hudspeth obtained water via the project and would in the future. He explained that "the Hudspeth District is entitled to no more water than the surplus waters which may exist at the Tornillo canal." Put another way, "Hudspeth District was entitled to receive no more water from the project than this unavoidable waste which is bound to occur through this 150 miles of operation between the dam [Elephant Butte] and the point of lowest delivery." Any additional water that Hudspeth landowners could obtain, according to Harwell, would be "by their own pumping operations for drainage…putting to use water which would otherwise be put to use in the stream bed by them or anyone else interested." He believed that with increased efficiencies in water use by the project and its completion to serve the full irrigable acres within the project, future water use downstream of the project would be "limited to… [that] which can be called legitimately unavoidable waste."[201]

The temporary compact of 1929 did not specifically address the relative water needs of the three states, save to endorse federal construction of a "closed basin drain" and "State line reservoir" in Colorado. Nevertheless, as noted above, Article XII acknowledged the importance of Elephant Butte Reservoir to lands below, lands that as the federal project was operated included lands in Hudspeth, and attempted to safeguard the reservoir's water supply:

> New Mexico agrees with Texas with the understanding that prior vested rights above and below Elephant Butte Reservoir shall never be impaired hereby, that she will not cause or suffer the water supply of the Elephant Butte Reservoir to be impaired by new or increased diversions or storage within the limits of New Mexico unless and until such

> depletion is offset by increase of drainage waters [i.e., through development of Colorado's Closed Basin].[202]

The water supply and needs of the lands between Fabens and Ft. Quitman were more specifically analyzed and considered in 1930s as Colorado, New Mexico, and Texas sought to arrive at a permanent compact.[203] As first discussed in Opinion I, critical to the development of the compact was the federal Rio Grande Joint Investigation of the National Resources Committee. This investigation provided much of the technical data for the drafting of the compact. Endeavoring to scope that work for the Rio Grande Compact Commission in December 1935, University of Chicago historical geographer Harlan H. Barrows and agricultural economist Frank Adams, both with NRC, suggested confining the study to "the water resources and irrigable and irrigated lands of the Rio Grande Basin above El Paso." Colorado, however, insisted that any investigation "should include the area between El Paso and Ft. Quitman" – an area inclusive of Hudspeth County – as the "duties of the Rio Grande Compact Commission relate to that area of the Rio

[202] Francis C. Wilson, Rio Grande Compact Commissioner, *Rio Grande Compact: Report of Commissioner for New Mexico and Memorandum of Law on Interstate Compacts on Interstate Streams* 2/19/29, 9. ff. 032.1, Rio Grande Basin. Water Rights: Rio Grande Compact. THRU 1929., Box 924 Rio Grande Basin 023.--032.02, Entry 7, RG 115, NARA Denver.

[203] There is some historical evidence that water users downstream of the Rio Grande Project did not figure into the compact negotiations of the 1930s. In the early 1950s, EP#1 retained Raymond Hill as a technical expert in a lawsuit filed in US District Court for the Western District of Texas, El Paso Division, by HCCRD #1. HCCRD #1 sued several parties, including EP#1, over the availability of water in the Rio Grande for appropriation. The district insisted that the construction of Caballo Reservoir had increased the water supply in the basin. EP #1, however, argued that despite Caballo's construction there was no water to be appropriated from the river; the federal Rio Grande Project had already fully appropriated the stream. Hill, Texas's engineering advisor, was called upon to submit an affidavit supporting this position. According that document, signed and dated by Hill on January 20, 1953 (but stamped as received on January 19), he

> participated in the negotiation of the Rio Grande Compact and particularly in the negotiations conducted by the engineers representing the Federal Government and the several States. At no time in such negotiations were the needs of the Hudspeth County Conservation and Reclamation District No. 1 in Texas considered. On the contrary, the representatives of Colorado and New Mexico consistently and emphatically refused to consider any rights or uses of water in the Hudspeth District.

In the United States District Court, for the Western District of Texas, El Paso Division, *Hudspeth County Conservation and Reclamation District No. 1, et al., Plaintiffs v. Howard E. Robbins, et al, Defendants*, Civil Action No. 1342, Affidavit of Raymond A. Hill in Support of Defendants' Cross-motion for Summary Judgment, January 20, 1953. ff. El Paso County Water Impr. Dist. No. 1 a/c Hudspeth CCRD No. 1 G3330, Box 4X189, RAHP, UTA. This single statement stands in stark contrast to a larger body of evidence discussed in this opinion that indicates that downstream water users were a consideration in the negotiations.

Grande Valley above Ft. Quitman." After some deliberation, the commission adopted a resolution that identified the study area as "the Rio Grande Basin above Ft. Quitman."[204]

The reliance of downstream water users on Rio Grande project water was also noted and intended to be a focal point in Texas's suit against New Mexico and the Middle Rio Grande Conservancy District before the US Supreme Court. In testimony before Special Master Charles Warren in November 1936, Fiock explained that under current operations Hudspeth received the waste water from the project, below the Tornillo district. By December 1936, with the hearings continuing, Frank Clayton, who was not only Texas's attorney in its original action and the state's Rio Grande Compact Commissioner but also the attorney for HCCRD #1, sought to demonstrate "that millions of dollars were added to tax valuations in Hudspeth County as a result of irrigation development under this project, commencing about 1918 and reaching its culmination about 1928."[205]

This information was apparently not introduced before Warren (as noted in Opinion I above) placed the proceedings on hold to enable the Rio Grande Joint Investigation to complete its work. Delayed by several months, a copy of the investigation's report, the *JIR*, was distributed to the compact commission in September 1937. In presenting the *JIR*, Barrows expressed his belief "that the report provides a basis, a factual basis, for an allocation of the waters of the river above Ft. Quitman that would be fair and just to each of the three states and to its citizens [*sic*] dependent upon the river."[206]

The *JIR* recognized the dependence of lands downstream of the project on the water captured, stored, and released from the Rio Grande Project's Elephant Butte Reservoir. It specifically included HCCRD #1's current water needs in its assessment of the available diversions necessary from the reservoir to supply the stretch of the Rio Grande between the reservoir and Ft Quitman. The investigation was truly a series of studies of the Upper Rio Grande Basin, undertaken by federal agencies that included Reclamation as well as the USGS and the US Department of Agriculture's Bureau of Agricultural Engineering. The summary report produced by the investigation noted that the Hudspeth district was located within the Elephant Butte-Fort Quitman section of the basin, and "maintenance of an adequate water supply for irrigation" of its lands and "maintaining satisfactory control of salinity" were both major problems. The latter

---

[206] Proceedings of the Rio Grande Compact, Held in Santa Fe, New Mexico, September 27 to October 1, 1937, 5. Unnamed folder 5, Box 2F463, RGCC-FBCP, UTA.

issue of salinity, in particular, was "an important consideration" in assessing the section's needs. The summary acknowledged that the district received "return water" below the Tornillo Canal heading. This water was "a direct diversion of drainage and waste waters of the Rio Grande Project" under a Warren Act contract. The contract applied "only to the return water as it occurs in the normal operation of the Rio Grande Project and puts no obligation upon the latter for delivery of any specific amounts of water."[207]

The report of the USDA Bureau of Agricultural Engineering specifically recognized the vital importance of this water for Hudspeth. It noted the "drain and tail water from the El Paso Valley system [of the project] becomes the irrigation supply for most of the remaining valley lands above Fort Quitman." Diversions to Hudspeth County lands were thus factored into the investigation's calculation of net diversion and stream-flow depletion between 1930 and 1936 for the Elephant Butte-Fort Quitman section. These diversions formed an essential part of the "necessary allowances for drain flow, wastes, arroyo inflow, and salinity control to derive the required diversion demand on Elephant Butte Reservoir." That diversion demand amounted to 736,000 af, but given the acres "actually irrigated" in the late 1920s into the early 1930s, 773,000 af was recommended to "be used as conservative estimate."[208]

As discussed in Opinion II above, the need to ensure a water supply of sufficient quality through the project lands and downstream to Ft. Quitman was precisely the reason Texas insisted upon 800,000 af from Elephant Butte. For the remainder of the compact negotiations, although no designated representatives from Hudspeth addressed the proceedings, Clayton and Hill advocated for both for the Rio Grande Project and the entire Elephant Butte-to-Ft. Quitman stretch. Barrows also included Hudspeth in his call for a dependable supply of low-alkali water for lands above Ft. Quitman.

Drafting of the compact itself focused on the "present uses of water" in the Rio Grande Basin above Ft. Quitman, a geographical area that included lands in Hudspeth County. New Mexico's own engineering advisor, John Bliss, recognized that Hudspeth was a part of the demand on Elephant Butte. In his own calculations of that demand, presented during the December 1937 meetings, he estimated the need for these lands between the project and Ft. Quitman as 70,000 af. As discussed in Opinion I above, at the commission's direction, the engineering advisors collectively prepared a report suggesting the schedule of deliveries to be specified in the compact, and in doing so "avoided discussion of the relative rights of water users in the three

[207] *JIR*, 7, 12, 23, 49, 62, 74, and 85-86.
[208] *JIR*, 99, 103-104, and 403.

States," and instead sought to protect the "present uses of water in each of the three States…because the usable water supply is no more than sufficient to satisfy such needs."[209]

When New Mexico State Engineer and Rio Grande Compact Commissioner Thomas McClure challenged some of the engineers' recommendations, Clayton defended their work as safeguarding Texas's entitlements to the waters of the Rio Grande. He argued in a January 1938 letter to Harper that "in the protection of Texas' water supply that the report contains no recommendations for the benefit of Texas than what she is plainly entitled to." Texas's commissioner insisted that the engineers had developed "a fairly workable basis for the equitable apportionment of the waters of the Rio Grande, without permitting further encroachments upon Texas' already inadequate supply." Indeed, Texas was "unwilling to recede from what we conceive to be the minimum requirements for the protection of Texas' water supply as embodied in the report."[210]

Texas eventually conceded to a lesser figure of 790,000 af, yet Clayton believed that he had secured the water to which all of the lands in Texas down to Ft. Quitman were entitled. As noted in Opinion II, after the conclusion of the compact negotiations, in a pamphlet "To Water Users Under The Rio Grande Compact," Clayton sought to reassure Texans anxious over the compact's provisions. The compact commissioner, the "engineering consultants who represented Texas in its lawsuit with New Mexico over the waters of the Rio Grande," and "the managers and attorneys of the Elephant Butte Irrigation District and the El Paso County Water Improvement District No. 1" were convinced "the Compact protects the water supply of users in New Mexico and Texas between Elephant Butte and Fort Quitman, and that it [the Compact] represents a fair and equitable solution of the controversy which has long existed between various interests in the three states." Clayton maintained that the compact "seeks primarily to protect vested uses of water above Fort Quitman, and guard them against future impairment, both as to quantity and quality." The commissioner explained further,

> Since the Rio Grande is essentially a torrential stream and its discharge varies widely from year to year, it is physically impossible to establish fixed and determinate deliveries into Elephant Butte Reservoir in terms of acre-feet per year. However, engineering

[210] Frank B. Clayton, Rio Grande Compact Commissioner for Texas, to Mr. S.O. Harper, Chairman, Rio Grande Compact Commission, January 27, 1938, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 3, 50-51. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

> investigation has shown that there have been in the past reasonably reliable relationships between the flow of the river and its tributaries above all principal points of diversion in Colorado and New Mexico, and at other points below all principal diversions in Colorado and New Mexico above Elephant Butte Reservoir. These relationships have been expressed in the Compact in tabular form, and this instrument imposes an obligation upon Colorado and New Mexico to maintain these schedules of relationship, regardless of any future development above the Rio Grande Project.

Colorado's obligation was to the Colorado-New Mexico state line (reflected in Article III), and New Mexico's was to San Marcial (reflected in Article IV). Clayton noted that the Compact established a debit-and-credit system, in recognition "that there will probably be departures from time to time from the schedules of relationship." A "definite limitation," however, existed on debits and credits "to insure a normal average release from the [Elephant Butte] Reservoir of 790,000 acre-feet of water per year, including the deliveries to Mexico."[211]

Clayton reiterated many of these same points at a May 1938 meeting of the Lower Rio Grande Water Users Association. Members of the association came from Cameron and Hidalgo counties, below Hudspeth County and Ft. Quitman. They were concerned that their water supply was not adequately protected by the compact. "From the legal standpoint," however, as Clayton explained, "our negotiations related to the division of the waters above Fort Quitman." Identifying the need to satisfy Mexican claims to water from the Rio Grande through the 1906 treaty as the essential background to the 1906 and 1908 filings made by Reclamation, he asserted that those filings were "for the purpose of impounding them in a storage dam [Elephant Butte] in the vicinity of Engle, New Mexico for the benefit of lands between that point and Fort Quitman" – not just for the lands within the project. He believed his "duty, as commissioner for Texas, [was] to see that Texas got every drop of water originating in Colorado and New Mexico that she was entitled to and to see that that water was delivered into the Elephant Butte Reservoir," and that he was successful: "By that compact Texas got all she is entitled to."[212]

Moreover, that water Texas received for its lands above Ft. Quitman was the same water that irrigated lands in New Mexico. "[A]s far as the Rio Grande project is concerned," Clayton told the attendees

Proceedings and Minutes 1935-1938, Box 2F463, RGCC-FBCP, UTA; and Littlefield*, Conflict on the Rio Grande*, 209-210.

> the interests of the Elephant Butte District, in New Mexico, and the districts in Texas above Fort Quitman are common interests ... and because our interests are common we determined long ago that no satisfactory, practical, legal, or engineering way could be devised by which the waters could be allocated between these districts at the Texas line. As far as they and we are concerned, our source is the same. If the supply is impaired above Elephant Butte, we all suffer alike.[213]

Harwell also tried to clarify matters for the association. In the process, he emphasized both Reclamation's control over the waters that entered Elephant Butte Reservoir, and the dependence of lands downstream of the project on releases from the federal reservoir. The EP #1 manager stressed that while the water supply below Ft. Quitman was "wholly without our control," the "supply of water at the end of this project [i.e., the Rio Grande Project]...will be substantially as it has been in the past." He acknowledged that there would be "a certain amount of operating water and a certain amount of summer runoff" entering the river "entirely beyond our control." Roughly 16,000 acres of land in Hudspeth County benefitted from the water passed beyond the project; these lands were irrigated "in part by surplus waters which we [EP #1] deliver into their canal for a consideration, and in part by diversion from the river." Harwell went on to invoke the argument that Hill had made for water quality: "it is necessary to pass excess amounts of water in order to maintain the salt balance." Lands below the project and above Ft. Quitman were the beneficiaries of this operational necessity.[214]

Following the meeting with the Lower Rio Grande Water Users Association, Clayton yet again emphasized that Texas obtained all that it was entitled from the compact negotiations in an August 1938 letter to Homer L. Leonard, a state representative from McAllen on the lower Rio Grande. The compact commissioner sought to secure Leonard's support for ratification of the compact in the face of opposition from his constituents. "It was the opinion," Clayton explained, "of every one of the Texas representatives attending the meeting that by the Compact Texas secured all that she was entitled to, and, indeed, all that could physically be delivered to her." He acknowledged that the "upper and lower water users in Texas" differed "as to whether the districts under the Rio Grande Project were obligated to deliver any water past Fort Quitman and if so, the amount." Clayton and the rest of the Texas delegation to the compact proceedings nonetheless believed this "was a matter of internal negotiation" and raising before the Colorado and New Mexico commissioners and their advisors "would gravely prejudice our case and

[214] *Proceedings of Meeting, held on Friday, May 27, 1938*, 16, 17, and 25. ff. Proceedings and Minutes 1935-1938, Box 2F463, RGCC-FBCP, UTA.

perhaps result in the collapse of the negotiations." "Obviously," he attempted to reassure Leonard,

> Colorado and New Mexico could not be asked to guarantee that any certain quantity of water would be delivered to any particular locality in Texas. Their only responsibility was to see that Texas' equitable share was delivered at the state line, or, rather, delivered into Elephant Butte reservoir, which is the point of control.[215]

Federal control of Elephant Butte Reservoir as well as the water needs served by releases from the reservoir were two essential points that Clayton also stressed to attorney Sawnie B. Smith in October 1938. Smith had been hired by lower Rio Grande water users to file suit to stop ratification of the compact. In a letter to Clayton in late September 1938, he questioned the absence of provisions in the signed-yet-unratified compact concerning the "division of waters below Elephant Butte between the States of New Mexico and Texas" and "the amount of water to which Texas is entitled." Smith could "not find anything in the compact…which ties down and limits the use or division of the waters according to present usage and physical conditions, and nothing that would prevent controversy between the two States in the future regarding the division of the waters between the two States." "This omission," the attorney bluntly wrote, "is too obvious to have been inadvertent, and therefore unquestionably, the Commissioners had what they considered valid reason for it." On behalf of his clients, Smith asked for that reason.[216]

Writing back to Smith, Clayton insisted that New Mexico's delivery of water above Elephant Butte constituted the delivery of water to Texas and that all of the releases from Elephant Butte made in the course of federal project operations served requirements below the dam down to Ft. Quitman. As far back as the negotiations for the temporary compact, the commissioner noted, Elephant Butte had been the focus for deliveries to Texas. The parties had, in Clayton's words, "decided…that New Mexico's obligations as expressed in the compact must be with reference to deliveries at Elephant Butte reservoir, and this provision was inserted in the temporary compact [i.e., Article XII of the temporary compact]." He insisted that that the "reasons" for this were "numerous," and "the obstacles in the way of providing for any fixed flow at the Texas were considered insuperable." Clayton drew specific attention to federal operational control of Elephant Butte and the flow of the water through the project's canals and down the river itself:

> The Rio Grande Project, as you know, is operated as an administrative unit by the Bureau of Reclamation, and the dam and releases from the reservoir are controlled by the Bureau and will continue to be at least until the federal government is repaid its investment, and

[215] Frank B. Clayton, Rio Grande Compact Commissioner for Texas, to Hon. Homer L. Leonard, August 3, 1938, 2. Box 2F466, RGCC-FBCP, UTA.

[216] Sawnie B. Smith to Mr. Frank B. Clayton, Rio Grande Compact Commissioner for Texas, September 29, 1938. Box 2F466, RGCC-FBCP, UTA.

> very probably even beyond that time. Obviously, neither Colorado nor New Mexico could be expected to guarantee any fixed deliveries at the Texas line when the operation of the dam is not within their control but is in control of an independent government agency.
>
> Moreover, measurements of the water passing the Texas state line would be very difficult and expensive, if not impossible. This, for the reason that irrigation canals, ditches and laterals cross the line, which is of a very irregular contour, at many different points, carrying water in addition to what is carries in the river itself, and it would require continual measurements in these various channels to make any reasonably accurate computations of the total flow.

Texas's commissioner nevertheless indicated that federal management of Elephant Butte facilitated ultimate delivery of the Rio Grande water allocated to Texas above Ft. Quitman. Clayton observed that lands below Elephant Butte Reservoir received water through project operations by either contract or treaty – lands in New Mexico in EBID; lands in El Paso County, in EP #1; lands in Hudspeth County in HCCRD #1; and lands in Mexico. Contractual arrangements between the two project districts, EBID and EP #1, established the irrigable acreages in each, and Clayton expressed his conviction "that there will never by any difficulty about the allocation of this water" as a result.[217] As for the "lands above Fort Quitman and below the Rio Grande Project," the commissioner observed, they

---

[217] According to Clayton, under "contracts between the districts under the Rio Grande Project [i.e., EBID and EP#1] and the Bureau of Reclamation…the lands within the Project have equal water rights, and the water is allocated according to the areas involved in the two States." "By virtue of the contract recently executed" – the so-called interdistrict agreement of February 16, 1938 – he explained to Smith,

> the total area is "frozen" at the figure representing the acreage now actually in cultivation: approximately 88,000 acres for the Elephant Butte Irrigation District, and 67,000 for the El Paso County Water Improvement District No. 1, with a "cushion" of three per cent. [*sic*] for each figure.

This "arrangement," Clayton acknowledged, was "of course a private one between the districts involved, and for that reason it was felt neither necessary nor desirable that it be incorporated in the terms of the Compact."

Historian Douglas Littlefield argues that the interdistrict agreement "rendered irrelevant" a New Mexico-Texas state line delivery. Characterizing the congressional authorization of the Rio Grande Project in 1905 as providing for a de facto "allocation" of water between New Mexico and Texas, he contends that the agreement "verified the Bureau of Reclamation's determination that the maximum irrigable acreage of the Elephant Butte Irrigation District was 88,000 acres and that of El Paso County Water Improvement District No. 1 was 67,000 acres." Littlefield, *Conflict on the Rio Grande*, 203 and 207.

The agreement was nonetheless "private" as Clayton recognized. While it was given Interior Department approval, the agreement was executed solely by the two districts, and it was concerned with the allocation of costs for the Rio Grande Project. Federal law obligated project water users to repay the costs incurred by the United States in building, operating, and maintaining a reclamation project. The original 1906 joint construction contract between EBWUA and EPVWUA, and the United States had specified "ten equal annual payments," "apportioned equally per acre among those acquiring such rights [i.e., the water users]." In 1918 and 1920, following the dissolution of the water users' associations and

---

their reconstitution as quasi-municipal entities with the power to tax individual members, new contracts were drafted that made irrigated acreage the basis for allocating shared projects costs between EBID and EP#1, respectively. Eight years later, in the summer of 1928, at the insistence of the water users and at the direction of Congress, the Interior Department extended the repayment schedule for the districts but retained acreage as the basis for repayments. See Construction Contract of Rio Grande Project, 6/27/06, section 4, page 4. ff. 430-A, Rio Grande Project. Joint Contract with Two Water Users Ass'ns, Box 818 Rio Grande 430- -430A, Entry 7; Department of the Interior, Bureau of Reclamation, Rio Grande Project-New Mexico-Texas, Contract Dated June 15, 1918 – between The United States of America and The Elephant Butte Irrigation For Repayment of Construction and Operation and Maintenance Charges, Article 6, Article 8, and Article 10; Department of the Interior, Bureau of Reclamation, Rio Grande Project-New Mexico-Texas, Contract Dated January 17, 1920 between The United States of America and The El Paso County Water Improvement District No. 1, For Repayment of Construction and Operation and Maintenance Charges, Article 7, Article 8, and Article 9, in Department of the Interior, Bureau of Reclamation, Rio Grande Irrigation Project, New Mexico-Texas, Contracts with Water User's Organizations (Copies), Compiled November 1, 1929. 232-29 RG Separate Folder, 249-H, Contracts with Water Users, Box 716 Old Box 509-510, Code 104.RG 37 through Code 402.RG 28, Engineering and Research Center, Project Reports, 1910-55, RG 115, NARA Denver; and *An Act Extending the time of construction payments on the Rio Grande Federal irrigation project, New Mexico-Texas*, May 28, 1928, chap. 815, 45 Stat. 785.

In early February 1929, facing the prospect of constructing additional drainage works for EP #1, Reclamation Chief Engineer R.F. Walter sought to determine more precisely the districts' respective obligations. He met with acting Rio Grande Project superintendent L.R. Fiock and EP #1 manager Roland Harwell; neither EBID's president nor its manager was able to appear but they made their opinions known. Harwell insisted that his district "wished to pay on 67,000 acres," with the caveat that nearly 2,000 acres currently in need of "river rectification or other work not provided by the district contract be delayed a reasonable length of time to permit such work being done by the land owners." As for EBID, its president "informally advised that 88,000 acres was desired by the district," and its manager telegrammed the same to Walter. Satisfied, federal reclamation officials agreed to a distribution of costs on the basis of these acreages: 88,000 acres for EBID and 67,000 acres for EP #1. Before a formal arrangement could be made, however, the global financial collapse precipitated by the US stock market crash of October 1929 cast into doubt the ability of any federal reclamation project's water users to meet their repayment obligations. See Elephant Butte Irrigation District, B.P. Fleming, Manager, telegram to R. F. Walter, Chief Engineer, Bureau of Reclamation, Feb. 16, 1929; Memorandum, From: Chief Engineer, To: Commissioner, Subject: Determination of irrigable acreage and total construction liability of the irrigation districts – Rio Grande Project, February 18, 1929. ff. 301. Rio Grande, Board & Engineering Reports on Construction Features, Oct. 1926 thru July 1929, Transfer Case, Box 913 Rio Grande 241.27—301; and Memorandum, From: Commissioner, To: Chief Engineer, Denver, Colo., Subject: Determination of irrigable acreage and total construction liability of the irrigation districts – Rio Grande Project, March 16, 1929. ff. 330. Rio Grande Project, Corres re Drainage of Seeped Lands. Thru December 31, 1928, Transfer Case, Box No. 921 Rio Grande 322.--430., Entry 7, RG 115, NARA Denver; and Donald J. Pisani, *Water and American Government: The Reclamation Bureau, National Water Policy, and the West, 1902-1935* (Berkeley: University of California Press, 2002), 149.

Congress twice extended the schedule for EBID and EP#1's repayments in the early 1930s, permitting continued deferment, and through 1936 both districts availed themselves of this opportunity. Execution of "adjustment contracts" in 1937, in which the districts relinquished their rights to hydroelectric power revenue at the newly-constructed Caballo Dam below Elephant Butte, reduced their obligations – but the allocation of repayment costs between the two districts remained outstanding. *An*

> receive only 'tail-end' or waste water, the land in the Hudspeth County district taking it water by virtue of a contract and the lands privately owned below the district lower boundary only by taking by gravity or pumps what happens to be in the river channel.

This was the "unavoidable waste" from the project-irrigated valleys above.[218]

Additional evidence that New Mexico's delivery of water at San Marcial was the delivery of water to Texas may be found in an undated "Analysis of the Terms of the Compact," authored by New Mexico State Engineer and Rio Grande Compact Commissioner Thomas B. McClure. In the piece, which summarizes the compact, McClure agrees with the explanation offered by Clayton to Smith regarding the absence of a state-line delivery to Texas, analogous to the state-line delivery to New Mexico from Colorado. "The subdivision of the basin at San Marcial," he stated

Act For the temporary relief of water users on irrigation projects constructed and operated under the reclamation law, April 1, 1932, 47 Stat. 75, chapter 94; *An Act To extend the operation of the Act entitled, "An Act For the temporary relief of water users on irrigation projects constructed and operated under the reclamation law," approved April 1, 1932*, March 3, 1933, 47 Stat. 1427, chapter 200; *Project History, Rio Grande Project, Calendar Year 1932*, 20; and *Project History, Rio Grande Project, Calendar Year 1933*, 16; *Project History, Rio Grande Project, Calendar Year 1934*, 16; *Project History, Rio Grande Project, Calendar Year 1935*, 16; *Project History, Rio Grande Project, Calendar Year 1936*, 15. USBR PHRGP 1912-1988 (mf); Department of the Interior, Bureau of Reclamation, Contract Dated Nov. 9, 1937, Ilr-982, Elephant Butte Irrigation District (Adjustment of project construction charges and other purposes). ff. 222.- Rio Grande Project. Contracts with Elephant Butte Irrigation District, Separate Folder, Box No. 917, Rio Grande Pro. 222._222.-; Department of the Interior, Bureau of Reclamation, Contract Dated Nov. 10, 1937, Ilr-981, El Paso County Water Improvement District No. 1 (Adjustment of project construction charges and other purposes). ff. 222.- Rio Grande Project. Irrigation Districts, El Paso County Water Improvement District No. 1, Separate Folder, Box No. 918 Rio Grande Pro. 222._222.-, Entry 7, RG 115, NARA-Denver.

Resolution of the cost apportionment question finally came with signing of the interdistrict agreement, six months of negotiations between the districts and Reclamation and Interior Department officials. The agreement memorialized the historical distribution of repayment costs for storage and general project features between EBID and EP#1 on the basis of the respective irrigated acreages that the districts themselves had committed to back in 1929 and which Reclamation agreed to serve in proportion to the available water supply: 88,000 acres in New Mexico, in EBID, and 67,000 acres in Texas, in EP #1. Contract between Elephant Butte Irrigation District of New Mexico and El Paso County Water Improvement District No. 1 of Texas, signed February 16, 1938, and approved by Assistant Secretary of the Interior Oscar L. Chapman, April 11, 1938. ff. 400. Rio Grande, Lands-General, 1930 thru, Box 932 Rio Grande Pro. 400.__400.08, Entry 7, RG 115, NARA Denver.

Whether the interdistrict agreement accomplished a de facto allocation of water between New Mexico and Texas as Littlefield maintains or was focused solely on the allocation of the cost of the federal project between the districts, this agreement, prior contracts between the federal government and EBID and EP #1, the Hudspeth Warren Act contract, and the 1906 Mexican treaty all underscore federal management and control over the waters delivered by New Mexico at San Marcial.

[218] Frank B. Clayton, Rio Grande Compact Commissioner for Texas, to Mr. Sawnie B. Smith, October 4, 1938. Box 2F466, RGCC-FBCP, UTA; and Littlefield, *Conflict on the Rio Grande*, 213-214.

unequivocally, "is necessary because the Rio Grande Project of the Bureau of Reclamation must be operated as a unit."[219]

As these statements by Clayton and McClure, and the service to lands beyond the Rio Grande Project down to Ft. Quitman make plain, New Mexico's San Marcial delivery per the compact was the state-line delivery to Texas. Water captured and stored in Elephant Butte Reservoir on release and re-use served lands not only within the Rio Grande Project but also downstream to Ft. Quitman. Calculations of the demands on the federal reservoir by federal engineers and the engineering advisors to the Rio Grande Compact commissioners recognized the dependence of these lands on the reservoir's water supply. The commissioners themselves understood that that water delivered to the reservoir would be under federal control, and thus a state-line delivery by New Mexico to Texas, similar to the state-line delivery by Colorado to New Mexico, was impractical.

[219] Thomas B. McClure, State Engineer, "Analysis of the Compact," undated, 21-22. NM_00164500 – NM_00164501.

Opinion V: Although irrigation water was the prime concern of compact commissioners and their engineering advisors in the 1920s and 1930s, the 1938 Rio Grande Compact ultimately did not limit the uses to which water in the Upper Rio Grande Basin could be put in the future.

As noted at various points in the opinions above, irrigation for agricultural development was a central theme of the negotiations leading to both the temporary 1929 and permanent 1938 compacts. The recorded compact proceedings are filled with discussions of how much land could be irrigated in the San Luis Valley in Colorado with the construction of a drain or other works, for instance, and the impact that the Middle Rio Grande Conservancy District could have on the Rio Grande Project and the need to prevent a decline in the quantity and quality of water reaching already irrigated lands within the federal Rio Grande Project and beyond were of equal concern. However, other uses – domestic, industrial, and municipal – were addressed in those proceedings and the federal Rio Grande Joint Investigation. Actions and statements by federal and state negotiators and engineers following the compact, moreover, indicate that the drafters both recognized the potential for non-agricultural uses of the Rio Grande's waters and intended for the three states, pursuant to the schedules of delivery established by the compact, to have autonomy in the development of the waters within their borders, post-1938.

At the first meeting of the Rio Grande Compact Commission in October 1924, the possibility of El Paso seeking a water supply from the Rio Grande as part of a compact was raised. Joseph Taylor, an attorney with EBID, in fact argued for the inclusion of Texas in the compact negotiations initiated between Colorado and New Mexico precisely for this reason. He insisted,

> In my District, the one warning I get from the water users, in going ahead with this procedure, is the possibility that our interests at sometime may be different from the interest of the El Paso Valley, and that unless we are very careful, that we proceed with the full acquiescence of the people of the lower valley, there may be question of water supply which may at some time limit the project, and which might be interpreted by our friends below as being a limitation which would effect [*sic*] New Mexico's interests only. We have the City water supply of El Paso that may come up, and our people are a little doubtful of the propriety of going ahead unless Texas is fully and legally represented in every respect.[220]

---

[220] First Meeting, Rio Grande River Compact Commission…October 26, 1924, 18-19. Folder 1. First Meeting Rio Grande Compact Commission. Oct. 26, 1924, Box 02-D.003, MS 0235, RGHC, NMSU Spec. Coll. As early as 1921, at the suggestion of consulting engineer John Lippincott, the City of El Paso was looking to the Rio Grande, and specifically the water stored in Elephant Butte Dam, to supplement its reliance on groundwater. For a brief overview of the early history of El Paso's municipal water development see A.N. Sayre and Penn Livingston, *Ground-water Resources of the El Paso Area, Texas*, prepared in cooperation with the El Paso Water Board and the Texas State Board of Water Engineers, United States Department of the Interior, Geological Survey, Water-Supply Paper 919 (GPO, 1945), 3 and 5-7.

Taylor was correct in his belief. When the Rio Grande Compact Commission met again in December 1928 with Texas "fully and legally represented," Major Richard F. Burges, legal advisor to Texas's compact commissioner T.H. McGregor and attorney for the City of El Paso, indicated that at the behest of "the municipal authorities at El Paso" he was there to present "before the commission the claims of the City of El Paso to a municipal water supply from the waters of the Rio Grande."[221]

Those claims were made in full at the next commission meeting in January 1929. El Paso mayor R.E. Thomason, appearing in person, read a statement asking for "consideration, recognition and establishment of [El Paso's] legal right to the municipal water supply from and out of the waters of the Rio Grande River…."[222] Noting that El Paso fronted on the river, the statement emphasized that the Rio Grande was "for many years…the source of the water supply of El Paso." It explained that "in recent years the City has obtained its water from wells, because the same could be more economically obtained than from the flow of the river." The supply from the wells was "limited

---

EBID was aware of the city's interest, with president and manager H.H. Brook noting in March 1923 letter to the US Reclamation Service (more than a year before Taylor made his remarks) that it was (in the later words of Reclamation Chief Engineer F.E. Weymouth) "probable the City of El Paso, Texas will request water from the Rio Grande project for domestic purposes." In his letter, Brook had sought additional information on "contracts in existence between the United States and municipalities within and without Reclamation Service projects where water is furnished for similar purposes."

Weymouth obliged. In his reply, he enclosed a copy of a "standard form of contract for water service to incorporated towns," and pointed out that Section 4 of the 1906 Town Sites and Power Act (34 Stat. 116) "provides for water rights for towns and contracts therefor…." Reclamation was therefore authorized to supply water "for municipal purposes which would include the watering of lawns and such general irrigation as may be practiced within the town limits." Towns, the chief engineer emphasized, had to pay for such water as agricultural areas and could not secure "more favorable" terms. A handwritten note on the letter, most likely made by Brook, indicates that this letter was read to the EBID board, who expressed their desire to oppose such "schemes…as unsatisfactory." F.E. Weymouth, Chief Engineer, to Mr. H.H. Brook, President & General Manager, Elephant Butte Irrigation District, March 31, 1923. Folder 3, Box 023.016, Subject File, 1906-1925. Unclassified. H.H. Brook [9.21], MS 0235, RGHC, NMSU Spec. Coll. Federal reclamation authorities later determined that the 1920 Miscellaneous Purposes Act was the pertinent federal legislation, and as briefly discussed in footnote 234, the United States, EP #1, and one instance, EBID, entered into water service contracts with the City of El Paso in the 1940s, pursuant to that act.

[221] Proceedings of the Rio Grande Compact Conference...1928, 11-13. ff. ff. Proceedings of the Rio Grande Compact Conference Held Dec. 19-20-21, Box 2F471, RGCCR, 1924-1941, 1970, UTA.

[222] Thomason had telegrammed Burges on December 20, 1928, during the first meeting, asking him that "If water rights of City of El Paso are to be in any affected by proposed treaty or if any definite action is to be taken at present session please advise me so I can send McBroom or Woods to represent city." R.E. Thomason, Mayor, to Major Richard F. Burges, telegram, Dec. 20, 1928. ff. Rio Grande Compact Commission Records, 1927-1941, 1970, Richard Burges Papers: Correspondence, 1924-1935, 1927, Box 2F468, RGCCR, UTA.

and uncertain," which was why the City of El Paso believed "it will become necessary again to obtain its water supply from the waters of the Rio Grande River." El Paso had grown steadily since the turn of the nineteenth century, and within a generation was projected to "attain a population of at least 250,000," which would "require an annual municipal water supply of twelve billion gallons." Citing Texas's "riparian rights doctrine," the city asserted its rights to the waters of the Rio Grande as "necessity" to which it may have "to resort…in the future from failure or inadequacy of such other present available source of supply or from deleterious changes that may occur in such present source of supply."[223]

---

[223] Proceedings of Rio Grande Compact Conference, Held January 21 to , 1929, At Santa Fe, New Mexico, 64-65. ff. Rio Grande Compact Commission Records, 1924-1941, 1970, Richard F. Burges Papers, Proceedings of Rio Grande Compact Conference, Held Jan. 21-, 1929 at Santa Fe, N.M. (84 pp.), Box 2F471, RGCC Records, UTA.

Thomason's efforts on behalf of his city were not limited to the submission of this statement. In December 1927, more than a year before he addressed the Rio Grande Compact Commission, Thomason and city water works superintendent A.H. Woods met with Interior Secretary Hubert Work to discuss the matter. Work advised him and Woods to meet with former Rio Grande Project superintendent and US International Boundary Commissioner L.M. Lawson. Lawson, in turn, recommended that the city wait until elections in EBID and EP#1 had been held. He also suggested that the city seek water within the project's operational 155,000-acre irrigable-acreage framework.

This suggestion, as Woods later explained to Work, was embodied in a letter that Thomason wrote to Work in February 1928. In that letter, Thomason noted that as much as 4,000 acres of the 67,000 acres allotted to Texas had not been brought under irrigation. He proposed for the City of El Paso to acquire those lands and thus obtain a right to water through the federal reclamation project. Woods for his part believed that this "should raise no objection on the part of the irrigation district, because of the fact that the City of El Paso would be expected to relieve the district of the construction repayments for such an area." Although the acting Rio Grande Project superintendent L.R. Fiock and EP#1 manager Roland Harwell were generally supportive of the city's proposal, before any further arrangements could be made, the temporary 1929 compact was adopted and progress towards the city obtaining Rio Grande water came to a halt. Footnote 234 below briefly discusses how the idea of securing Rio Grande project water was revived in 1940. See R.E. Thomason to Honorable Hubert Work, Secretary of the Interior, February 16, 1928; A.H. Woods to Hon. Hubert Work, Secretary of the Interior, February 17, 1928; Hubert Work, Secretary, to Hon. R.E. Thomason, Mayor of El Paso, Texas, Feb. 25, 1928; P.W. Dent, Acting Commissioner to Mr. A.H. Woods, Superintendent, City Water Works, March 2, 1928; Memorandum, From: Acting Superintendent [L.R. Fiock], To: The Secretary (Thru The Commissioner, Washington, D.C.), Subject: Water Supply for City of El Paso – Allotment of Irrigable Area to The Texas District – Rio Grande Project, El Paso, Texas, March 27th, 1928; A.H. Woods to Honorable Hubert Work, Secretary of the Interior, Department of the Interior, El Paso, Texas, April 13, 1928; Hubert Work, Secretary, to Mr. A.H. Woods, Superintendent, City Water Works, Apr. 20, 1928; Memorandum, From Commissioner [Elwood Mead], To Superintendent, El Paso, Tex., Subject: Proposed purchase of water by City of El Paso, April 21, 1928; and Memorandum, From: Acting Superintendent [L.R. Fiock], To: The Secretary (Thru The Commissioner, Washington, D.C.), Subject: Proposed purchase of water by City of El Paso – Rio Grande Project., El Paso, Texas, June 26th, 1928. ff. 223.02 Rio Grande, Corres re Lease or Sale of Water thru 1929, 1 of 2, Transfer Case, Box 907 Rio Grande 223.02, Entry 7, RG 115, NARA Denver.

Although there is no record of the commissioners discussing or deliberating El Paso's claim prior to congressional ratification of the 1929 temporary compact, the compact was intended to preserve existing water uses within the basin. It therefore recognized "domestic" and "municipal" purposes of water along with the "agricultural." Article XI, in particular, offered a strong statement of the relative importance of "domestic" and "municipal" uses:

> Subject to the provisions of this Compact, water of the Rio Grande or any of its tributaries, may be impounded and used for the generation of power, but such impounding and use shall always be subservient to the use and consumption of such waters for domestic, municipal and agricultural purposes. Water shall not be stored, detained nor discharged so as to prevent or impair use for dominant purposes.

For Colorado's compact commissioner and the father of the Colorado River Compact Delph Carpenter, the provision's meaning was clear. Article XI "provides for the development of power by use of waters of the Rio Grande but makes such use subservient to uses for domestic, municipal and agricultural purposes which are made dominant."[224]

When discussions towards a permanent compact resumed in December 1934, existing or present uses and needs of water for agriculture remained centerstage. Former Colorado governor George Corlett, for instance, under questioning from Texas commissioner T.H. McGregor argued for "parity" among the three states on the basis of "the present acreage now under cultivation." Pushed further by McGregor about what "parity" meant, Corlett clarified: "Present requirements, then."[225]

The federal Rio Grande Joint Investigation pushed the commissioners to think more expansively about the basin's water needs. In his first appearance before the commission in December 1935 to offer the assistance of the National Resources Committee, University of Chicago historical geographer and consultant Harlan H. Barrows posed pertinent questions as to future uses of the water to be equitably apportioned among the three states:

> What, in the long run, will be your needs for water, not for irrigation supply, but for all other purposes, for city and town water supply, for industry, and the like? What are the prospects with respect to growth in population, and the prospects for now and greater needs for water associated with that growth? What are the possibilities for decentralized

> industry, involving the use of more or less water? What are your prospective, no less than your existing, aggregated needs? To what extent can these prospective needs be met effectively?[226]

The commissioners were not dismissive of learning more about their respective states' future needs, but did not immediately embrace a study as wide ranging as Barrows sought. Colorado State Engineer and compact commissioner M.C. Hinderlider, for one, expressed his desire to obtain

> all factual data…of an engineering character, as Mr. Barrows has intimated, having to do with availability of water supply, the demands upon those supplies, the deficiencies, the surpluses, when they occur, and, in fact, all matters pertaining to the efficient, and I believe, ultimate utilization of this entire natural resource provided by the Rio Grande.[227]

Texas's commissioner Frank Clayton, McGregor's successor, while concerned mostly with safeguarding the water supply to Texas via the Rio Grande Project, supported the idea of a federal study of the Rio Grande. The resolution he introduced to provide for that study emphasized "a determination of all salient facts bearing on the present and potential water resources of the Rio Grande Basin above Ft. Quitman, and bearing on past and present uses therein."[228]

Barrows and fellow NRC consultant and agricultural economist Frank Adams pressed the issue, seeking a more open investigative mandate. Their suggested resolution called for an "investigation of the water resources and of the irrigable and irrigated lands of the Rio Grande Basin above El Paso, and of the present and prospective uses of water for agricultural and other purposes in such basin." Hinderlider largely accepted this, but Clayton remained more interested in focusing the federal efforts. In a second draft resolution, the Texas commissioner acknowledged that the compact commission sought "a thorough finding of all facts," including those "relevant to the use of water for irrigation and other beneficial purposes," but he proposed

> that such investigation be restricted to the findings of facts relevant to the water supply available in said [Rio Grande] Basin, and which could be made available from outside thereof, and relative to the use and consumption of water within said basin….

---

Adams was concerned that this resolution, if adopted, would severely circumscribe the investigation and he instead urged "a broader study of this whole basin problem…."[229]

New Mexico State Engineer and compact commissioner Thomas McClure was more inclined to Clayton's position, that the federal investigation be directed to a "factual survey" that would address more directly the issue of equitable apportionment of the Rio Grande among the three states. Yet, he too recognized "other purposes" for the river's waters. McClure's proffered resolution read, in part,

> that the National Resources Committee, through the Water Resources Committee, be hereby requested to arrange immediately for some investigation of the water resources and of the irrigable and irrigated lands in the Rio Grande Basin, and of the respective uses for agricultural and other purposes in such Basin….[230]

The compromise resolution adopted by the commission expressly "limited" the "cooperative investigation…to the collection, correlation and presentation of factual data," unless the commissioners unanimously requested "recommendations." An early version defined that investigation to be "of the past, present and prospective uses of water for agricultural and other beneficial purposes in such basin." When Texas's engineer advisor Raymond Hill expressed concern that such language may "be construed as omitting consideration of natural losses," a consideration that he believed was "a major factor in any investigation," Barrows suggested that the phrase be revised to "read 'of the past, present and prospective uses of water and other consumption of water in such basin." Hill explained to the commissioners that this language was inclusive of "Domestic uses, and then consumption, which takes place naturally, striking out 'for agricultural and other beneficial uses.'"[231]

The resulting report of the federal investigation, the *JIR*, consequently considered "Uses and requirements other than for irrigation." These uses included municipal purposes, for "cities, towns, and villages" as well as "power purposes." The "General Report," which summarized the individual reports by various federal agencies, observed that these uses were "but a small fraction of the irrigation use" that was common from the Rio Grande's headwaters in Colorado to Fort Quitman, Texas. "As general average," the report noted, "the water requirement of cities and towns corresponds closely to the irrigation requirement of agricultural lands of an equivalent area." Nearly all the area cities, towns and villages derived their water supply from "pumping

[230] Proceedings of Rio Grande Compact Commission…December 2-3, 1935, 31-32. ff. 032.1 (2/3), Box 1326, Entry 7, RG 115, NARA Denver.
[231] Proceedings of Rio Grande Compact Commission…December 2-3, 1935, 37-38 and 42-43. ff. 032.1 (2/3), Box 1326, Entry 7, RG 115, NARA Denver.

ground water which, in turn, has its source in stream flow and in precipitation on the floor of the valleys," and the report determined that "[f]rom a basin-wide standpoint…this use constitutes a stream-flow depletion." To the USDA Bureau of Agricultural Engineering fell the task of assessing these depletions within the various sections of the basin. The agency included these urban and semi-urbanized areas within the "total area for which consumptive requirement [were] estimated," and thus "no special consideration of this use or allowance for it" was made. The City of Albuquerque, for example, was "included in the figures [of stream flow depletion]" for the so-called "Middle section" of the basin that extended "from the Colorado-New Mexico state line to San Marcial at the head of Elephant Butte Reservoir."[232]

The City of El Paso was excluded from this calculation of urban water consumption in the basin (which totaled 21,000 af) because of its dependence on wells located east of the city. These were, wells that drew upon groundwater fed by precipitation. Albuquerque likewise relied upon groundwater. Yet, the calculation of water consumption for the Middle section included the city because engineers involved with Albuquerque's proposed Jemez Creek development (which aimed to replace municipal wells with a direct diversion from one of the Rio Grande's tributaries) believed that the city's groundwater use was "undoubtedly a draft, direct or indirect, on Rio Grande; that therefore construction of the Jemez project amounts only to a change in point of diversion…."[233]

The *JIR* nevertheless made note that "the future of the water supply for El Paso" could include a direct diversion from the Rio Grande. It quoted at length from a letter that Harlowe Stafford, the federal engineer in charge of the investigation, received from the superintendent of El Paso's municipal waterworks:

> We are contemplating the drilling and construction of three additional wells within the very near future, said construction to be contingent upon the recommendations and advice which will be contained in a report of a survey of the underground water resources of El Paso and vicinity which was made during 1935 and 1936 by the United States Geological Survey.
>
> The records which this department has maintained over a period of years indicate that the static level of our ground-water supply is slowly receding. This, of course, can mean but one thing; that is, that the pumping in this area exceeds recharge.
>
> Should the static level continue to drop during the next 10 or 20 years as it has during the last 15 years, we believe that we shall find it necessary to seek another source of supply. Of course, there is but one other source of supply available and that is the Rio Grande.

---

[232] *JIR*, 1, 20, and 104-105. The Bureau of Agricultural Engineering's data is offered in Part 3: Water Utilization: Report of the United States Bureau of Agricultural Engineering, Section 7 – Consumptive Use of Water Requirements, in *JIR*, 368, 370-371, and 422-423.
[233] *JIR*, 105-106.

> However, we do not think that it will be necessary for us to use water from that source for several years, it at all.[234]

---

[234] *JIR*, 106.

The superintendent may have been optimistic in his assessment. In the summer of 1940, El Paso city officials, having had to cut back on water use on city-owned properties and confronting the possibility of having to supply the nearby US Army post, Fort Bliss, with additional water, approached federal reclamation authorities again. El Paso's new proposal was much like its previous proposal from the 1920s: to purchase land within EP#1 and thereby obtained water from the project. Working with the EP #1 manager Roland Harwell and El Paso City Attorney and former Texas compact commissioner Frank Clayton, Rio Grande Project Superintendent L.R. Fiock and Reclamation District Counsel H.J.S. Devries drafted a contract, pursuant to the 1920 Miscellaneous Purposes Act in November 1940. That contract, which EBID approved but did not join as a party, was finalized in February 1914 by the United States, EP #1, and the City of El Paso. A supplemental contract, with EBID as a party, was approved in 1944, and a third supplemental contract between EP #1 and the city (without either EBID or the US as a party, although the US approved the agreement) was prepared in 1949. See Ashley G. Classen and J.N. Hinyard, *Report on the Use of Rio Grande River Water as a Supplemental or Total Supply for the City of El Paso*, Lance Engineers, Inc., May, 1940), 1-8 and 13-124. 090-2000-028-W054, Box 090 028 W044-W054, El Paso Historical Society, El Paso, Texas; W.E. Krug, Sec'y of the Interior, Sept. 23, 1949. ff. B-12.2.12.1 Water Control &

Neither in the December 1937 "Report of Committee of Engineers" nor in the recorded proceedings leading up to the formal drafting and signing of the permanent compact in March 1938 is there explicit discussion of other possible or future uses of compact water. As addressed in Opinion I, "present uses of water" was the focus of the engineering advisors' report and the predominant use of water in the basin circa 1938 was irrigation. The compact itself references "irrigation demands" and "irrigation."[235]

There is no language in the compact, however, explicitly precluding the use waters of the Rio Grande for domestic, municipal, and industrial uses. Historical evidence exists, moreover, that those most involved with the negotiations did not see the compact as foreclosing opportunities to use water for purposes other than irrigation within the basin. Bliss, for one, in reviewing the general outlines of the technical basis of the compact to McClure in December 1937, noted "Developments in the three valleys [i.e., the San Luis Valley, the Middle Rio Grande, and the Elephant Butte-Ft. Quitman section of the upper basin] will be limited only by certain restrictions in reservoir storage during period of extremely low run off and by limitation of debits which may be incurred at any time."[236]

Clayton, for another, construed his responsibility as Texas's commissioner to secure all the waters to which Texas was entitled – not just water for irrigation. A little over two months after signing the compact, at a May 1938 conference of water users below Ft. Quitman, he unequivocally stated that it was his duty "to try and get every drop of water Texas had a right to claim, irrespective of how or where it was to be used in Texas." Such a statement indicates that Clayton saw the uses to which the waters Texas obtained under the compact were put were immaterial.[237]

New Mexico's pursuit of the Jemez Creek project in the wake of the compact's signing similarly suggests that interests in that state did not see the waters of the Rio Grande as dedicated exclusively to agriculture. Clayton's response to that project also bolsters the notion that he and others saw other possible uses for the water within the confines of the compact. After the compact's signing but before its ratification by the states and Congress, the City of Albuquerque sought funds from the Public Works Administration to initiate the Jemez Creek Project. Federal

funds for water development within the Rio Grande Basin had been frozen by executive order pending the Rio Grande Joint Investigation, but now with the compact nearly in place long-contemplated projects were pushed forward in New Mexico and Colorado. Albuquerque consulting engineer H.C. Neuffer (who also played a pivotal role in the development of the compact as consultant to the Middle Rio Grande Conservancy District, as discussed in Opinion I) urged Clayton – as the Texas commissioner later related to engineering advisor Raymond Hill – "to clear the Jemez Creek water supply project for the City of Albuquerque."

Clayton demurred on giving Neuffer assent, not so much on the basis of the project itself but because the compact had not yet been adopted. This was a position that the Texas commissioner reportedly shared with EBID and EP #1 representatives, all of whom likewise opposed Colorado's Wagon Wheel Gap project for the same reason. For Wagon Wheel Gap, Clayton wrote Hill, "Our attitude was that until the compact had been ratified, we could not give clearance to any project involving the use of water of the Rio Grande," and he gave Neuffer "the same answer" as to Jemez Creek. Although the engineer and Colorado's representative Ralph Carr both "threaten[ed] to defeat ratification if our refusal to clear these projects result in the loss of federal funds," the Texas commissioner informed his engineering advisor that he could "not see my way to give them clearance, and this was the unanimous attitude of the officials of the Elephant Butte and El Paso County district." Should federal monies be "earmarked pending ratification of the compact," however, "we shall probably have no objection." For Clayton, EBID, and EP #1, it would appear that so long as the compact was in place, the nature of water use within the states was irrelevant.[238]

More compelling evidence of water use agnosticism in the compact comes from statements and analyses prepared by the compact drafters themselves following the compact's singing. As noted in Opinion I above, both Colorado commissioner M.C. Hinderlider and New Mexico commissioner Thomas McClure in letters to their respective governors urging adoption of the compact stated that the agreement safeguarded "present and future uses" of the Rio Grande waters in their states.

An undated "Analysis of the Terms of the Compact," authored by McClure, twice made the point that future, unspecified water uses were protected by the compact. Citing the "schedules of delivery of water at the Colorado-New Mexico State Line and at San Marcial at the head of Elephant Butte Reservoir," the New Mexico state engineer wrote,

> they provide that the three major basins [i.e., Colorado's San Luis Valley, New Mexico's Middle Rio Grande, and the Elephant Butte-Fort Quitman stretch] may make the best use

[238] Frank B. Clayton, Rio Grande Compact Commissioner for Texas, to Mr. Raymond Hill, August 24, 1938. Box 2F466, RGCC-FBCP, UTA.

> of their available supplies by the conservation and use of waters now being beneficially consumed and particularly by the construction of additional reservoirs to make use of waters which would otherwise spill from Rio Grande Project storage and be lost to the entire area [i.e., the Upper Rio Grande Basin, above Ft. Quitman].

Further in the "Summary" to the piece, McClure noted that among the compact's accomplishments,

> It permits each State to make the best possible use of her available supply and by means of storage, to conserve considerable flood waters which must otherwise spill from Project storage and be lost to the basin.[239]

Raymond Hill, recalling the compact negotiations three decades later, agreed. For a Supreme Court original action involving the three Rio Grande states in the late 1960s, Hill prepared a narrative account, "Development of the Rio Grande Compact of 1938," and sat for a deposition. His narrative largely summarizes the available engineers' reports and commission proceedings, yet much like the compact itself does not expressly deny water uses other than irrigation. In fact, in reviewing the events leading to the compact, Hill's narrative suggests that future water developments were not tied exclusively to irrigation:

> The Committee of Engineering Advisers was instructed to prepare schedules of deliveries by Colorado and by New Mexico that would insure [*sic*] maintenance of the relationships of stream inflow to stream outflow that had prevailed under the conditions existent when the Compact of 1929 was executed. The Committee of Engineering Advisers was also instructed to provide for freedom of development of all water resources in the drainage basin of Rio Grande above Elephant Butte subject only to compliance with these schedules.[240]

An exchange that Hill had with United States attorney Donald Redd at a December 1968 deposition further clarified the engineer's meaning as to "freedom of development":

> <u>By Mr. Redd</u>:
>
> Q. Mr. Hill, I call your attention to your statement on page 20 and on page 62 of your report [i.e., "Development of the Rio Grande Compact of 1938"] and on page 62 where you stated that the objective in the negotiations was to base the use on the 1929 conditions [i.e., the passage quoted above], is that correct?
>
> A. Yes, the primary instructions to the Committee of Engineers, of which I was a member, were to develop a relationship between the supply entering the valleys, each valley, and the outflows from the valley, and to development schedules which would reflect that relationship as near as possible. That was the first instruction.

---

[239] McClure, "Analysis of the Compact," undated, 21 and 29. NM_00164500, NM_00164509.
[240] Hill, "Development of the Rio Grande Compact of 1938," 62.

> Q. But in doing so, you contemplated improvements that would make more water available or could make more water available?
>
> A. Yes, that's exactly what I referred to in the second instruction, and it was the clear intent, I am positive, that we were instructed in the development of the schedules and in the provision for operation. Article VI [of the compact, which addressed debits and credits for the states of Colorado and New Mexico], for example, as drafted by the engineers, almost no change in the final text, was to provide for freedom of development between these points of upper index and lower index in each case, so that each State would be free to change its use and the manner of use, each State would be free to provide storage, but subject always to the delivery in accordance with the schedules.
>
> Colorado, for example, had been promoting the Wagon Wheel Gap Reservoir for many, many years, and all of the provisions in the Compact that referred to storage of water in the Reservoirs and how they would be operated were all to make it possible – for example, Wagon Wheel Gap – so the 200,000 acre-feet could be stored in Wagon Wheel Gap that otherwise would have passed over Elephant Butte and down the river and have been of no value to anybody. Obviously, you could not store that flood water in Elephant Butt, then pump it back to San Luis, it had to be stored in Wagon Wheel Gap.
>
> So the whole theory of the thing, the premise under which the Compact was negotiated, that subject only to the maintenance of depletions that had occurred, subject only to not increasing those overall depletions, there is a freedom in each State to store, develop, improve or do anything else within that State. That was the whole intent.[241]

Hill's understanding of the intent of the compact aligned with McClure's: each state was free to utilize the waters of the Rio Grande within their borders as they saw fit, pursuant to the schedules of delivery adopted in the compact that allocated the available water supply of the Upper Rio Grande Basin.

The December 1937 report of the compact engineering advisors and the compact proceedings themselves indicate that "only present needs" within the basin could be considered in the formulation of a compact given the "usable water supply." Irrigation was the predominant use of water in the basin at time. The compact references "irrigation demands" and "irrigation," yet it does not specifically prohibit other uses of the Rio Grande water it apportioned. There is evidence, moreover, from direct participants in the negotiations that, pursuant to the schedules of delivery established by the 1938 compact, Colorado, New Mexico, and Texas were to have autonomy in the development of the waters within their borders – both at the time of the compact and in the future.

---

[241] In the Supreme Court of the United States, October Term 1967, No. 29, Original, *State of Texas and New Mexico, Plaintiffs, vs. State of Colorado, Defendant,* Deposition of: Raymond A. Hill, Taken December 4, 1968, Denver, Colorado, 35-36. ff. Texas & New Mexico v. Colorado, w. Texas vs. Colorado 66-1061, Box 1989 41-240, LF-TAG, TSA.

Opinion VI: The Special Master fairly described the background history leading to the 1938 Rio Grande Compact on pages 31 through 187 and 203 through 209 of the *First Interim Report of the Special Master*, dated February 9, 2017.

Having reviewed the background history leading to the 1938 Rio Grande Compact presented on pages 31 through 187 and 203 through 209 of the *First Interim Report of the Special Master*, dated February 9, 2017 as well as the materials appended to it, it is my expert opinion that the Special Master fairly described that history. I base my opinion not only on my professional knowledge and expertise, but also on the historical records that I examined in the course of researching and analyzing the history of the 1938 Rio Grande Compact, many of which are cited in the opinions above.

Resume of Scott A. Miltenberger, Ph.D. – May 31, 2019

Scott A. Miltenberger, Ph.D.

Partner / Consulting Historian

Summary

Dr. Miltenberger is a professional consulting historian, specializing in environmental and natural resources issues. Since joining JRP in 2006, he has researched alleged riparian and appropriative water rights, historical ground water rights, and Native American and federal reserved water rights in California and throughout the American West. Dr. Miltenberger has also led historical investigations of flood events, land ownership, survey / boundary disputes, and potentially-responsible parties for toxic clean-up under the provisions of CERCLA. His clients have included local, state, and federal agencies, as well as private parties. Dr. Miltenberger has qualified as an expert historian and given expert witness testimony in Sacramento County Superior Court, Santa Clara County Superior Court, and in Arizona's San Pedro-Gila River Adjudication.

Selected Professional Experience

Expert Witness Work, Deposition, and Trial Testimony over the Past 4 Years

State of Texas v. State of New Mexico and State of Colorado, No. 141, Original, Supreme Court of the United States. Preparation of expert historian report and anticipated expert witness deposition and trial testimony concerning the development of the Rio Grande Compact of 1938. Sacramento, CA: Somach Simmons & Dunn, 2012-Present.

Matt Pear and Mark Pear, Plaintiffs, vs. City and County of San Francisco, a municipal corporation, Does, 1-50, inclusive, Case No. 112CV227801, Superior Court of the State of California, County of Santa Clara. Provided expert witness testimony concerning historical land use and urban/suburban/industrial development of Santa Clara County in the 1950s as related to the Hetch Hetchy Aqueduct Right of Way. San Francisco, CA: City and County of San Francisco, City Attorney's Office, San Francisco Public Utilities Commission, 2017.

Summary

This expert report documents the methods and results of estimating acreages and change from 1936 to 2018 for agricultural and riparian land uses. This report also documents methods for estimating agricultural and riparian consumptive use, and changes over the same time period.

Opinions

Expert opinions are at the beginning of each major section: agricultural land use, riparian land use, and agricultural consumptive use.

Purpose, Methodology Overview, and Image Resource Selection

The purpose in the extensive efforts to determine acreages of agricultural crops and riparian areas over time was to establish an accurate acreage of each crop or vegetation type for accurately estimating consumptive use for dominant land use types.

To generate comprehensive estimates of consumptive water use, accurate historical land use information was required. Proven methods were used to generate spatial land use mapping from 1936 through 2018 to inform and generate a comprehensive database of agriculture and riparian land uses within modeled service areas. This was performed annually either spatially or in a tabular format.

It was necessary to identify available and suitable image/photo resources covering the project area. The imagery was evaluated for the period 1936–2018, providing source data for the remotely sensed mapping and analytical efforts. Primary sources for these images included the U.S. Geological Survey (USGS-Landsat), online state archives, the U.S. Department of Agriculture (USDA) National Agriculture Imaging Program (NAIP), and commercial vendor products.

To analyze spatial land use on an approximate decadal time step, or more frequently in recent years, available images and photos were evaluated to select suitable dates and sources. Images were evaluated based on the following criteria:

- Year (target of approximately once every ten years or more frequently if available);
- Date of acquisition (within the primary growing season for most crops between April and August/September), and also for off-season rotational crops during more recent years;
- Completeness of coverage (for at least one or more of the valleys evaluated);

- Cloud-free over area of interest;
- Resolution/scale (resolution varied over time, but had to be suitable enough to at least verify permanent versus annual crops, and irrigated versus non-irrigated crops);
- Color (natural color, color infrared, and/or black and white);
- Quality (imagery containing the expected quality to allow for image processing or photo interpretation);
- Ability to distinguish/verify land use via photo interpretation; and
- Relationship to other non-spatial resources (e.g., crop reports, other historical documentation).

Various selected image dates and resources were used for this analysis (Exhibit 1). The complete list of evaluated images also is provided (Appendix 1).

Imagery Dates

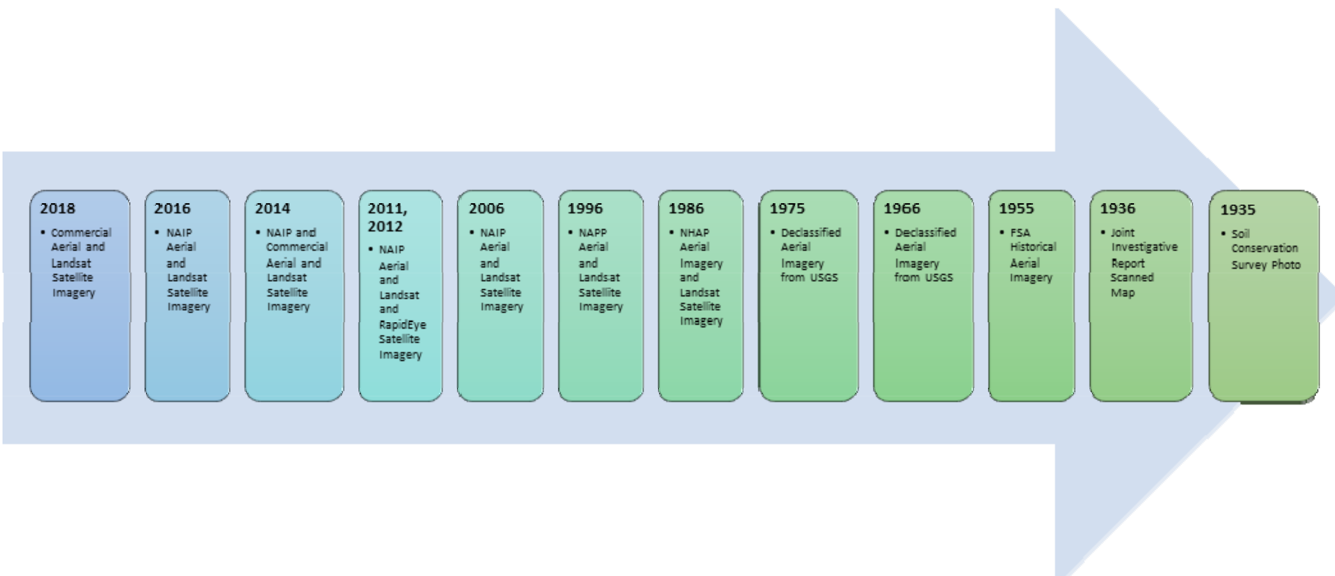

Exhibit 1. Image/photo sources selected for approximately decadal mapping efforts.

The initial year, 1936, was analyzed as a primary comparative year using a simple digital evaluation. The plates (figures) provided in the 1936 Lower Rio Grande Joint Investigative Report (JIR) were georeferenced to image resources. All fields were digitized to create a digital map of irrigated croplands throughout all valleys. These plates were based on field-by-field surveys included in the 1936 Lower Rio Grande JIR. Detailed crop acreages also were reported in the JIR that were the actual surveyed acreages by crop type for 1936. Therefore, for this key bookend year, both spatial and tabular survey data on crop type acreage were available and considered highly accurate.

The final bookend year in this analysis was 2018, when USDA NAIP and USGS-Landsat imagery were used. A rigorous ground truthing effort in 2014 (2x), 2016 (in office), and in 2018 (1X), coupled with these imagery sources, allowed for detailed field delineations and crop classifications to a high level of accuracy on a field-by-field basis.

Ground truthing allows for calibration of remotely sensed image processing algorithms to what is actually growing on the ground for a similarly timed image. Ground truthing also allows the analysis to be verified (i.e., accuracies can be determined) by setting aside a subset of the ground truth data, using the algorithms to classify crops by field, and then comparing that classification to the actual observation in the field. Accuracies are reported later in this report and are consistently in the mid-90s percentage or higher. For most minor misclassifications, the crops are similar (and, therefore, similar consumptive use), and the overall goal to accurately estimate consumptive use across a landscape is not compromised. For each of the three years that nearly one-week ground truth exercises were conducted, approximately 3,200 to 4,000 individual field data points were collected, depending on the year and season.

The 1936 and 2018 spatial analysis years, and other mapped years, allow for an accurate comparison between the differing cropping systems, crop change, and corresponding consumptive use change.

To provide a representative transition for crop changes over this 80-year span, additional image resources were used, when suitable, for analysis. The analysis years included 2018, 2016, 2014, 2012/2011, 2006, 1996, 1986, 1975, 1966, and 1955. USGS-Landsat satellite imagery was used (post 1984) whenever possible to help identify crop types and cropping systems throughout the year.

The selected imagery was acquired, processed, and georeferenced to various control points to ensure accuracy of location and consistency among years.

The result of this effort was a high-quality image dataset best representing the desired historical periods for temporal comparisons, analysis, and mapping.

Development of Spatial Land Use Database

1. Once the image analyses were completed for a selected year, a land use GIS spatial database was compiled for the period of study (1936-2018). Images were initially segmented into two main categories of land use: Agricultural Land Use

2. Riparian Land Use

For Rincon and Mesilla Valleys, agricultural land use was mapped approximately once per decade for the entire period of study and more frequently in recent years. Image quality and other constraints limited riparian mapping to three years: 1955, 2005, and 2014. Data from multiple years were combined to complete the analysis for El Paso Valley, again based on the availability of the image resources. Riparian areas were not classified in the El Paso Valley. A summary of image classifications is provided (Exhibit 2).

Exhibit 2. Summary of Spatial Land Use Analysis Completed by Year and Valley

	Agriculture			Riparian	
Year	Rincon	Mesilla	El Paso	Rincon	Mesilla
2018	X	X	X		
2016	X	X	X		
2014	X	X	X	X	X
2011	X	X	X		
2006	X	X	X	X 2005	X 2005
1996	X	X	X		
1986	X	X	no data		
1975/77	X	X	no data		
1966	X	X	no data		
1955	X	X	winter image	X	X
1936	X	X	X		

The resultant land use maps were interpolated with annual crop reports to generate a comprehensive, annual land use dataset that could be disaggregated spatially into model service areas. A summary of the agricultural and riparian mapping efforts follows. Annual database interpolations and completions follow the land use sections of this report (Appendix A).

Agricultural Land Use

Opinions

The following opinions are based on the results of the agricultural land use determination from 2018 through 1936. All crop acreages are provided in Appendix B.

- The overall irrigated agricultural land in the Rincon and Mesilla Valleys decreased from 98,130 acres in 1936, to 78,157 acres in 2018.
- The overall irrigated agricultural land in the Rincon Valley increased from 15,207 acres in 1936 to 18,238 acres in 2018.
- The overall irrigated agricultural land in the Mesilla Valley decreased from 82,923 acres in 1936 to 59,919 acres in 2018.
- From 1936 to 2018, specific crop acreages transitioned in both valleys; however, the major crop types that dominated the period were: alfalfa, chili peppers (chili), corn/silage, cotton, and pecans.
- Alfalfa in Rincon and Mesilla Valleys generally decreased from 20,310 acres in 1936 to 9,806 acres in 2018.
- Chili in Rincon and Mesilla Valleys increased from 397 acres in 1936 to 8,627 acres in 1989, and then decreased to 1,641 acres in 2018.
- Corn/Silage in Rincon and Mesilla Valleys generally increased from 6,862 acres in 1936 to 8,082 acres in 2018.
- Cotton acreage in Rincon and Mesilla Valleys decreased from 58,126 acres in 1936 to 11,679 acres in 2018.
- Pecan acreage in Rincon and Mesilla Valleys increased from near 0 acres in 1936 to 35,698 acres in 2018.
- The El Paso Valley is primarily dominated by alfalfa, cotton, and pecans. Other crops (e.g., chili, corn/silage, grain, etc.) exist, but in lesser acres consistently throughout time.
- Alfalfa in the El Paso Valley generally decreased from 16,649 acres in 1936 to 3,105 acres in 2018.
- Cotton in the El Paso Valley increased from 44,501 acres in 1936 to approximately 56,622 acres in 1951, and then decreased to 19,161 acres in 2018.
- Pecans in the El Paso Valley increased from almost 0 acres in 1936 to 15,412 acres in 2018.
- This spatial/agricultural land use investigation is the most comprehensive analysis that is known to exist to date.

Methods

Agricultural land use maps were developed for the following years: 2018, 2016, 2014, 2011, 2006, 1966, 1986, 1977/75 (1977 was a small portion of the Mesilla Valley not covered in 1975), 1966, 1955, and 1936.

The 1936 crops were extracted from a hardcopy map produced for the Rio Grande JIR and the JIR survey tabular acreages. Crop distribution maps for all other years were derived from aerial photos and/or satellite imagery. The crops were delineated and classified on a field-by-field basis. The level of detail of crop classes that could be mapped varied depending on the imagery sources and quality, but at a minimum, fields were determined to be irrigated or not irrigated. Crop reports from a number of sources provided information on the dominant types and relative percentages of crops in the different years. Individual crops were classified in the most recent years (1986–2018).

As a starting point for the mapping, field boundaries were digitized from the highest resolution imagery available for each year of analysis. The fields were then classified either using remote sensing techniques and/or traditional photo-interpretation methods. A variety of mapping methods were employed, depending on the imagery resources available and quality of images. The more recent dates were analyzed using a remote sensing approach in which automated classification techniques were used to map crop types. As verification, each classification was reviewed using a photo-interpretive approach. More traditional methods (i.e., photo-interpretation) were used for earlier years as much of the imagery was black and white, and usually of coarser spatial resolution. The classification legend also varied with image resolution. In earlier years, lower image resolution and quality only allowed for classification of broader cropping categories, while higher resolution–multispectral imagery available in more recent years and multi-temporal data resources–allowed classification of 26 individual crop and land use classes. The mapped classes for each year of the analysis are provided (Exhibit 3).

Annual Land Use Analyses

For each year of spatial analysis, a summary of the specific imagery resources, dates, resolution, quality, and other attributes follow. For each year, two or more mapping exhibits are provided (Exhibits 4-32). These exhibits also are provided in larger map size by valley in Appendix 2. The most recent years are listed first.

2018 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	Planet Labs Landsat 8 Google Earth	Multiple dates Multiple dates Multiple dates	5 m 30 m Various	Natural Color Multispectral Natural Color
Mesilla	Planet Labs Landsat 8 Google Earth	Multiple dates Multiple dates Multiple dates	5 m 30 m Various	Natural Color Multispectral Natural Color

- **Field Data** – Ground truth data for summer crops in all three valleys was collected in August 2018 and used as training data for the 2018 classification.

- **Ancillary Data** - Ancillary data used to validate and assist the development of the 2018 crop map included the 2016 classification results, the closest available dates of the Elephant Butte Irrigation District (EBID) crop report (2013), and the El Paso County Water Improvement District #1 (EPCWID) crop report (2012). These data informed the analysts as to the likely dominant crop types and their relative percentages in the years immediately preceding the analysis date but were not used for spatial analysis.

Mapping Methodology

Planet Labs, Google Earth, and multiple dates of Landsat 8 imagery (30 m) from across the growing season were used as the image base. An object-based (i.e., field-based) image classification was used to map the crop types for Rincon and Mesilla Valleys with the 2018 imagery. Field data were stratified by crop type and divided into training and validation data. Mean values of the various image bands were extracted from each imagery date. The mean image values and training data were input to a random forest statistical classification algorithm that assigns a crop type to each field based on the field's statistical similarity to training data.

After the random forest classification was completed, an accuracy assessment was performed using independent validation field data. The resultant accuracy assessment matrix provides information on the overall 2018 classification accuracy and the accuracy of individual crop types (Appendix C).

Following the accuracy assessment, additional photo-interpretation editing was performed to refine the classification. Fields with low classification probability values were inspected and evaluated against the imagery. When a low probability was identified through expert photo-interpretation, the class label was corrected. The high resolution of the aerial imagery provided textural cues that were correlated to crop type. Row structures and even some plant structures could be discerned, allowing for a high level of discrimination between crop types during the review/editing phase.

Mapped Classes

Multiple dates of high-resolution imagery and ground truth data supported highly detailed crop mapping for 2018. The crop legend accounted for 34 individual crop types and land uses. Using the Landsat imagery in conjunction with the other imagery, early and late season crops were identified and mapped (e.g., small grains, onions, lettuce, cabbage, melons, etc.).

2016 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	NAIP Landsat 8	May/early June Multiple dates	1 m 30 m	Natural Color Multispectral
Mesilla	NAIP Landsat 8	May/June/August Multiple dates	1 m 30 m	Natural Color Multispectral

- **Field Data** – Ground truth data for summer crops in all three valleys was collected in June 2014 and used as training data for classification efforts.

- **Ancillary Data** - Ancillary data used to validate and assist the development of the 2016 crop map included the 2014 classification results, the 2013 Cropland Data Layer (CDL) produced by the National Agricultural Statistics Service (NASS) of the USDA, the closest available dates of the Elephant Butte Irrigation District (EBID) crop report (2013), and the El Paso County Water Improvement District #1 (EPCWID) crop report (2012). These data informed the analysts as to the likely dominant crop types and their relative percentages in the years immediately preceding the analysis date, but were not used for spatial analysis.

Mapping Methodology

Source imagery included NAIP imagery (1m) from late May/early June, and multiple dates of Landsat 8 imagery (30 m) from across the growing season. An object-based (i.e., field-based) image classification was performed to map the crop types for Rincon and Mesilla Valleys with the 2016 imagery. Field data were stratified by crop type and divided into training and validation data. Mean values of the various image bands were extracted from each image date. The mean image values and training data were input to a random forest statistical classification algorithm that assigns a crop type to each field based on the field's statistical similarity to training data.

After the random forest classification was completed, an accuracy assessment was performed using independent validation field data. The resultant accuracy assessment matrix provides information on the overall accuracy and the accuracy of individual crop types.

Following the accuracy assessment, additional photo-interpretation editing was performed to refine the classification. Fields with low classification probability values were inspected and evaluated against the imagery. When a low probability was identified through expert photo-interpretation, the class label was corrected. The high resolution of the aerial imagery provided textural cues that were correlated to crop type. Row structures and even some plant structures could be discerned, allowing for a high level of discrimination between crop types during the review/editing phase.

Mapped Classes

Multiple dates of high-resolution imagery and ground truth data supported detailed crop mapping for 2016 and 2014. The crop legend accounted for 34 individual crop types and land uses. Using the Landsat and NAIP imagery, early and late season crops were identified and mapped (e.g., small grains, onions, lettuce, cabbage, melons, etc.).

2014 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	Aerial Imagery NAIP Landsat 8	Aug 19-20, 2014 May/early June Multiple dates	0.33 feet 1 m 30 m	CIR (# bands) Natural Color Multispectral
Mesilla	Aerial Imagery NAIP Landsat 8	Aug 19-20, 2014 May/early June Multiple dates	0.33 feet 1 m 30 m	CIR (# bands) Natural Color Multispectral
El Paso	Aerial Imagery NAIP Landsat 8	Aug 19-20, 2014 Aug/Oct 2014 Multiple dates	0.33 feet 1 m 30 m	CIR (# bands) Natural Color Multispectral

- **Field Data** – Ground truth data for summer crops in all three valleys was collected in June 2014. Additional ground-truth data for fall annuals was collected during September 2014. A total of 3,812 ground truth points were collected, representing 25 crop classes. The resulting GIS dataset consisted of a point layer with attributes indicating crop, irrigation method, date of collection, and field comments.

- **Ancillary Data** - Ancillary data used to validate and assist the development of the 2014 crop map included the 2013 Cropland Data Layer (CDL) produced by the National Agricultural Statistics Service of the USDA, and the closest available dates of the Elephant Butte Irrigation District (EBID) crop report (2013) and the El Paso County Water Improvement District #1 (EPCWID) crop report (2012). These data informed the analysts as to the likely dominant crop types and their relative percentages in the years immediately preceding the analysis date but were not used for spatial analysis.

Mapping Methodology

Source imagery included high resolution aerial imagery (0.33 feet) from Aug. 2014, NAIP imagery (1m) from late May/early June, and multiple dates of Landsat 8 imagery (30 m) from across the growing season. An object-based (i.e., field-based) image classification was performed to map the crop types for Rincon and Mesilla Valleys with the 2014 imagery. Field data were stratified by crop type and divided into training and validation data. Eighty percent of the ground data sites for crop type were used for training, while 20% were set aside for independent validation/accuracy assessment. Mean values of the various image bands were extracted from each date of imagery. The mean image values and training data were input to a random forest statistical classification algorithm that assigns a crop type label to each field based on the field's statistical similarity to training data.

After the random forest classification was completed, an accuracy assessment was performed using independent validation. The resultant accuracy assessment matrix provides information on the overall

2014 classification accuracy and the accuracy of individual crop types (Appendix C). The year 2014 served as the baseline year for change analysis for historical years. It was also the only year for which detailed ground-truth data were available.

Following the accuracy assessment, additional photo-interpretation editing was performed to refine the classification. Fields with low classification probability values were inspected and evaluated against the imagery. When an error was identified through expert photo-interpretation, the class label was corrected. The extreme high resolution of the aerial imagery provided textural cues that were correlated to crop type. Row structures and even some plant structures could be discerned, allowing for a high level of discrimination between crop types during the review/editing phase.

Because of the relatively low crop type diversity and the level of detail provided by the very high resolution of the aerial imagery, the El Paso Valley was mapped solely based on photo-interpretation. The ground-truthing sites were used to guide the classification.

A rainfall event that occurred during the collection of the aerial imagery covering Rincon Valley resulted in a slight difference in the spectral characteristics of the aerial imagery between the north and south parts of Rincon Valley. Additionally, the aerial imagery showed some cloud shadows in the center of the Rincon Valley, and one data band (NIR) was missing from two small areas in this valley, resulting in small "holes" in the imagery. The inclusion of the other imagery sources (e.g., NAIP) mitigated the impact of these limitations.

Mapped Classes

Multiple dates of high-resolution imagery and ground truth data for 2014 supported a highly detailed crop mapping. The crop legend accounted for 36 individual crop types and land uses. Using the Landsat imagery in conjunction with the multiple high-resolution images, early and late season crops also were identified and mapped (e.g., small grains, onions, lettuce, cabbage, melons, etc.).

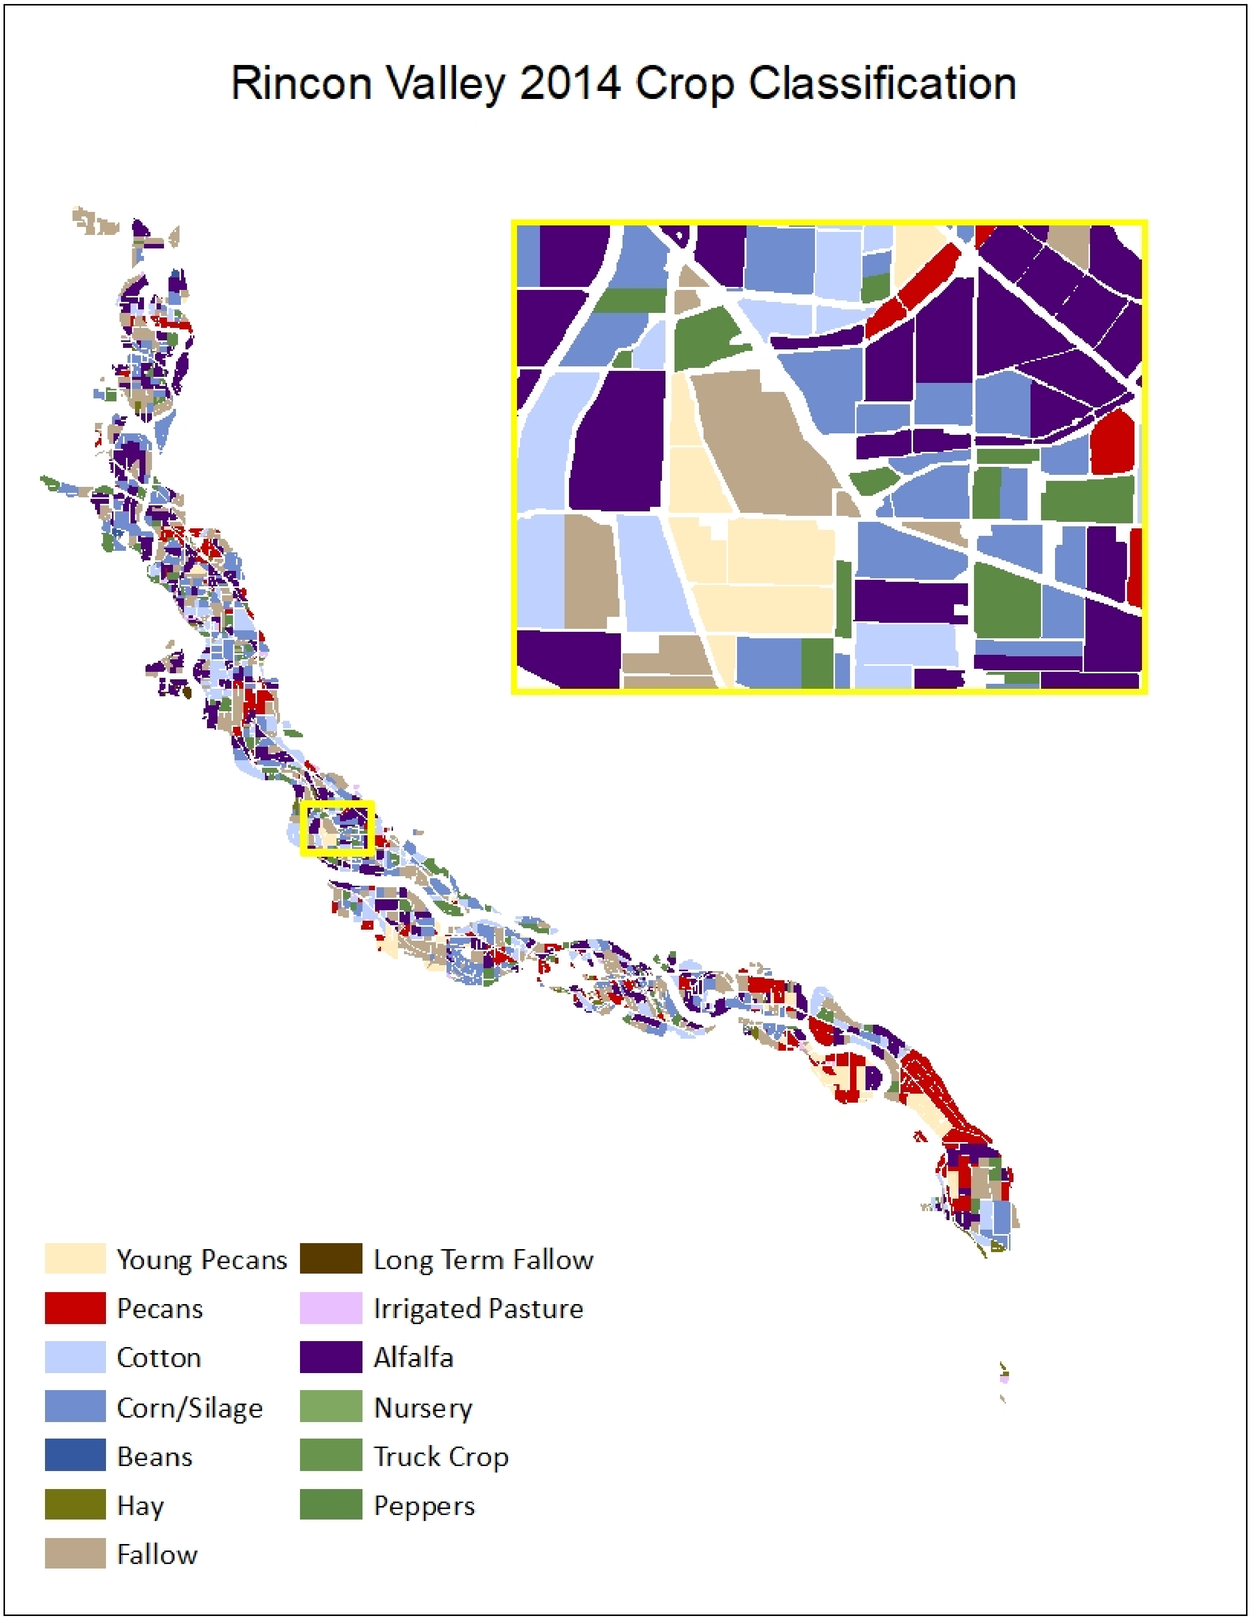

Exhibit 11. 2014 Crop Classification – Mesilla Valley

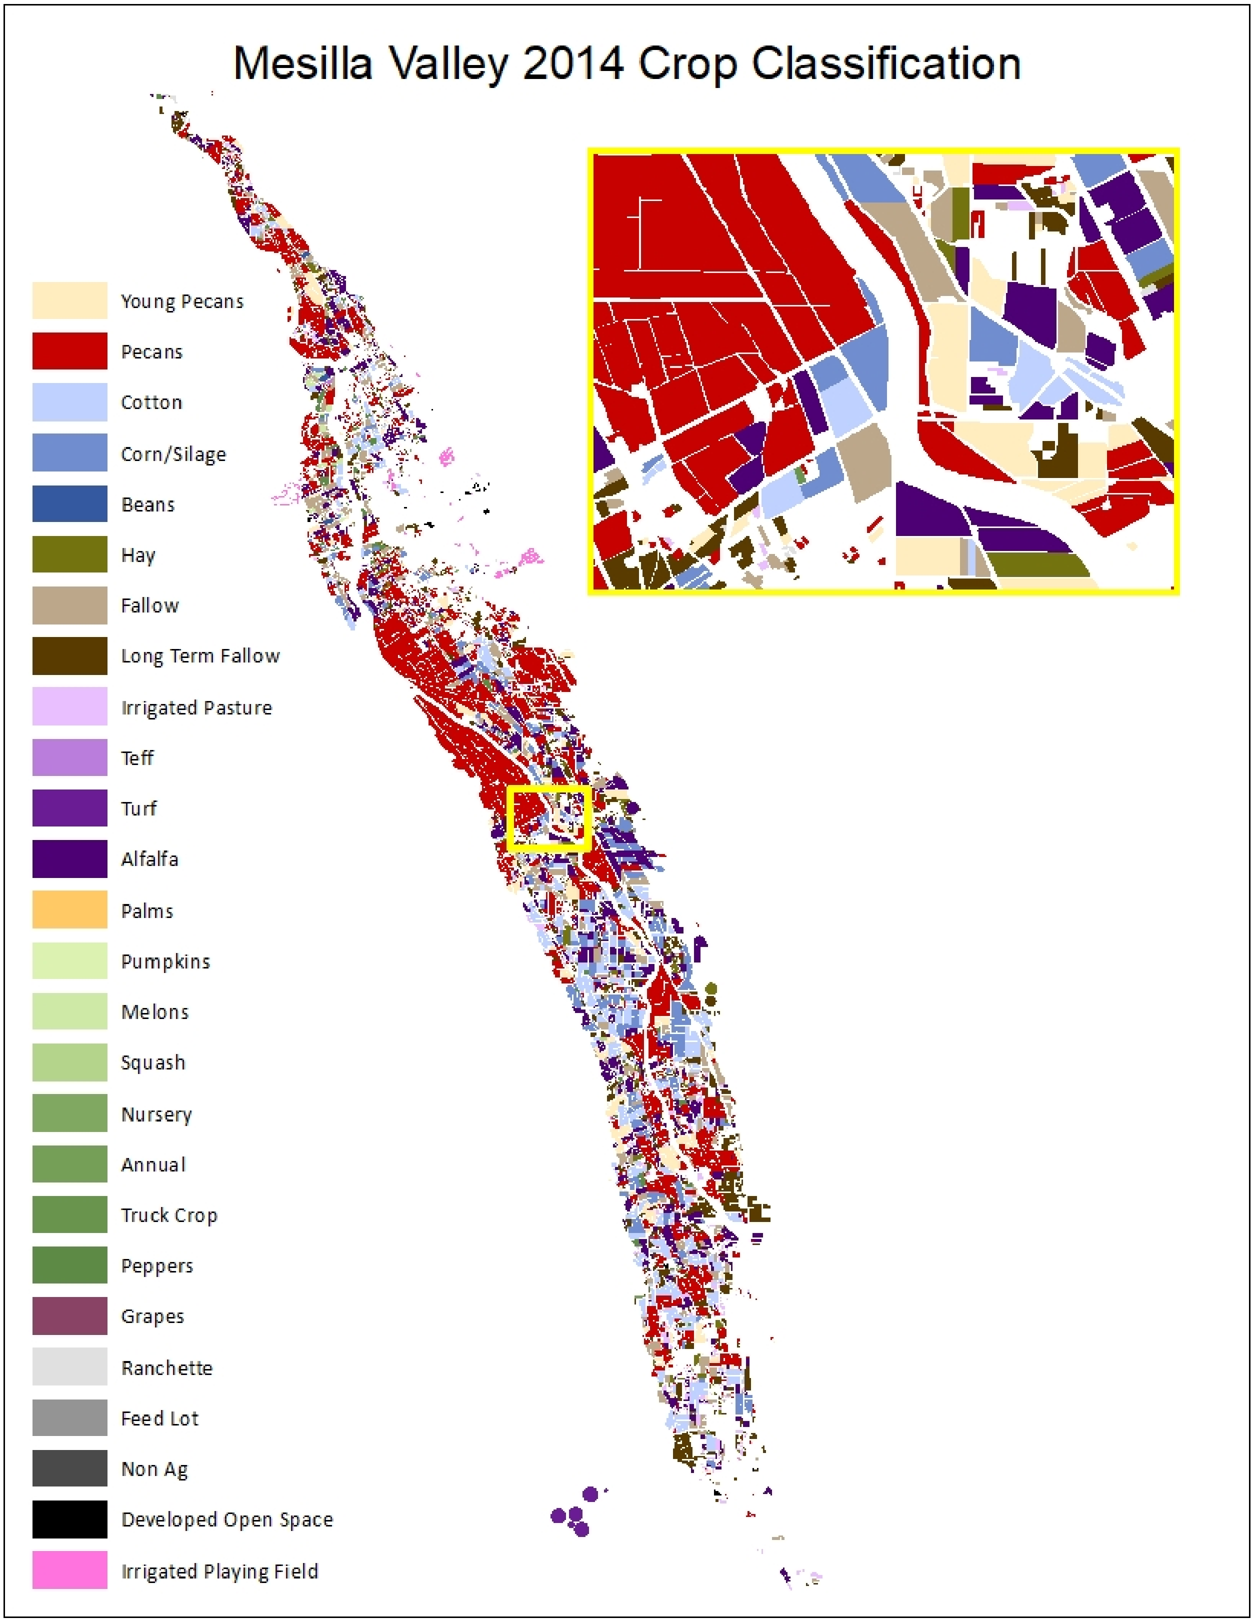

Exhibit 12. 2014 Crop Classification – El Paso Valley

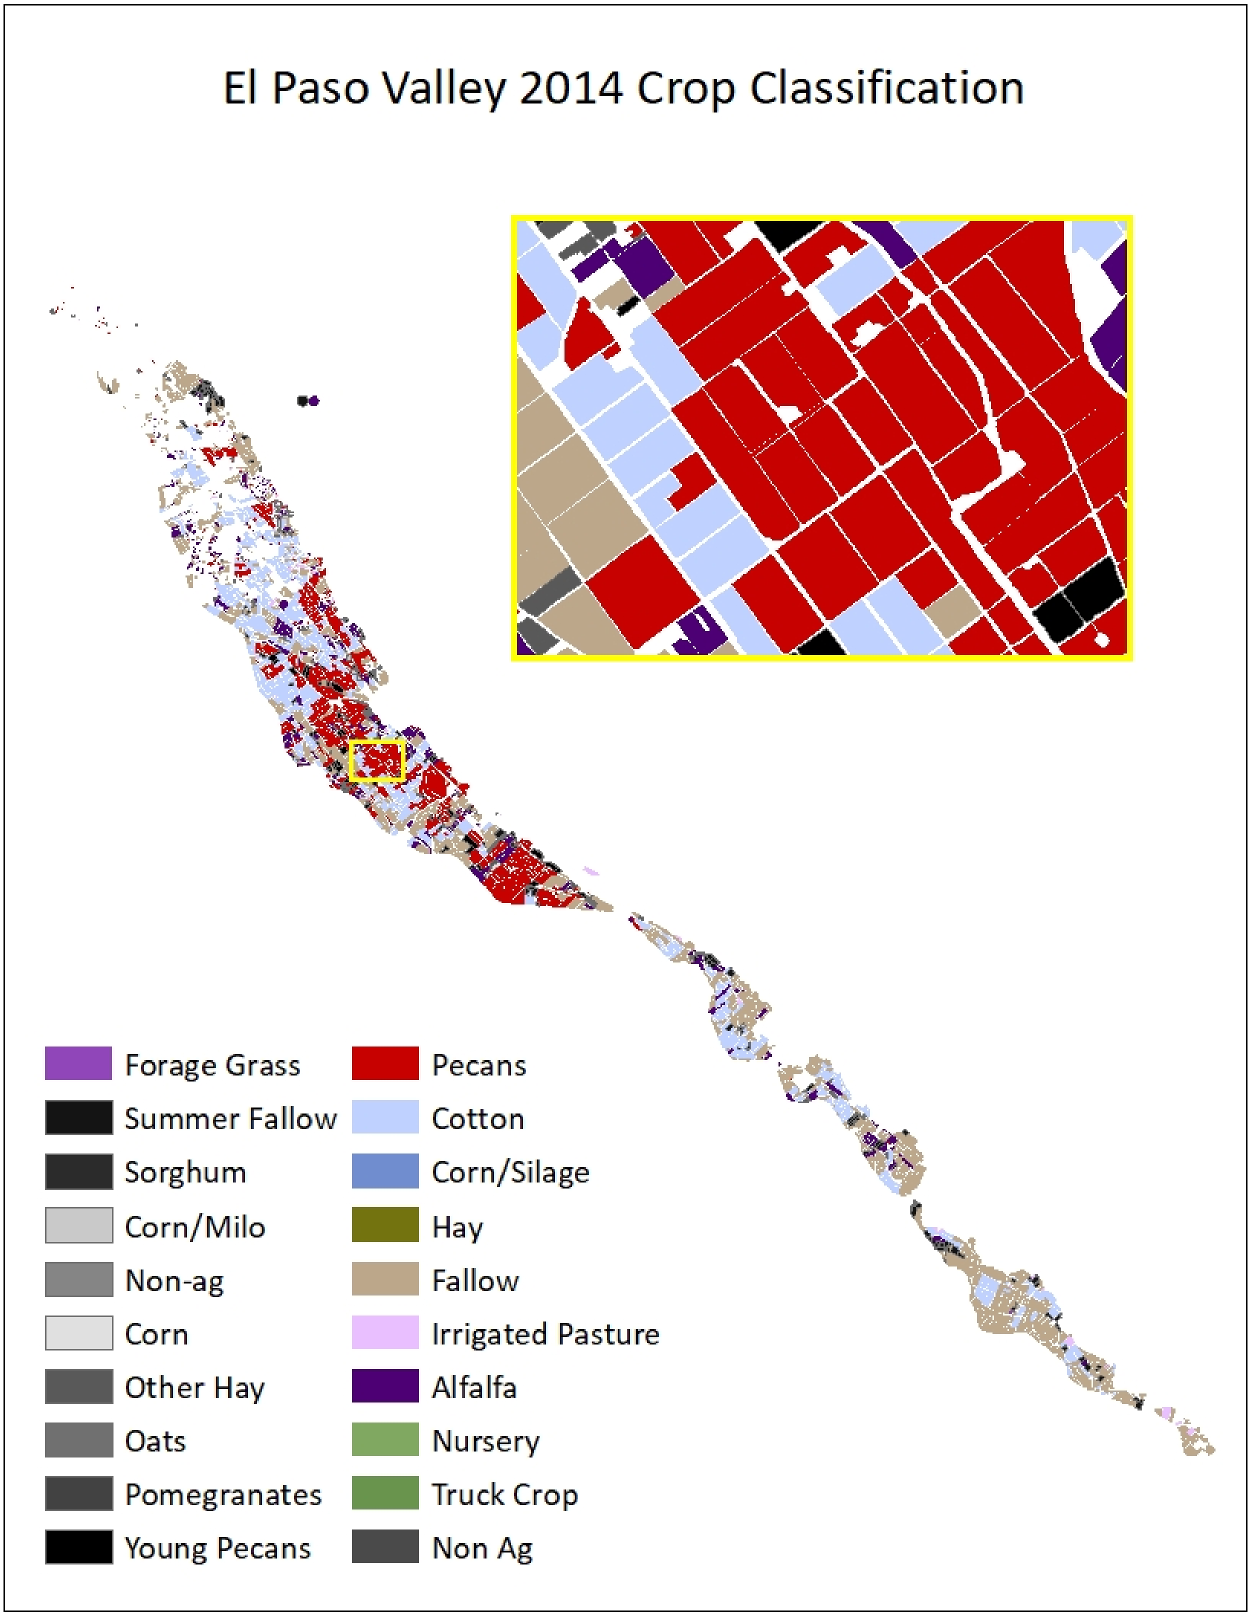

2012/2011 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	NAIP	May 2011/Nov 2011	1 m	CIR
	RapidEye	Aug 7 & 23, 2011	5 m	Multispectral
	Landsat 5	Multiple dates	30 m	Multispectral
Mesilla	NAIP	May 2011/Nov 2011	1 m	CIR
	RapidEye	Aug 6 & 23, 2011	5 m	Multispectral
	Landsat 5	Multiple dates	30 m	Multispectral
El Paso	NAIP	Aug 30, 2012	1 m	Natural Color
	RapidEye	May 24 & Jun 21, 2012	5 m	Multispectral
	Landsat 5	Multiple dates	30 m	Multispectral

- **Ancillary Data** - Ancillary data used to validate and assist development of the 2011/2012 crop map included 2011 Cropland Data Layer (CDL) produced by USDA and the EBID and EPCWID crop reports from 2011 and 2012. These data informed the analysts as to the dominant crop types and their relative percentages in 2011. Google Earth high-resolution imagery from November 2011, covering much of Rincon Valley and all of Mesilla Valley, provided a valuable source of additional photo-interpretation information.

Mapping Methodology

Source imagery for the 2011 agriculture mapping of Rincon and Mesilla Valleys consisted of:

- High resolution (1 m) NAIP imagery from May;
- RapidEye satellite imagery from late summer (August); and
- Landsat 5 imagery from throughout the growing season.

Similar imagery was used to map El Paso Valley, except that the NAIP imagery was from August and the RapidEye imagery was from May/June. Because no field data was available from 2011, training sites representing the different crop types were identified by photo-interpretation of the high-resolution imagery only when crop type was certain. A random forest classification was conducted to assign class labels to each field based on each field’s spectral similarity to the input training sites. The results of the random forest classification were inspected and refined based on photo-interpretation. The review/editing stage benefitted from Google Earth’s high-resolution, natural color image from November 11, 2011, covering all of Mesilla Valley and all but the northern 20% of Rincon Valley. This imagery was a valuable photo-interpretation resource for validating and refining the final crop map. In particular, this November imagery greatly facilitated the discrimination of cotton from other crops. The mature cotton bolls gave the cotton fields a distinct visual signature.

Mapped classes

The crop legend for 2011 was similar to the crop legend developed for 2014 because of the availability of timely, high resolution imagery sources. In total, 26 individual crop and land use classes were mapped.

Exhibit 13. 2011 Crop Classification – Rincon Valley

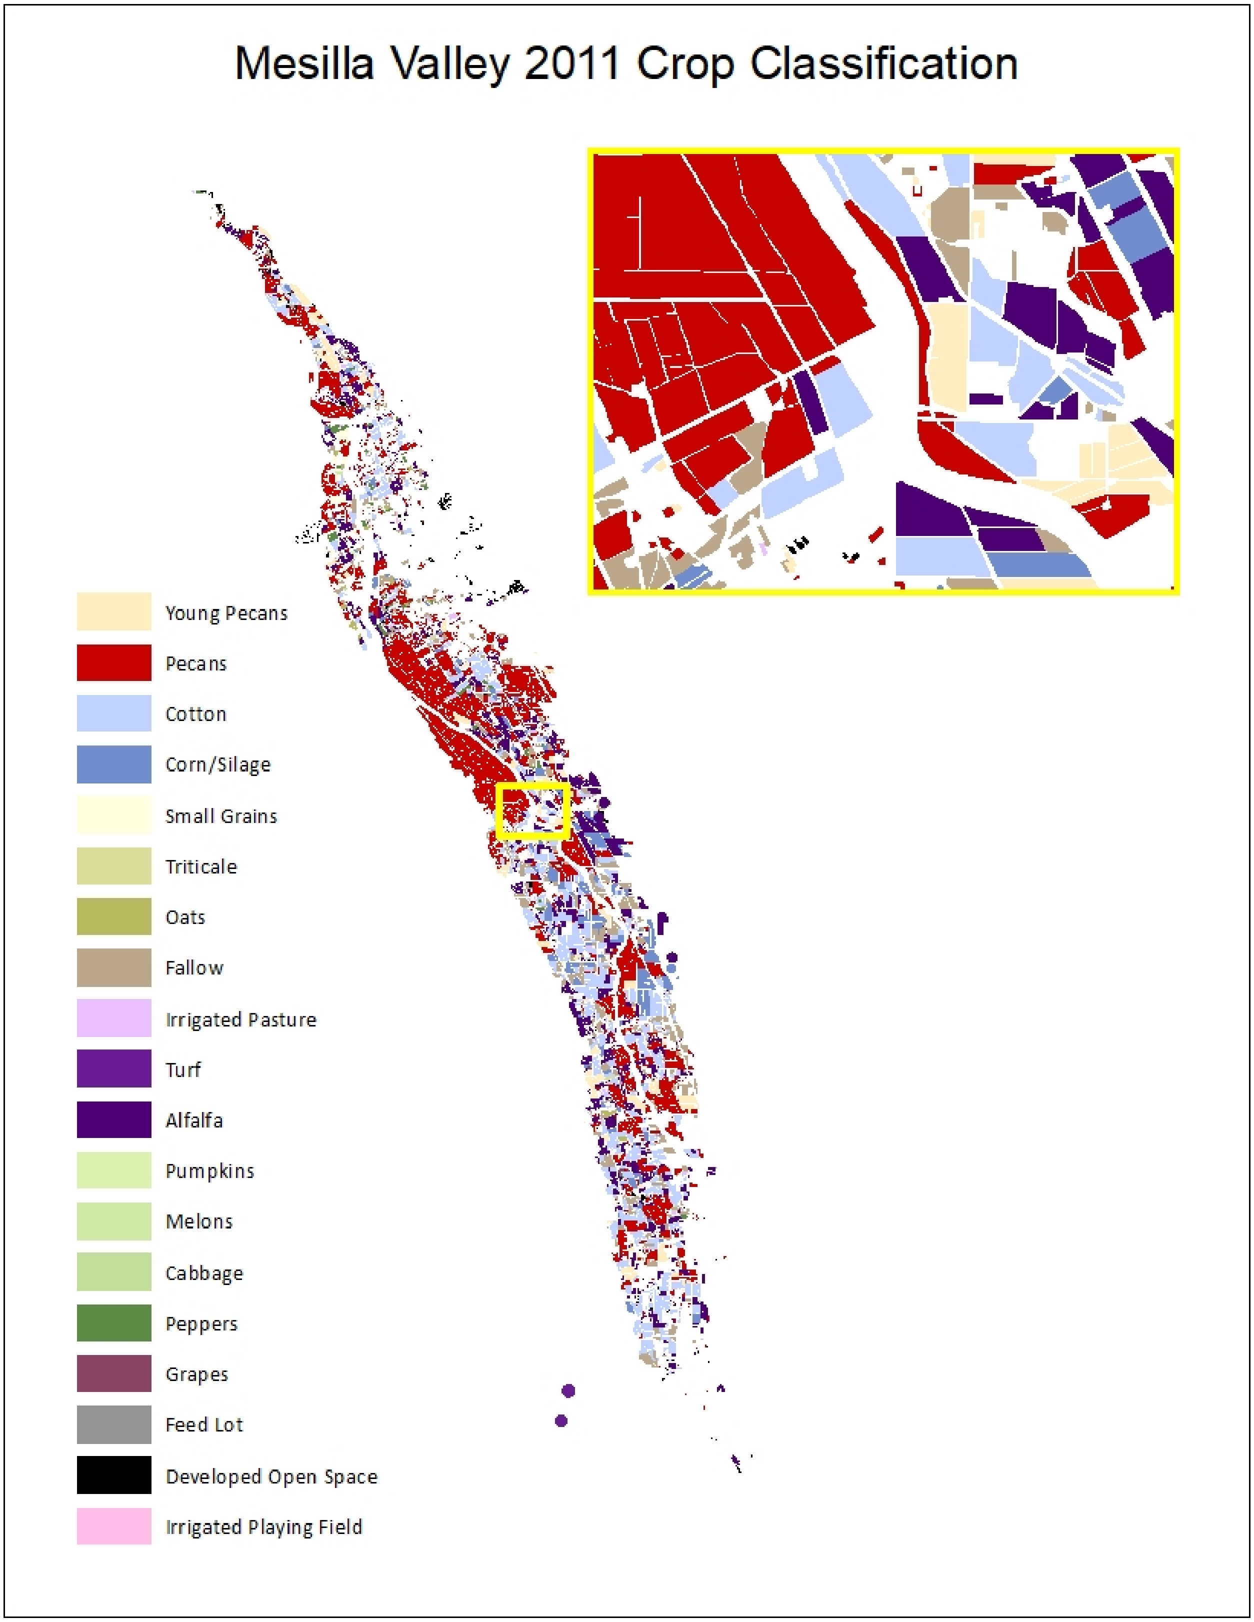

Exhibit 15. 2012 Crop Classification – El Paso Valley

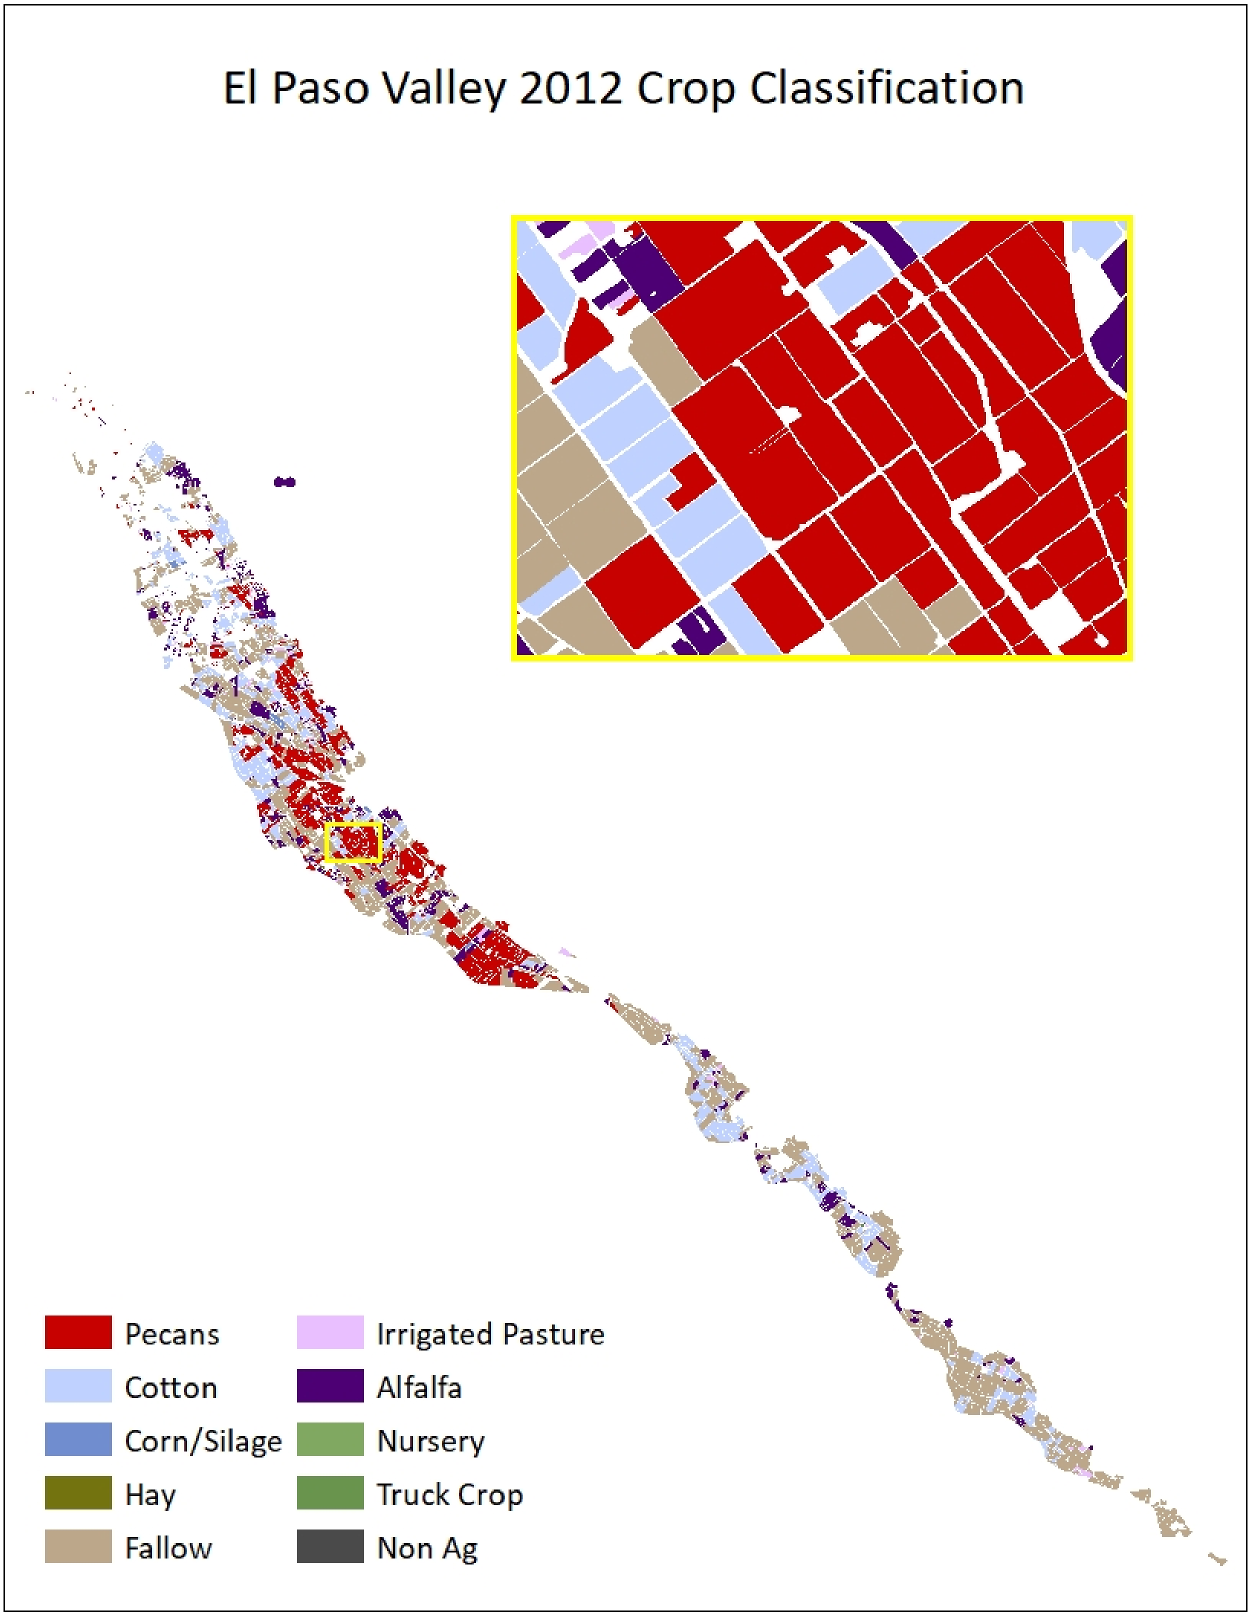

2006 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	NAIP	Aug 24, 2006	2 m	Natural Color
	Aster	July 20, 2006	15 m	CIR
	Landsat 5	Multiple dates	30 m	Multispectral
Mesilla	NAIP	Aug/Sept, 2006	2 m	Natural Color
		Aug 2006	15 m	CIR
	Landsat 5	Multiple dates	30 m	Multispectral
El Paso	NAIP	Sept, 2012	2 m	CIR
	Landsat 5	Multiple Dates	30 m	Multispectral
	Landsat 5	Multiple dates	30 m	Multispectral

- **Ancillary Data** - Ancillary data used to validate and assist the development of the 2006 crop map included the EBID 2006 crop report.

Mapping Methodology

Similar to the 2011 analysis, a random forest classification was conducted to map the individual crop types for all three valleys for 2006. Imagery sources included:

- High resolution NAIP imagery from August (Rincon and Mesilla) and September (El Paso);
- ASTER satellite imagery from various summer dates; and
- Landsat 5 satellite imagery from across the growing season.

Training sites representing the different crop types were identified by photo-interpretation.

Mapped classes

The level of detail and crop classes mapped for 2006 were similar to 2011 and 2014, with 26 individual crop and land use classes identified. For 2006, the late summer grain and silage were grouped together as the imagery resolution was not sufficient to separate corn, sorghum, and sudangrass. However, these three crops have similar consumptive use quantities.

Exhibit 16. 2006 Crop Classification – Rincon Valley

1996 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	NAPP Landsat 5	Sept/Oct, 1996 Multiple dates	1 m 30 m	CIR Multispectral
Mesilla	NAPP Landsat 5	March/Oct, 1996 Multiple dates	1 m 30 m	CIR Multispectral
El Paso	NAPP Landsat 5	Jan – March, 1996 Multiple dates	4 m 30 m	CIR Multispectral

- **Ancillary Data** - Ancillary data used to validate and assist development of the 1996 crop map included the EBID and Bureau of Reclamation (BOR) 1996 crop reports. These data informed the analysts as to the dominant crop types and their relative percentages in 1996.

Mapping Methodology

Data sources for the 1996 mapping consisted of:

- National Aerial Photograph Program (NAPP) aerial photos; and
- Landsat 5 imagery from across the growing season.

NAPP was captured in Sept./Oct. for Rincon Valley, and in March and October for Mesilla Valley. NAPP for El Paso Valley was captured between January and March.

Although the NAPP digital imagery had a spatial resolution (i.e., pixel size) of 1-square meter for Rincon and Mesilla, and 4-square meters for El Paso, the NAPP imagery was of lower quality than the 1-meter resolution NAIP imagery available for more recent dates. The NAPP imagery was collected as 1:40,000 scale film photographs from an altitude of 20,000 feet. The film was later scanned by USGS and orthorectified to produce the 1-meter resolution digital imagery.

A random forest classification was performed for mapping Rincon and Mesilla Valleys. While the NAPP imagery was used for some of the training site selection and to review/edit the classification results, they were not included in the random forest automated classification because the NAPP dates did not represent the summer growing season. Only the multiple dates of the Landsat imagery were included as independent variables for the random forest classification. Thus, the temporal and spectral patterns of the Landsat imagery were used to differentiate crop types. This corresponded to a crop calendar for yet another line of evidence resulting in a crop type designation. Although cotton and chilis have similar temporal and spectral characteristics, the late summer/early fall NAPP imagery allowed for confident differentiation of cotton and chili by photo-interpretation following the automated classification.

In addition, temporal NDVI values from each date of Landsat imagery were plotted for each field. These time series plots provided additional information for discriminating between different crop types, as certain crops have distinctive NDVI time profiles.

The El Paso Valley was manually classified in 1996, relying primarily on NDVI time series plots and photo-interpretation. Due to the limited number of crop types in the El Paso Valley, this was a suitable method to use to employ image resources during the growing season.

Mapped classes

Image resolution allowed for a crop and land use legend of 22 classes for Rincon and Mesilla Valleys, and a crop legend of 13 classes for the El Paso Valley, with the major crops of pecans, cotton, alfalfa, and corn/sorghum/milo all being separated into their own classes.

Exhibit 19. 1996 Crop Classification – Rincon Valley

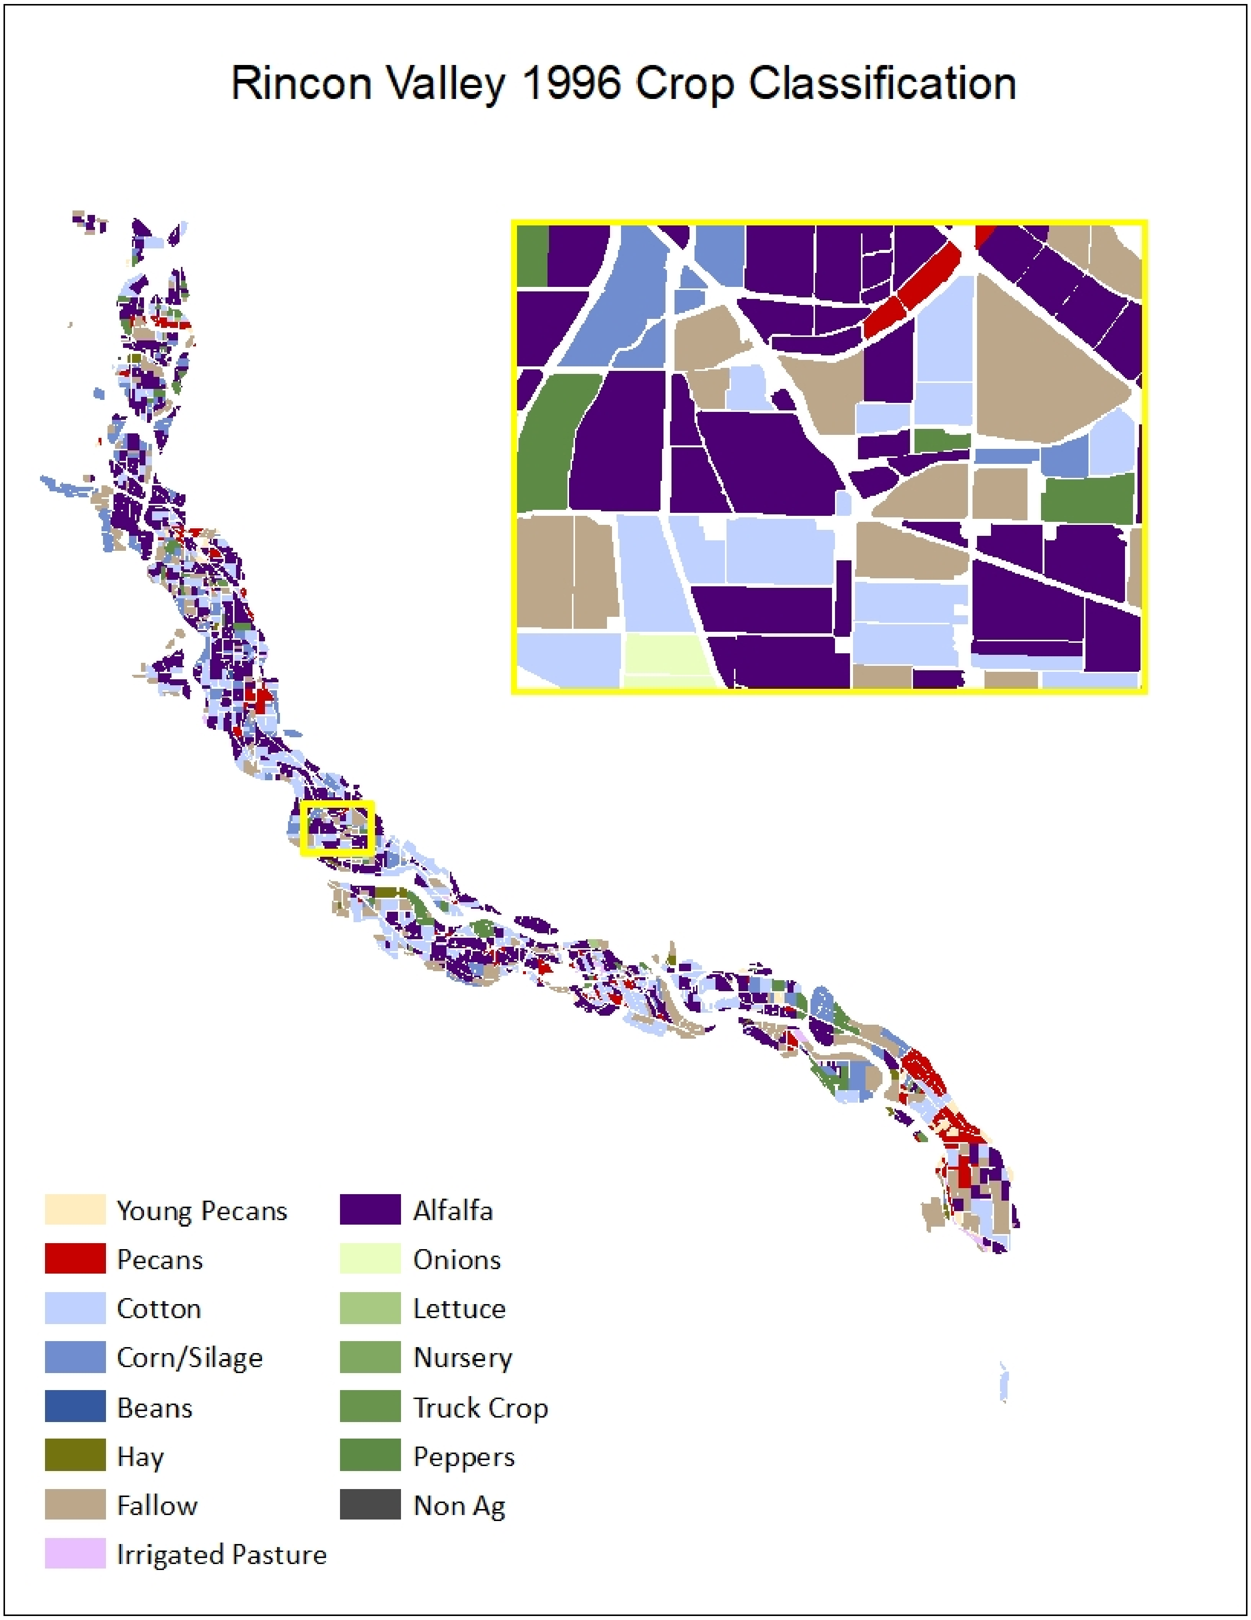

Exhibit 20. 1996 Crop Classification – Mesilla Valley

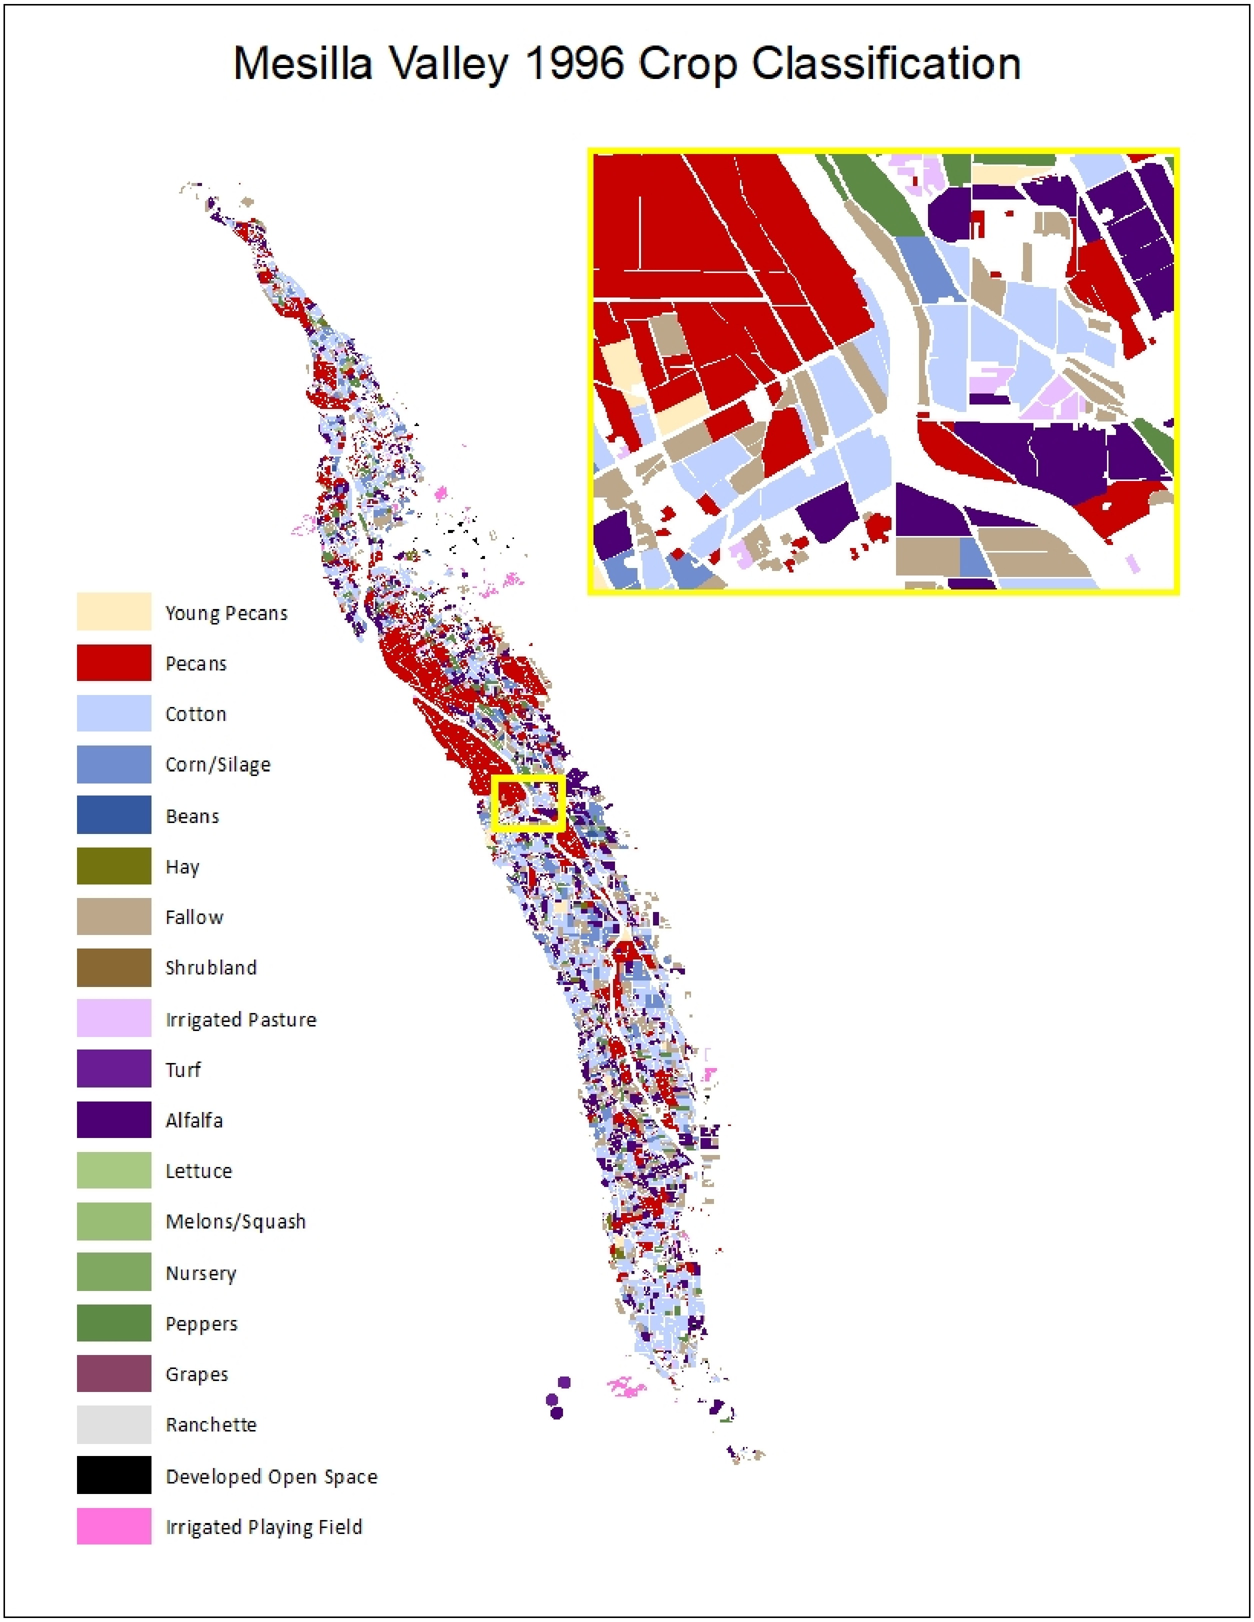

Exhibit 21. 1996 Crop Classification – El Paso Valley

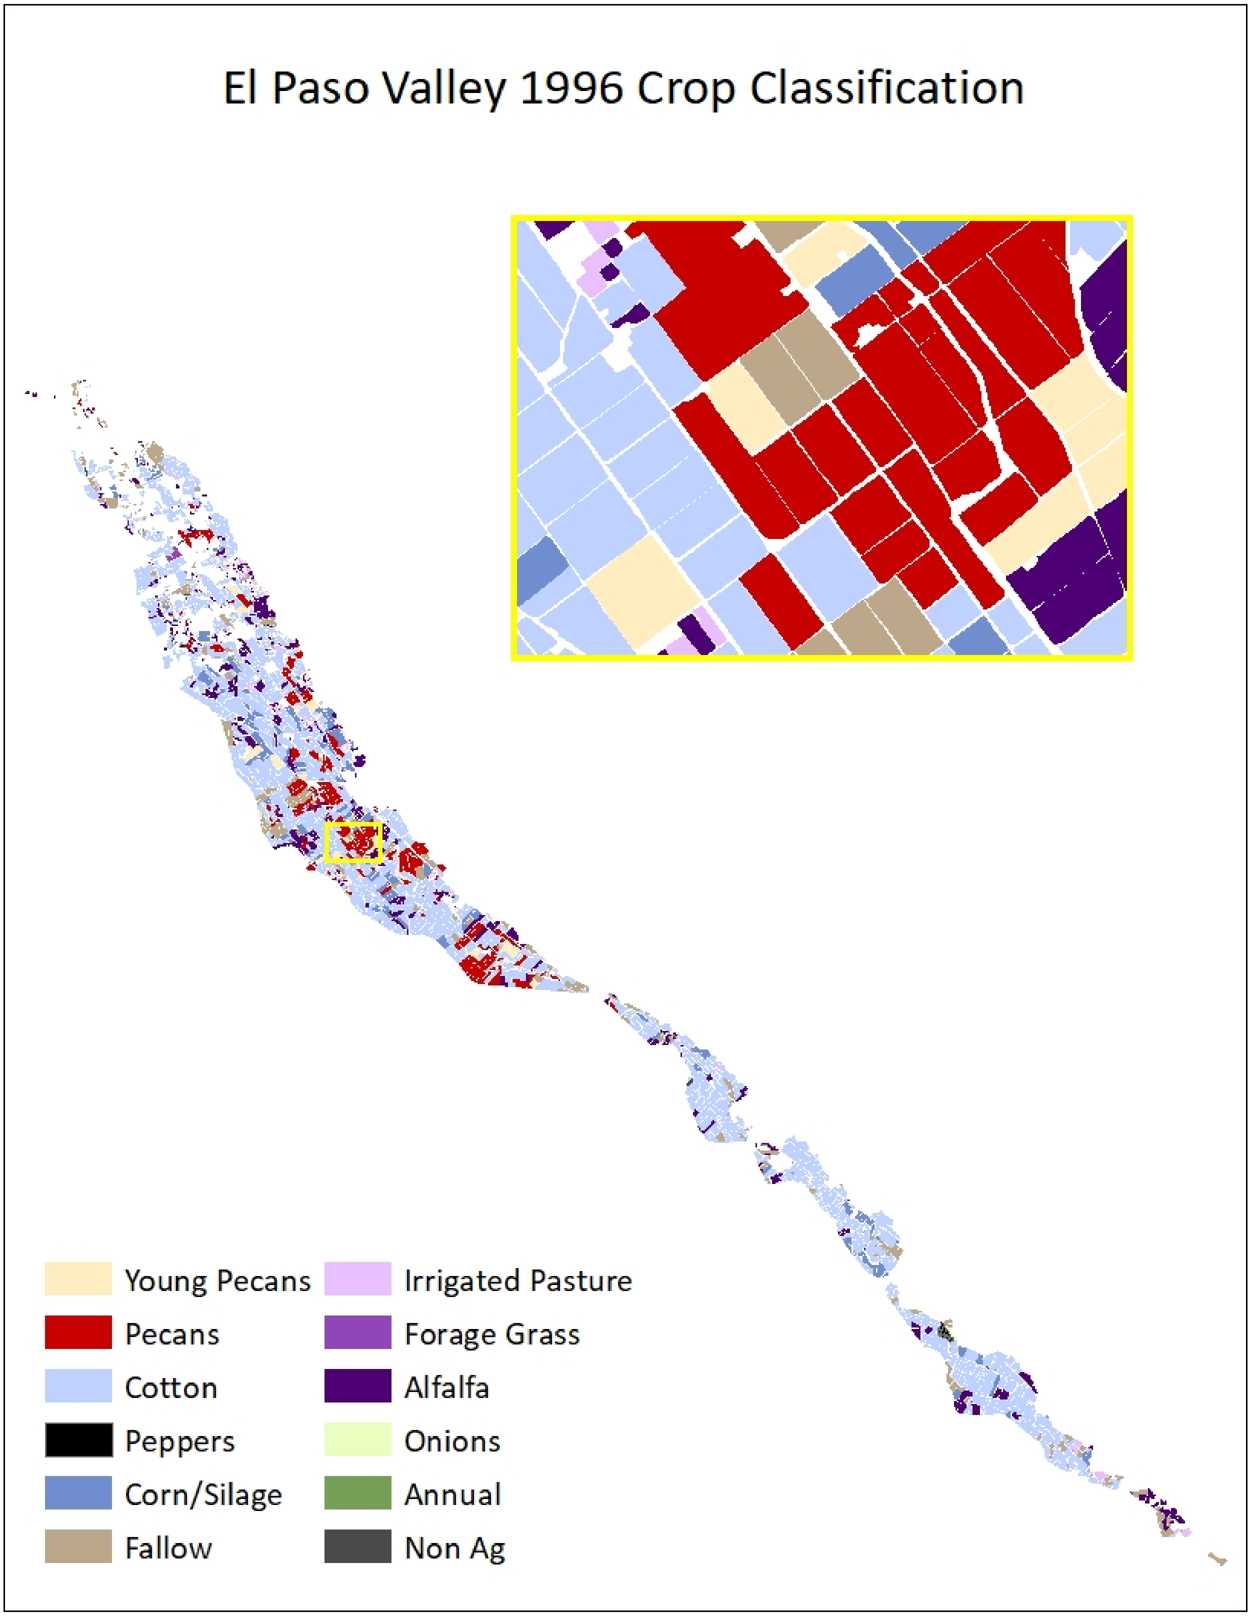

1986 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	NHAP Landsat 5	May & Sept, 1986 Multiple dates	4 m 30 m	CIR Multispectral
Mesilla	NHAP Landsat 5	June/July, 1996 Multiple dates	4 m 30 m	CIR Multispectral
El Paso	No appropriate imagery available			

- **Ancillary Data** - Ancillary data used to validate and assist the development of the 1986 crop map included the EBID and BOR 1986 crop reports.

Mapping Methodology

Source imagery for the 1986 analysis of Rincon and Mesilla consisted of:

- National High Altitude Photography (NHAP) program CIR aerial photos; and
- Landsat 5 imagery from multiple dates across the growing season.

The NHAP photos were originally acquired as film photos at an altitude of 40,000 feet, resulting in a scale of 1:58,000. The photos were then scanned by USGS and georeferenced with an output pixel resolution of 4 square meters.

The crop types were classified using a random forest classification methodology, with training sites selected via photo-interpretation and the Landsat data as independent variables. The 4-meter resolution of the NHAP imagery resulted in a classification with more grouped crop types compared to more recent years with higher resolution. The NHAP imagery for the Mesilla Valley was from June/July, and for both spring and late summer for the Rincon Valley. As in previous year classifications, time series profiles of the Landsat NDVI values were used to assist with the classification.

El Paso crops were not mapped in 1986 because no appropriate imagery was available.

Mapped classes

Decreased resolution of imagery resources for this date resulted in a reduced crop and land use classification legend; 17 individual classes were mapped. Textural, tonal, and structural differences of individual fields allowed for confident classification of alfalfa and pecans. Temporal and tonal differences allowed for some identification of spring and fall annuals, while the mid-summer annuals (corn, milo, sudangrass, cotton, and chili) had to be grouped as they could not be convincingly differentiated.

Exhibit 22. 1986 Crop Classification – Rincon Valley

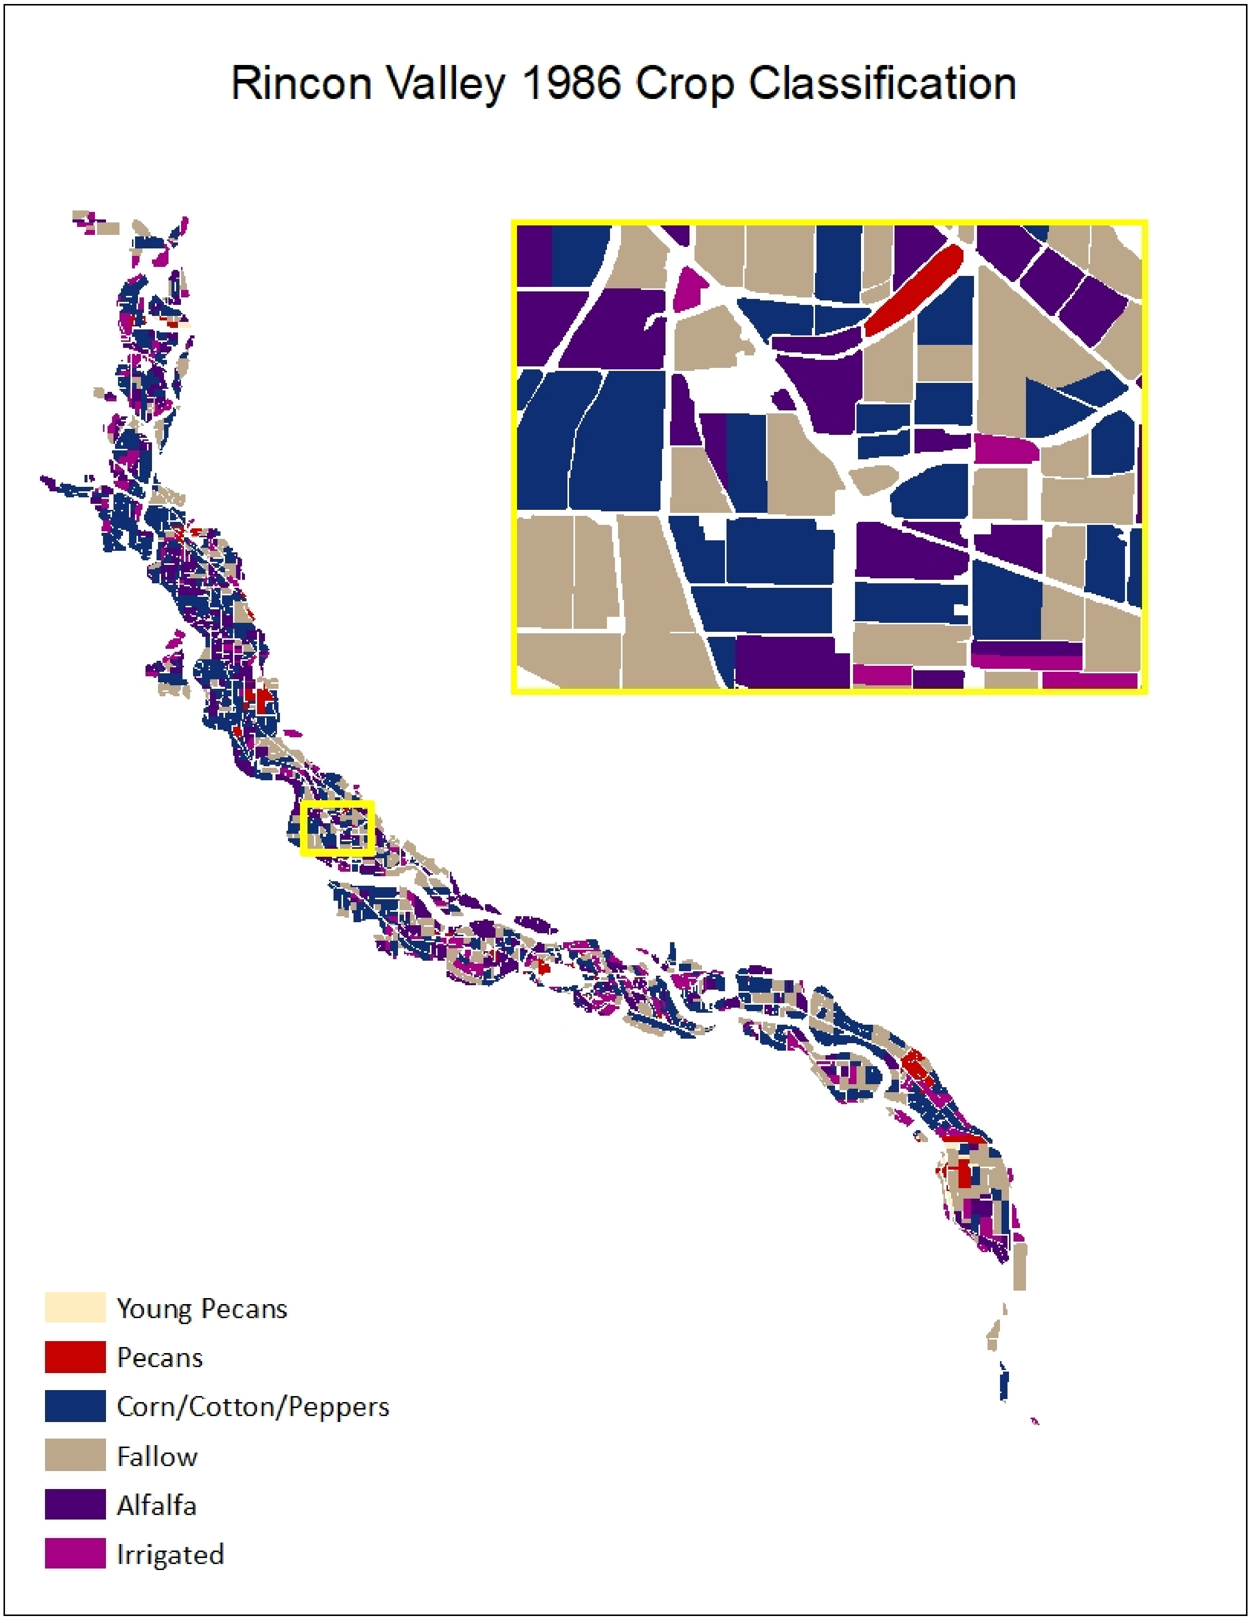

Exhibit 23. 1986 Crop Classification – Mesilla Valley

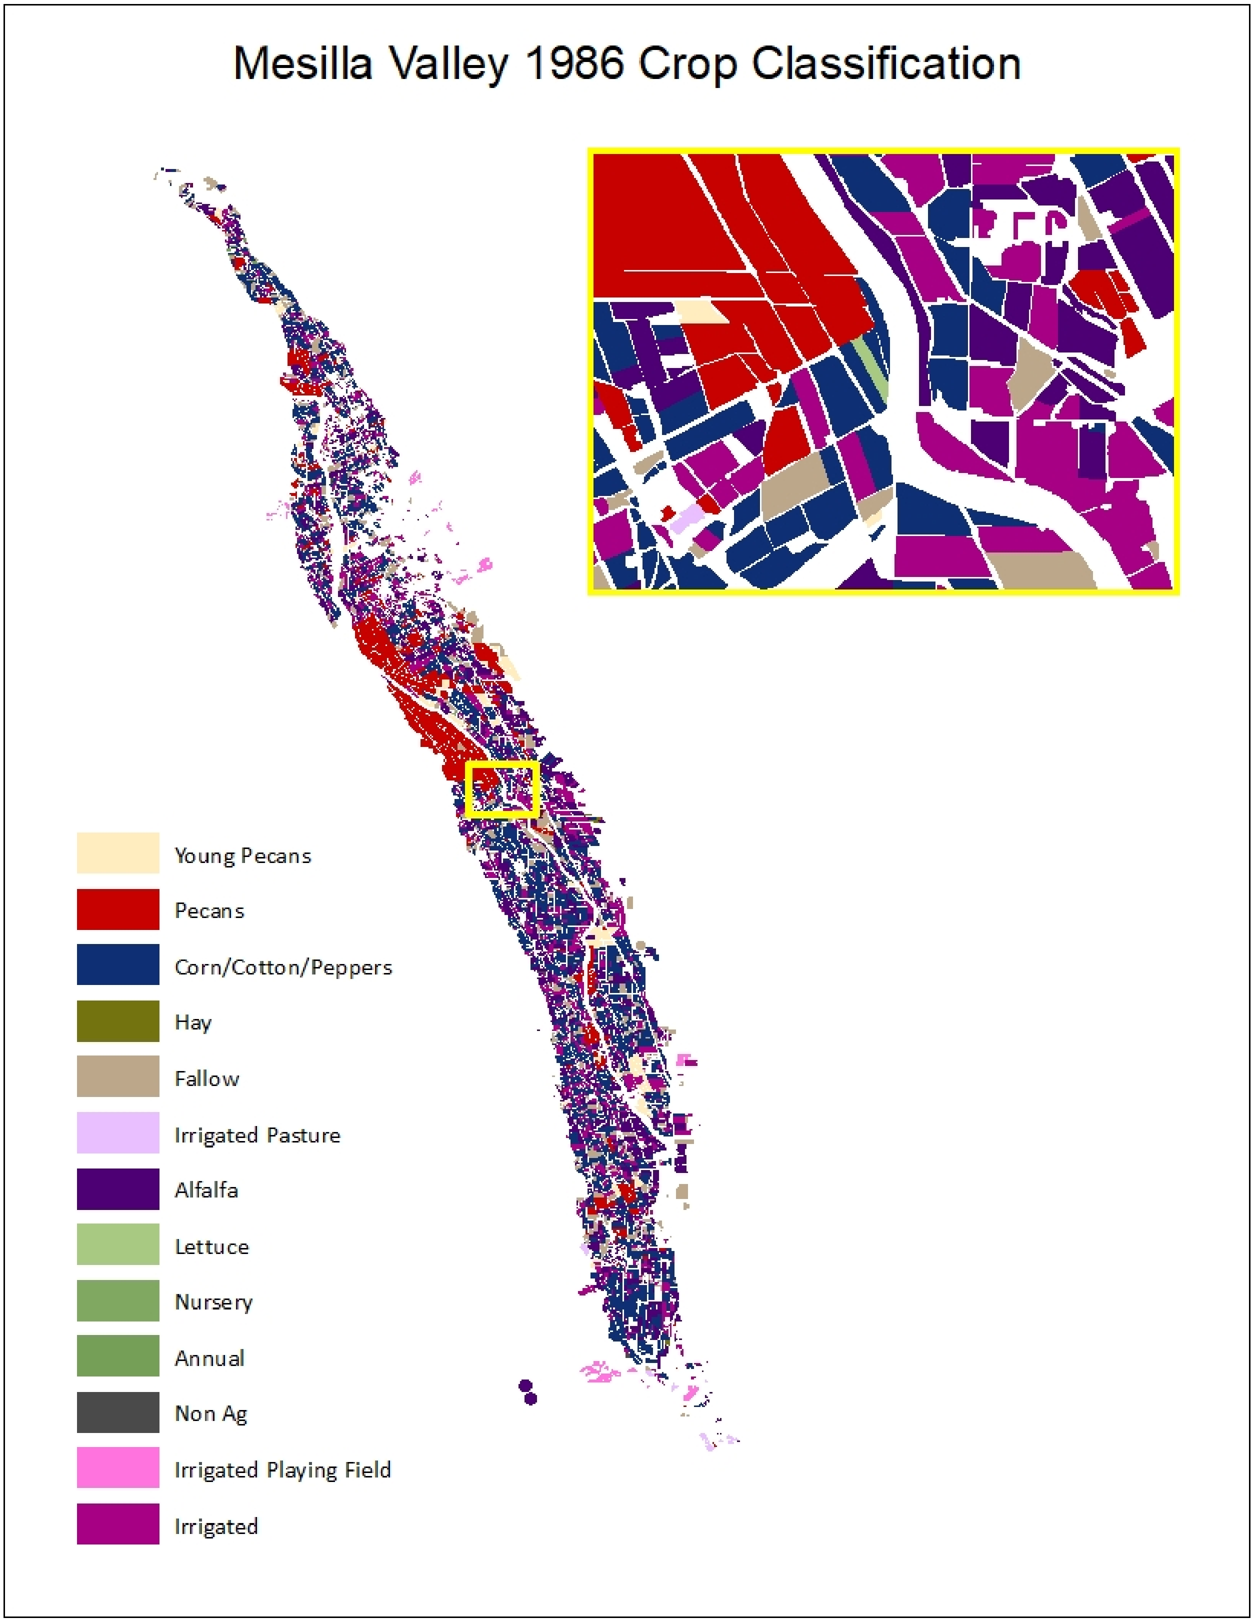

1977/1976/1975 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	Declassified air photo	June 1976	4 m	B/W
Mesilla	Declassified air photo (only northern 60% of Mesilla covered)	June 1975	4 m	B/W
El Paso	Declassified air photo	Sept 1977 (not adequate for agricultural mapping		

- **Ancillary Data** - Ancillary data used to validate and assist the development of the crop map included the BOR 1975 crop report.

Mapping Methodology

The single image/photo source available for 1975 Rincon and Mesilla Valley was a declassified aerial photo from June 1975. The photo covered 100% of Rincon Valley and 60% of Mesilla Valley. The area was mapped accordingly. The remaining 40% of the Mesilla Valley was estimated from irrigated land classification, =with consideration of the distribution of crops from the prior and following decadal years, and the relative distribution of crop types from crop reports of that year. Due to the quality of the imagery, the classification was partitioned into crop groupings. The resolution was adequate to allow the distinction between pecans, alfalfa, and other field crops. Because of resolution limitations and the timing of the photo capture, the remaining field crops were not separated into individual crop types, but were instead grouped into a single irrigated crop class. For the purposes of estimating consumptive use and the knowledge of the distribution of the cropping systems from the crop reports, this was the most accurate approach. Fallow parcels were identified from surface tone and texture, and very light color (indicating increased reflectance of the land surface different from a cropped field). Fields that were prepared for planting, or had been planted, were clearly identifiable via photo interpretation.

Crop mapping was not completed for El Paso in 1977 because image collection dates for that period were outside of the growing season, and the few available image resources were of very poor coverage and quality. For example, a September 26, 1977, declassified image was of insufficient quality for this analytical effort.

Mapped Classes

Based on textural and field structure cues, four crop and land use classes were established. Alfalfa and pecans were identifiable, with the remaining fields grouped into either irrigated or fallow.

Exhibit 24. 1976 Crop Classification – Rincon Valley

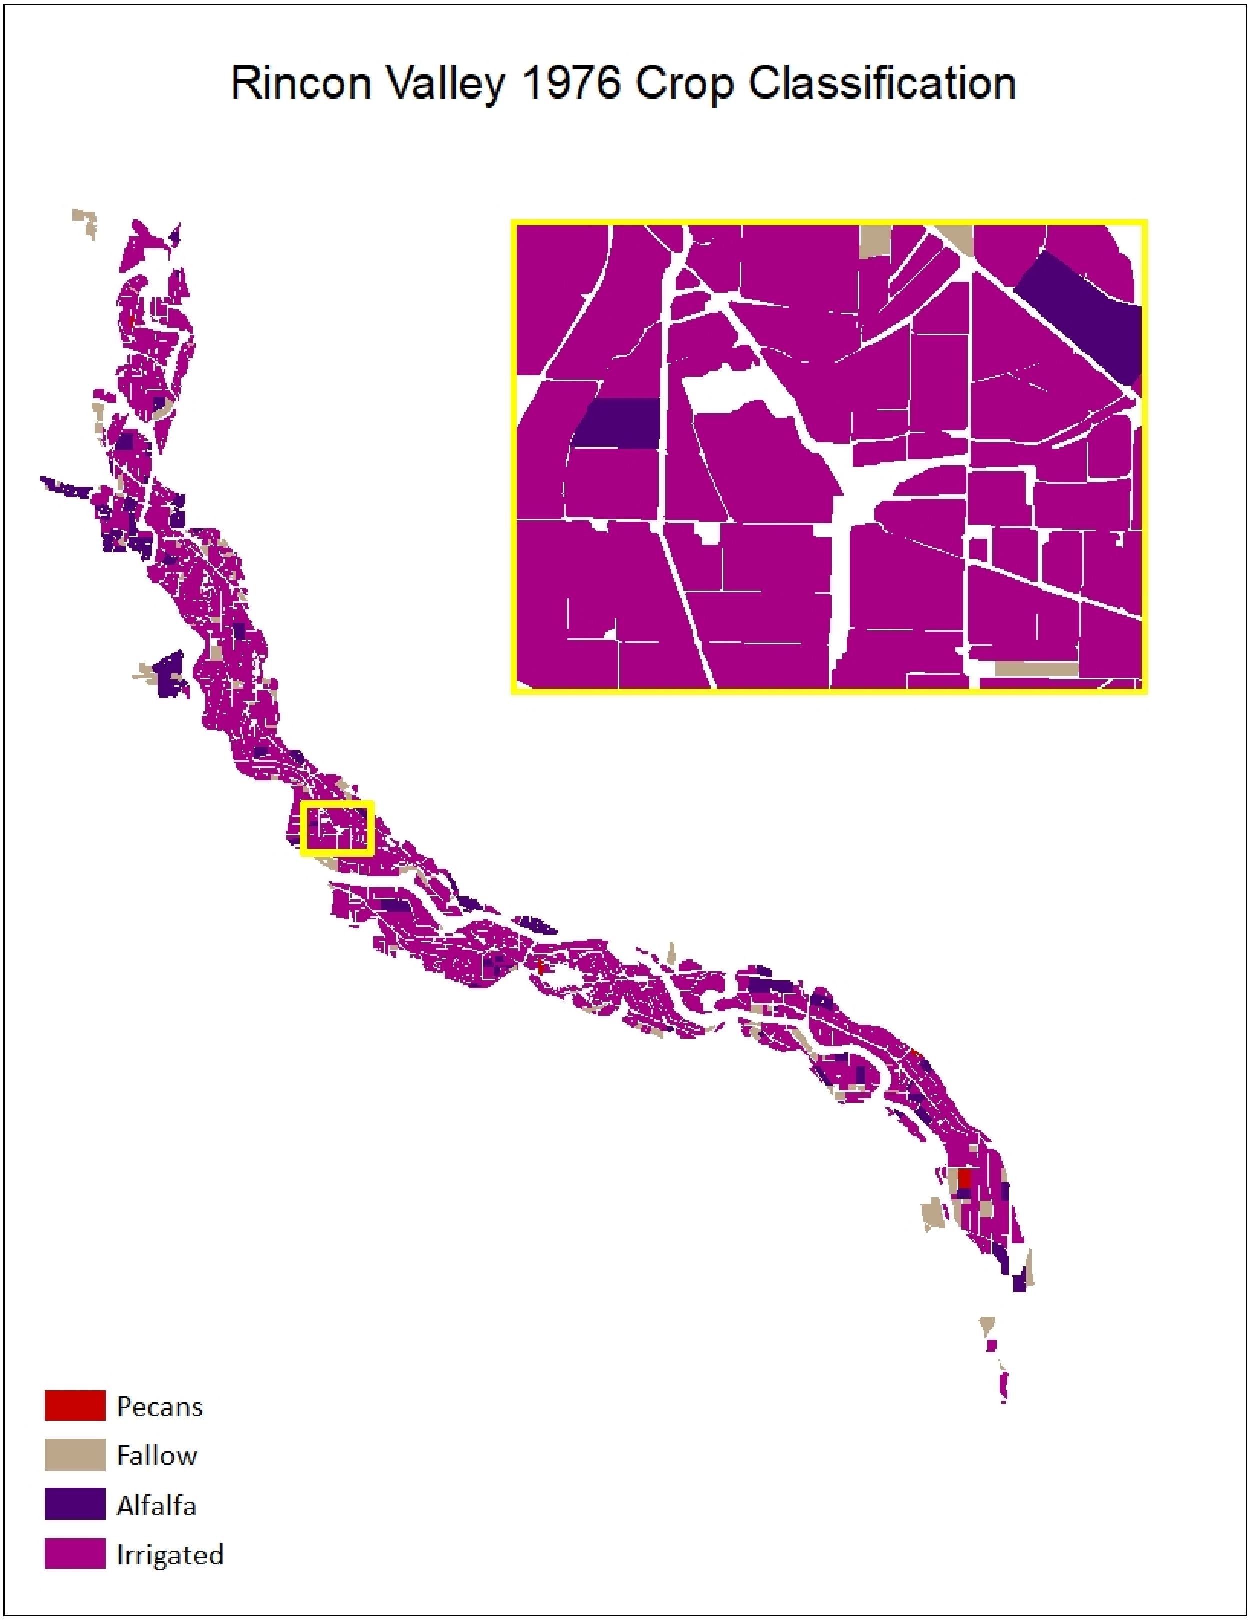

Exhibit 25. 1975 Crop Classification – Mesilla Valley

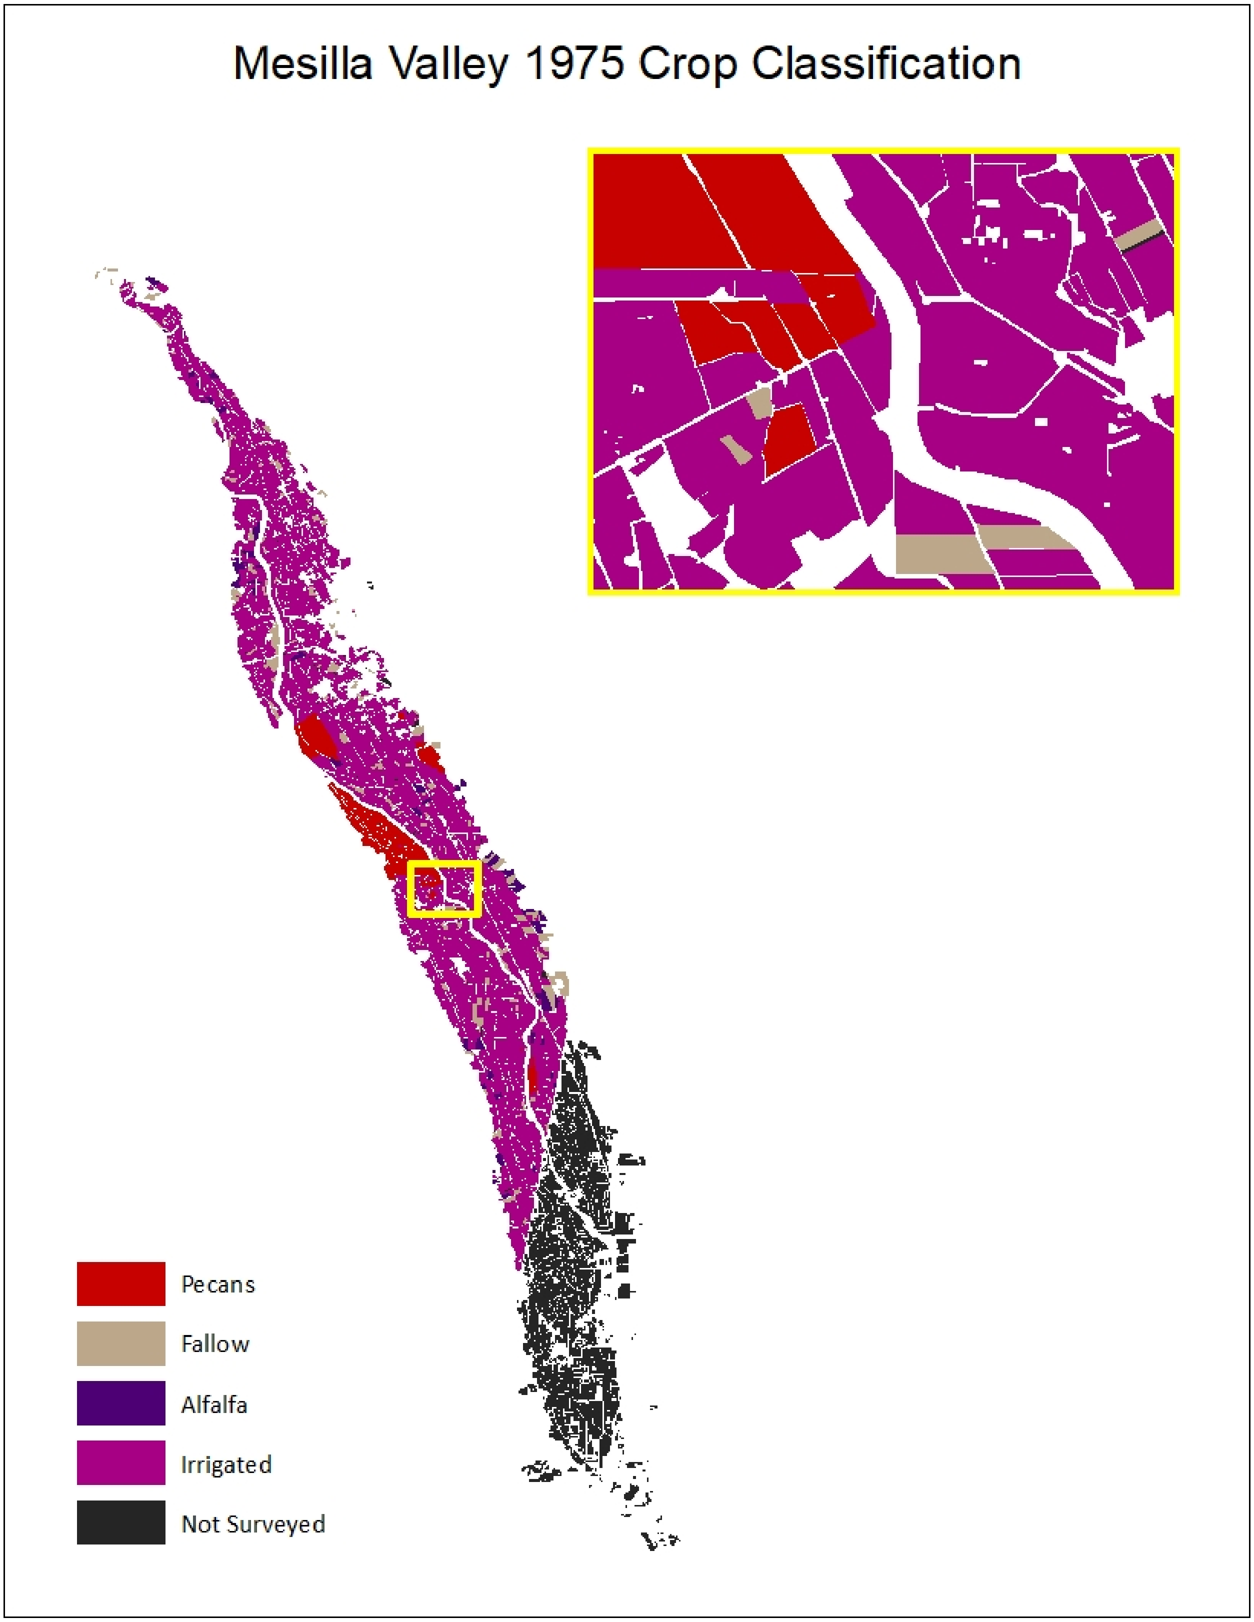

1966 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	Declassified air photo	September 22, 1966	3 m	B/W
Mesilla	Declassified air photo	September 22, 1966	3 m	B/W
El Paso	Not mapped due to lack of sufficient image resources/coverage	September 22, 1966		

- **Ancillary data** – Ancillary data used to validate and assist the development of the 1966 crop map included the BOR 1966 crop report.

Mapping Methodology

Photo interpretation of the declassified photos was the sole method used to classify the 1966 Rincon and Mesilla crops. The resolution of the imagery was fine enough to allow the distinction between pecans and field crops. Alfalfa was primarily identified by expert photo-interpretation. Because of resolution limitations and the timing of the image capture, the remaining fields crops could not be separated into individual crop types (however, irrigated versus non irrigated, and/or cropped versus fallow was easily identifiable). Crops were instead grouped into a single irrigated crop class. Fallow parcels were identified via the surface tone and texture; fallow parcels appeared very light colored (indicating that the soil had not been disturbed by tillage) and may have had some heterogeneous weed growth throughout the field. Fields prepared for planting, or recently had been planted, appeared dark, homogeneous, and were weed free.

El Paso crops were not mapped in 1966 due to a lack of available imagery resources. The only dates that had complete coverage of the valley were two years prior to 1966, and those images were obscured with clouds/smoke/etc., preventing comprehensive photo interpretation.

Mapped classes

Much like 1975, based on textural and field structure cues, four crop and land use classes for 1966 were mapped. Alfalfa and pecans were generally identifiable, with the remaining fields grouped into either irrigated or fallow.

Exhibit 26. 1966 Crop Classification – Rincon Valley

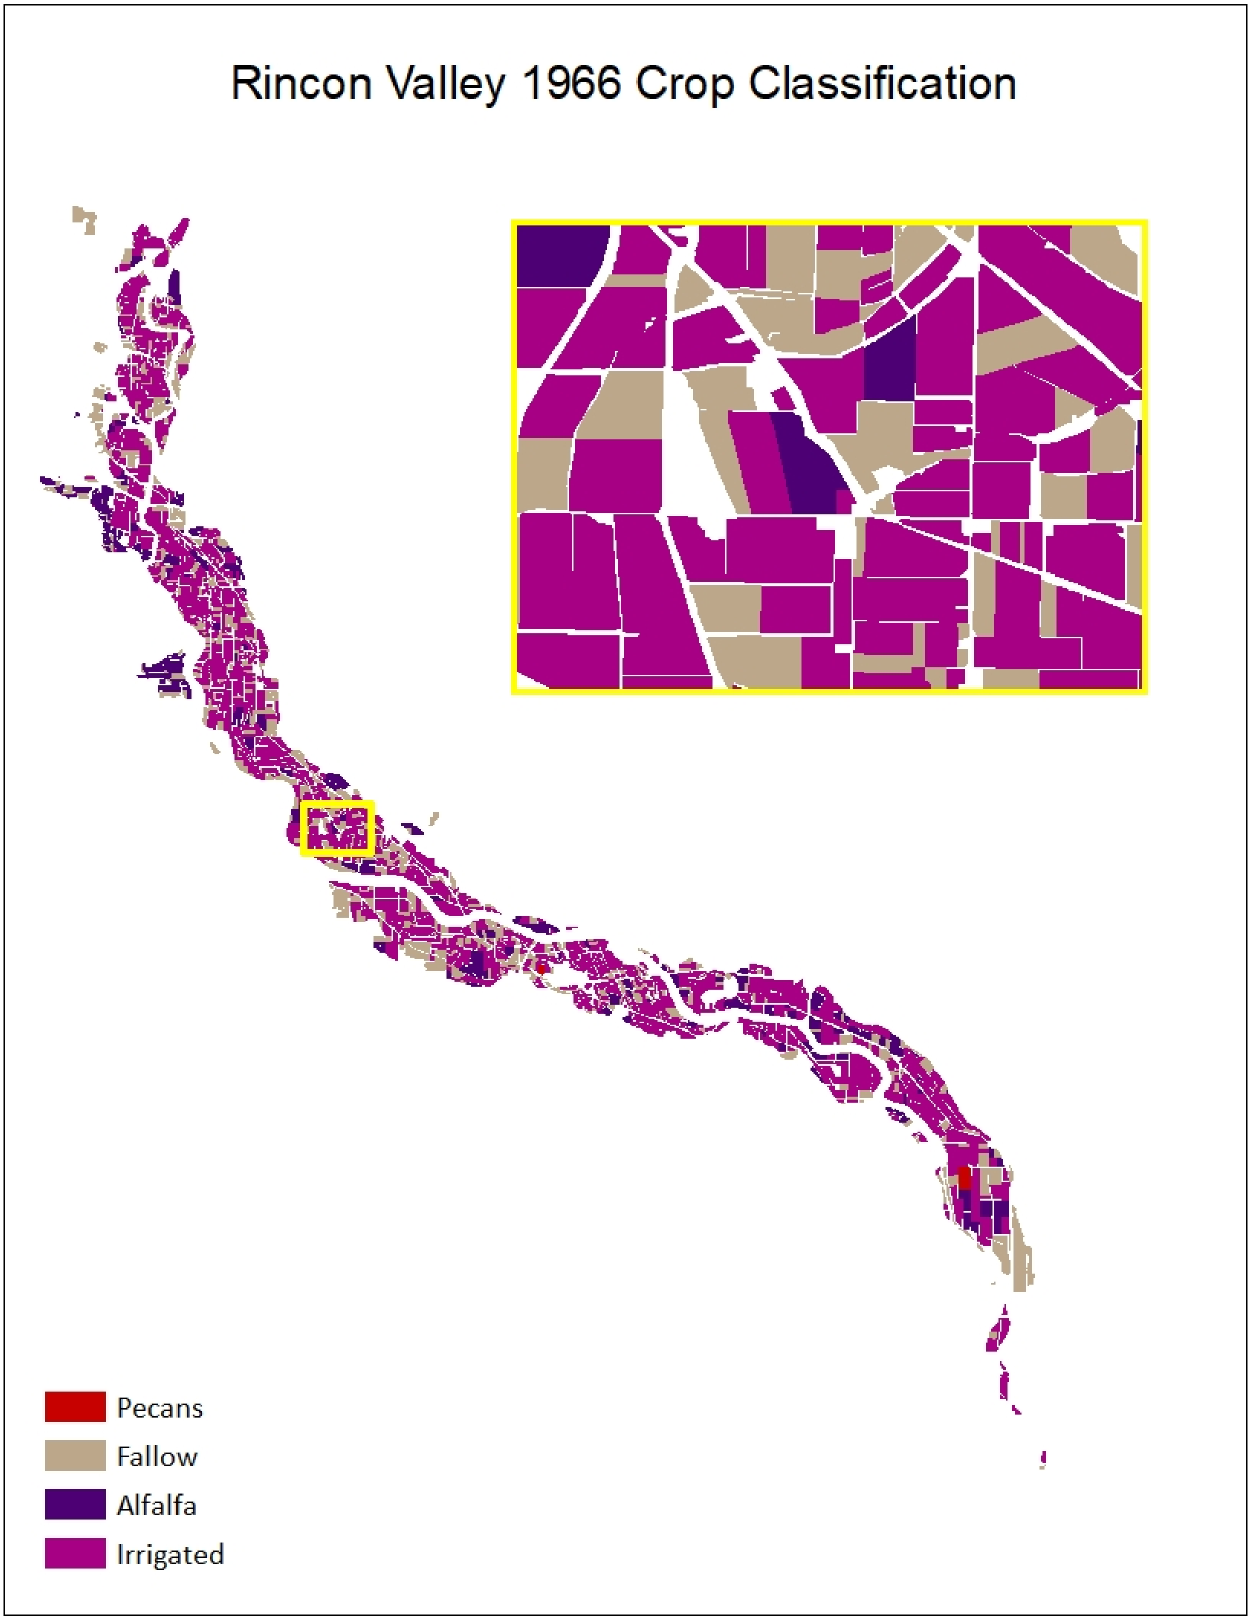

Exhibit 27. 1966 Crop Classification – Mesilla Valley

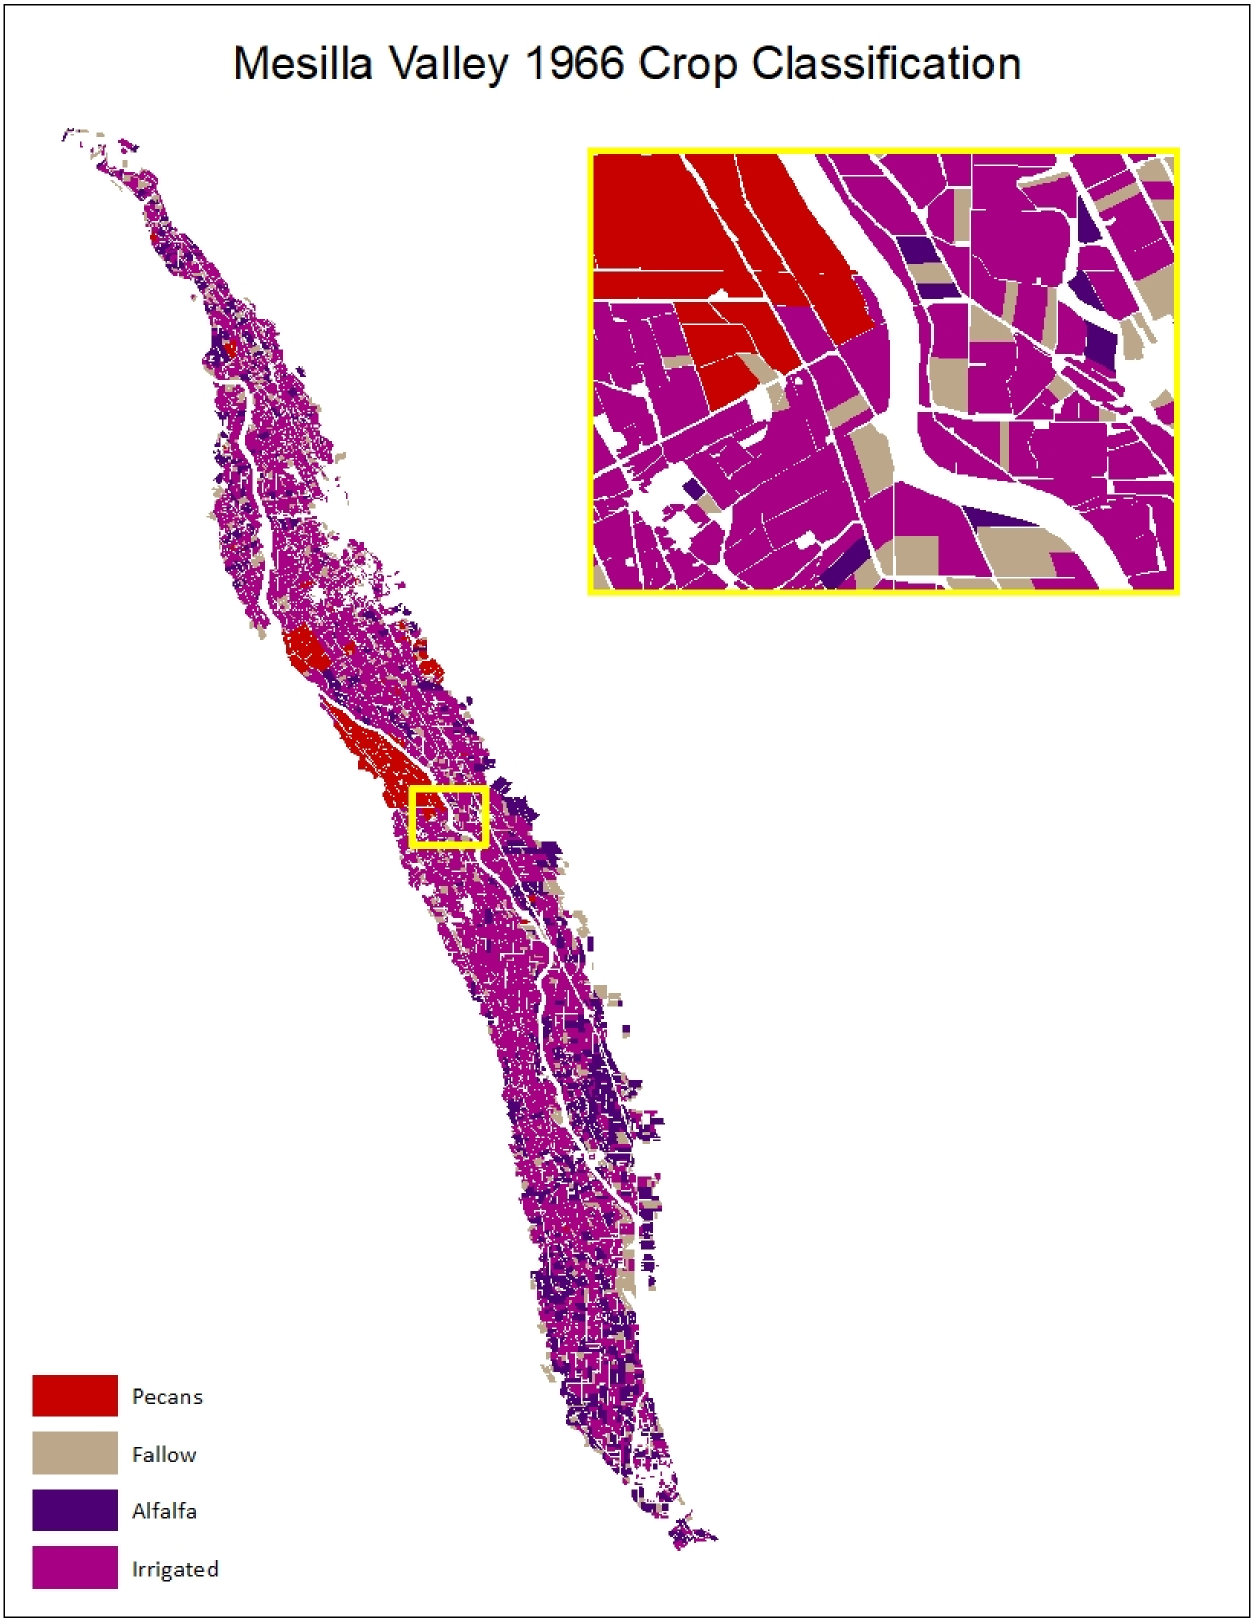

1955 Analysis

Data Sources

- **Imagery** - Images used for this analytical year are summarized below.

	Imagery	Date	Resolution	Color
Rincon	Farm Service Agency air photos	June 1955	0.5 m	B/W
Mesilla	Farm Service Agency air photos (only 90% of valley covered)	June 1955	0.5 m	B/W
El Paso	No appropriate imagery available			

- **Ancillary data** – Ancillary data used to validate and assist the development of the 1955 crop map included the BOR 1955 crop report.

Mapping Methodology

Data sources for Rincon and Mesilla Valleys in 1955 were limited to USDA Farm Service Agency black and white aerial photos from June 1955. The imagery covered all of Rincon Valley, and 90% of Mesilla Valley.

Despite the black and white imagery, the relatively high resolution of the aerial photos provided sufficient detail to confidently classify the two valleys. All of the mapping was done via photo-interpretation.

Final Classes

The analysis resulted in a legend of nine crop and land use classes. Textural and tonal quality allowed for the differentiation of alfalfa, pecans, lettuce, onions, and irrigated pasture, with remaining crops grouped into irrigated annuals, small grains, nursery, and other hay.

Exhibit 28. 1955 Crop Classification – Rincon Valley

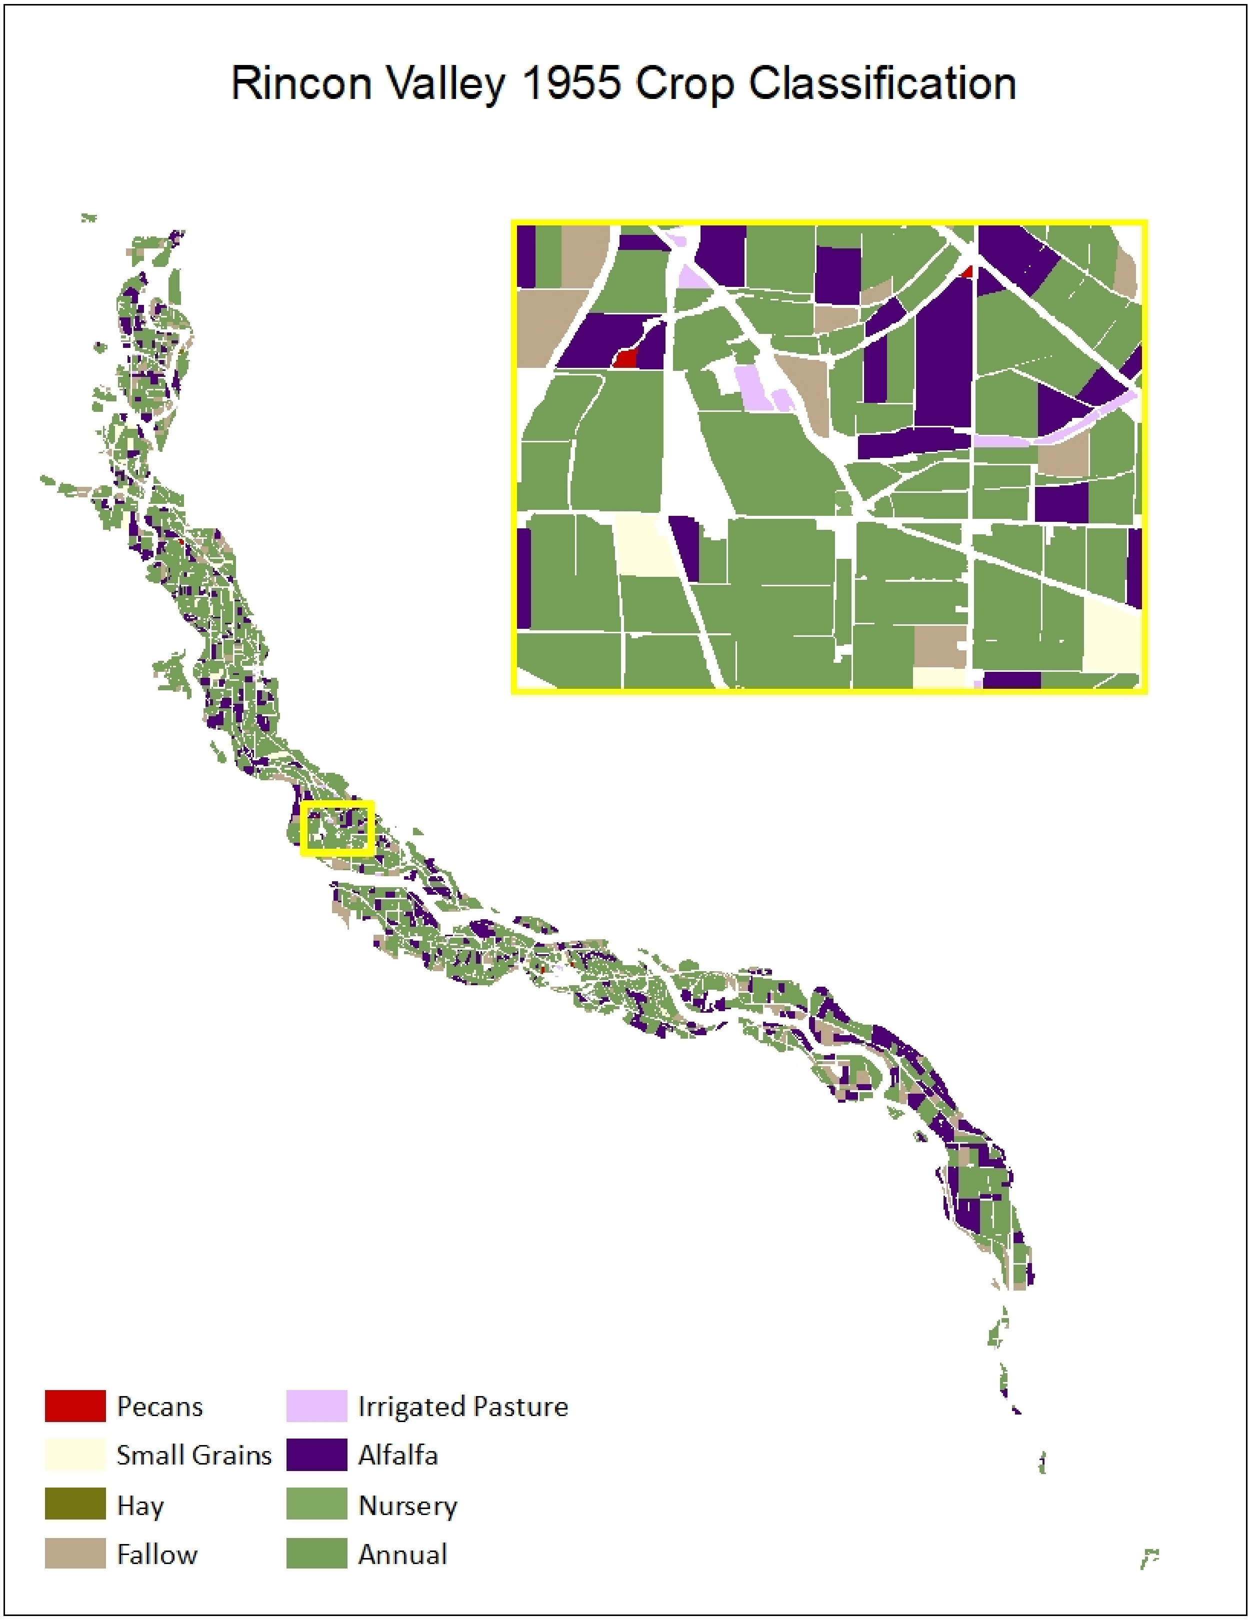

Exhibit 29. 1955 Crop Classification – Mesilla Valley

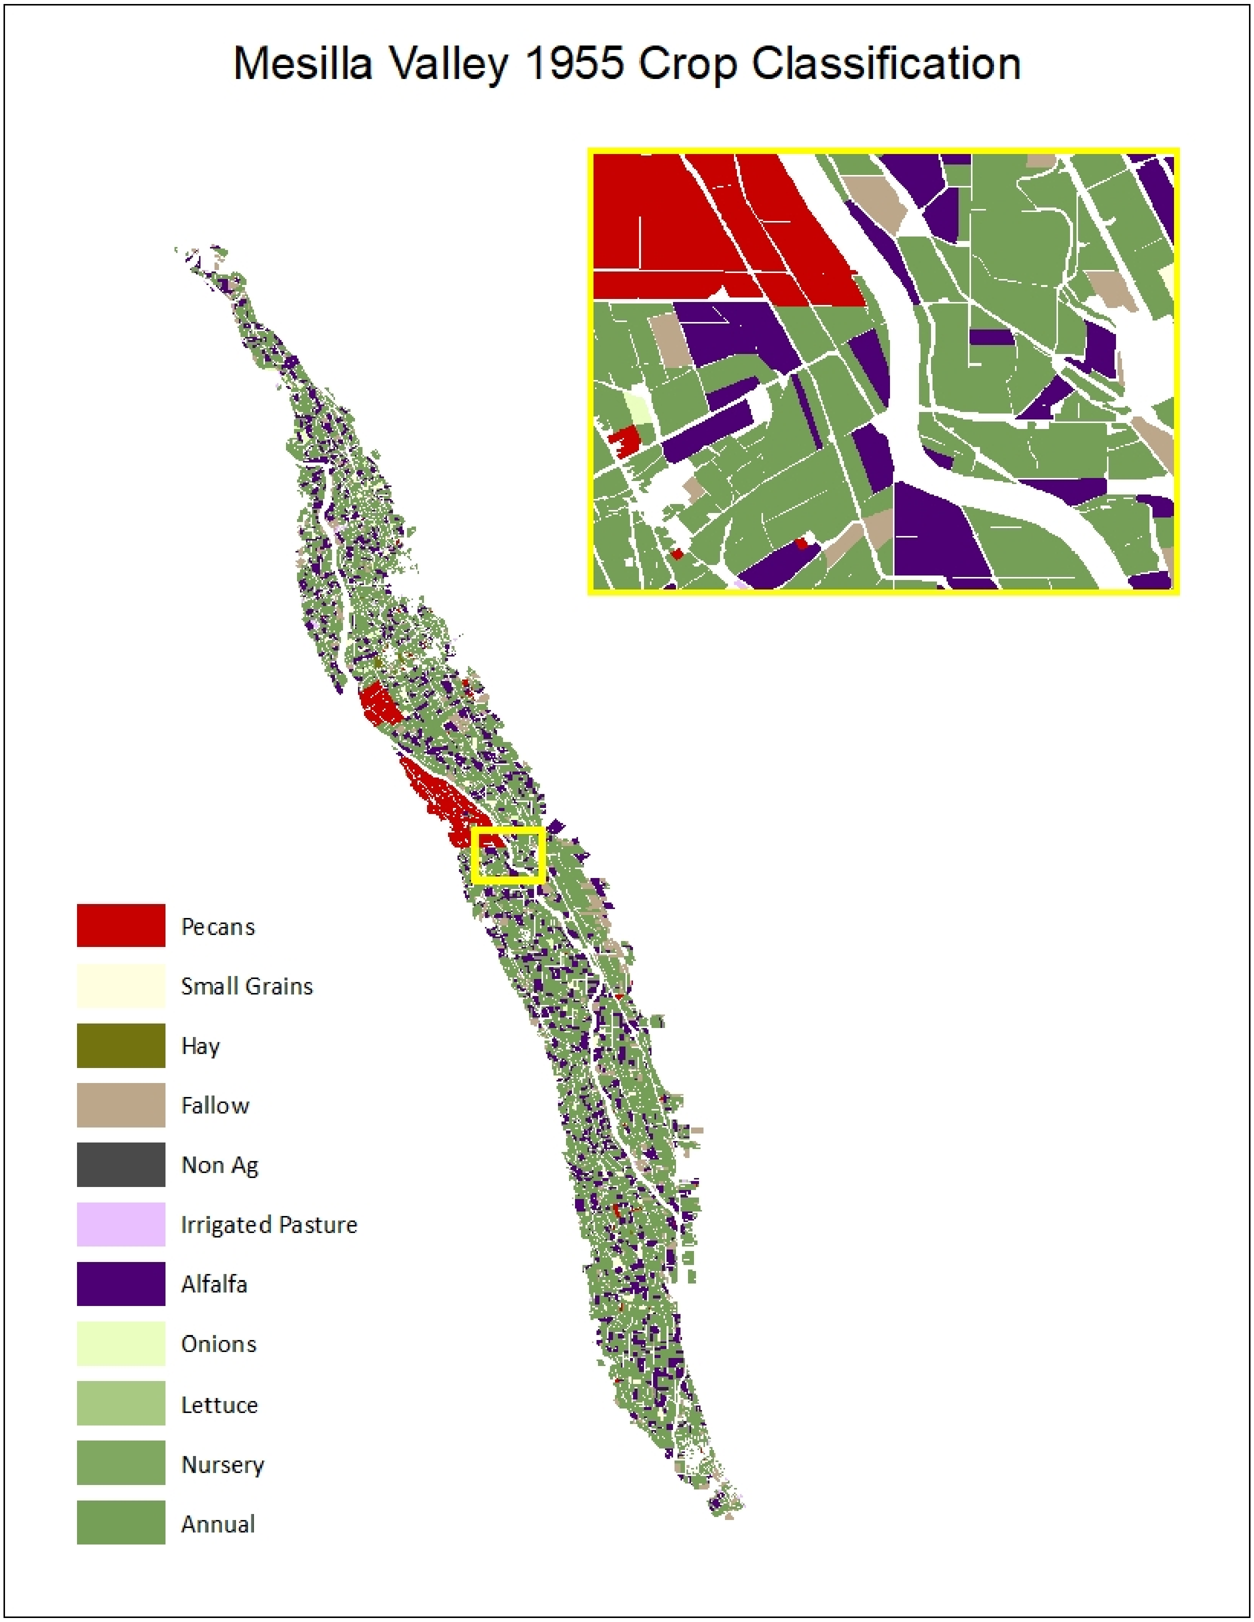

1936 Analysis

Data Sources

- 1936 maps from the Rio Grande Joint Investigation report; and
- 1935 imagery for general reference only.

Mapping Methodology

Although image resources existed that could be used to roughly determine general crop types, the plate maps and tabular acreages from the Rio Grande JIR were more accurate resources for analysis purposes. This was because the effort extended at the time of crop production in 1936 to survey and inventory all crops and acreages was far more accurate than any current-day photo interpretation or remotely sensed effort to classify crops from a 1935 image.

The JIR plate maps for Rincon, Mesilla, El Paso, and Hudspeth were scanned and georeferenced. The crop delineations were then digitized off the digital maps to produce a GIS crop map. The map digitization efforts produced similar acreages to those reported in tabular form, but were not identical due to limitations in the detail of the historical scanned maps. This mapping was therefore used to spatially distribute the tabular acreages from the report. This map and the tabular acreages then served as a highly accurate historical baseline data for determining change in consumptive use over time.

Final Classes

The crop classes from the 1936 maps included alfalfa, cotton, hay, idle, irrigated annuals, pasture, and miscellaneous /other.

US_MSJ_00001745

Pecan Spacing and Age Analysis

Purpose

A pecan age and spacing analysis was conducted to test the hypothesis that newer planted orchards contain more trees per acre than older planted orchards (i.e., are more densely planted). This has been a trend in all tree nut crops throughout the western United States, especially in California. Especially in earlier years of an orchard (until the canopy closes in), it is expected that more trees per acre will result in more consumptive use as compared to older, less dense orchards. The first step in conducting a density analysis by age was to establish the age component; then tree density by age of orchard was determined.

Spacing Procedure

An age analysis of pecans was performed within the area of interest (Rincon, Mesilla, and El Paso Valleys) dating from 1984 and to 2018. All orchards less than ten acres were removed from this analysis to ensure selection of a representative sample of commercial pecan production. Pecan orchards were grouped by age in two-year periods beginning in 1985 to create the following sample year classes:

- 2018-2017
- 2016-2015
- 2014-2013
- 2012-2011
- 2010-2009
- 2008-2007
- 2006-2005
- 2004-2003
- 2002-2001
- 2000-1999
- 1998-1997
- 1996-1995
- 1994-1993
- 1992-1991
- 1990-1989
- 1988-1987
- 1986-1985

- 1984

Within each sample year class, twenty-five orchards were randomly selected across all three valleys for analysis of pecan tree spacing, for a total of 450 orchards analyzed. Pecan tree spacing was measured by overlaying a one-acre digital fishnet over the area of interest. Within each orchard, the number of trees within each 1-acre square was counted, yielding the number of trees per acre within each orchard.

NAIP 2016 was the main source of imagery used for counting trees for sample year classes 2016-2015 and 2018-2017. Google Earth Pro was a secondary source of imagery as some orchards were not clearly visible in NAIP 2016, or had yet to be planted at the time of NAIP 2016 acquisition.

Rincon and Mesilla Valleys' 1955 imagery was obtained and used to analyze tree spacing of pecan orchards planted in 1955 or prior. Ninety orchards greater than 10 acres were analyzed in this group.

Spacing Results

During the spacing analysis, it was observed that some orchards had differing tree spacing between rows rather than a conventional grid-shaped planting pattern. These orchards are referred to as alternately spaced orchards. Exhibit 33 shows the relative frequency of alternately spaced orchards observed within each sample year class. Orchards planted between 1991–1992 had the most alternately spaced orchards at 28% of the total sample size. No alternately spaced orchards were observed after the sample year class of 1999–2000.

Two of the seventeen alternately spaced orchards were first planted in a traditional grid pattern, but were later thinned as observed in 2016 NAIP imagery. The trees per acre were counted as shown in 2016 NAIP imagery. It is hypothesized that these orchards were mostly planted at a 30-foot spacing within rows and were later thinned to a 60-feet spacing in thinned rows. Thinning mostly occurred in every other row.

More recent higher-resolution Google Earth imagery shows that many of these orchards are being replanted to the original 30-foot spacing in rows that were once thinned, while retaining the original tree-starting grid (Exhibit 34). In these replanted orchards, the youngest trees were not counted in the 1-acre square because 2016 NAIP imagery did not have high enough resolution to identify these young trees among older trees, although it is assumed that they existed.

The majority of orchards, however, are not thinned in this manner, and represent common pecan production practices (Exhibit 35).

Exhibit 33. Pecan Orchards with Alternately Spaced Tree Rows.

Sample Year Class	Sample Size	Count of Alternately Spaced Orchards	Frequency of Alternately Spaced Orchards (%)

2018-2017	25	0	0
2016-2015	25	0	0

Exhibit 34. An alternately spaced pecan orchard in (A) June 2010 and (B) May 2018. Images from various valleys.

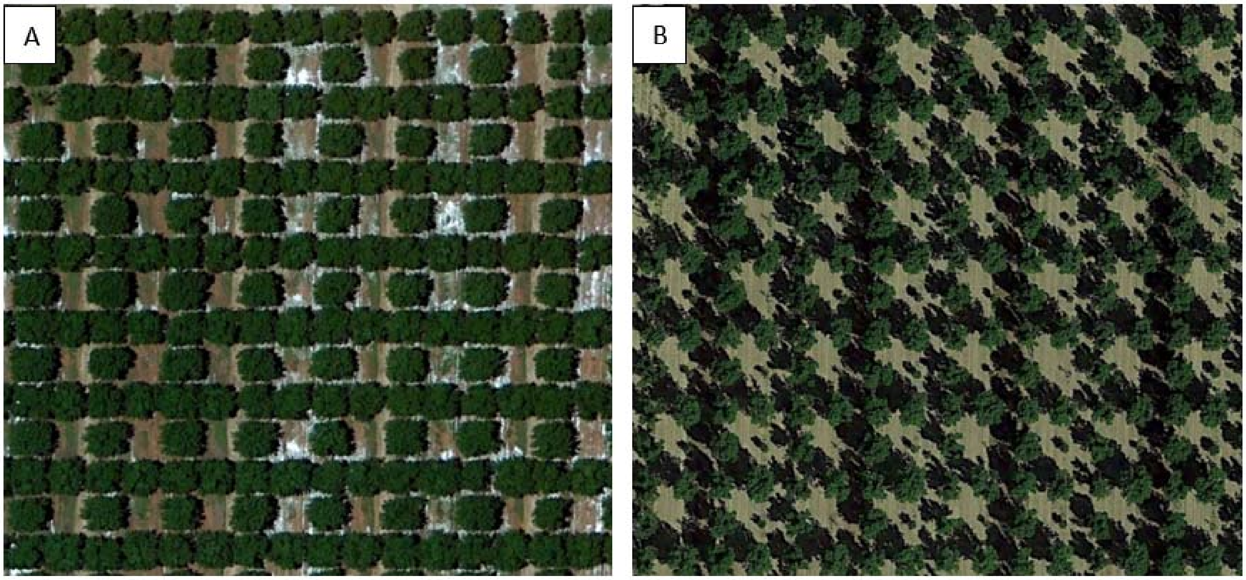

Exhibit 35. Image examples of common pecan spacing and production practices. Images from various valleys

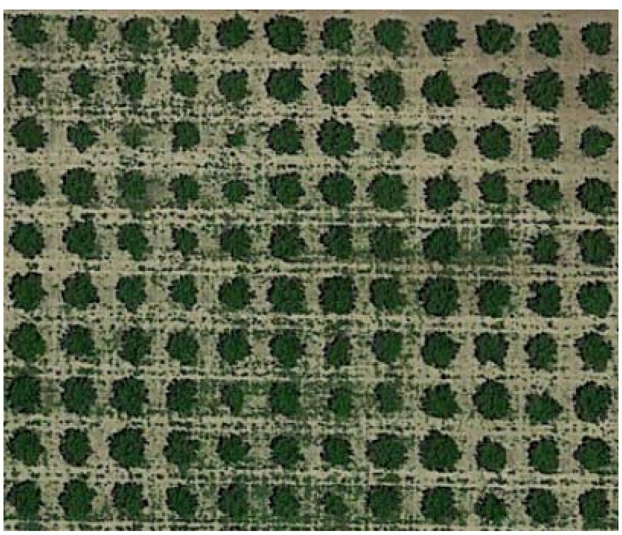

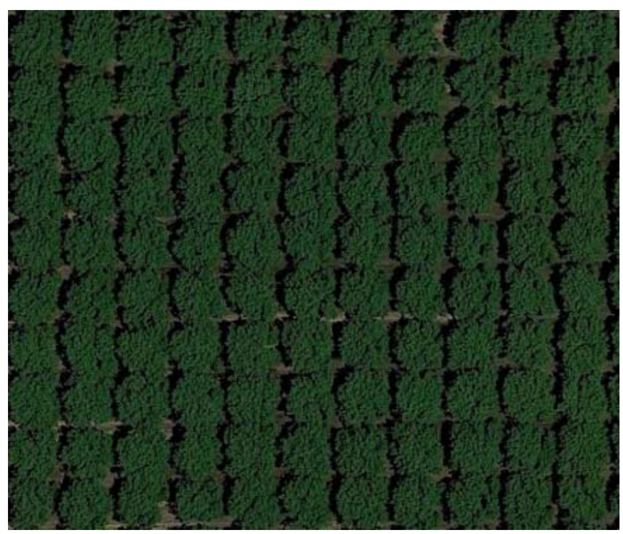

Exhibit 36 shows the results of the pecan spacing analysis. Older orchards tend to have more widely spaced trees, while younger orchards tend to have tighter spacings.

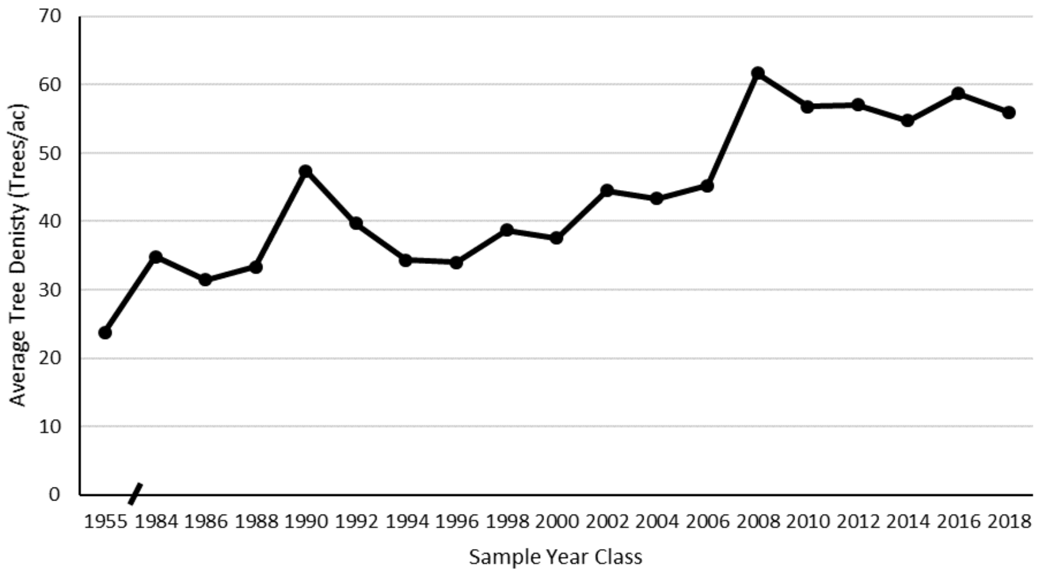

Exhibit 36. Pecan spacing analysis results by year planted.

Note: The sample year class axis label includes the year shown and the year prior. For example, the axis label 1986 included the year 1985–1986. The sample year class of 1955 represents orchards planted in the year 1955 or prior. The sample year class of 1984 represents orchards planted in 1984 or prior.

Pecan Age Analysis Results

An age analysis of pecans was performed in all three valleys from 1984 to 2018. The age analysis identifies the year that an orchard was planted and is based on the standing 2018 pecan acreage. Therefore, a pecan orchard planted in 1985 and removed in 2015 would not be included in this age analysis.

Exhibit 37 shows the cumulative acres of pecans planted by year. There were 15,420 acres planted in the year 1984 and prior and there are 49,877 acres standing in 2018 (Exhibit 37). Exhibit 38 shows the non-cumulative acreage planted by year. The year 1984 shows a much greater amount of planted acreage relative to other years because it includes pecans planted both in and prior to 1984. Because the remaining years are difficult to visually represent at the scale needed to display the acreage of 1984, Exhibit 39 shows the acreage planted without the year 1984.

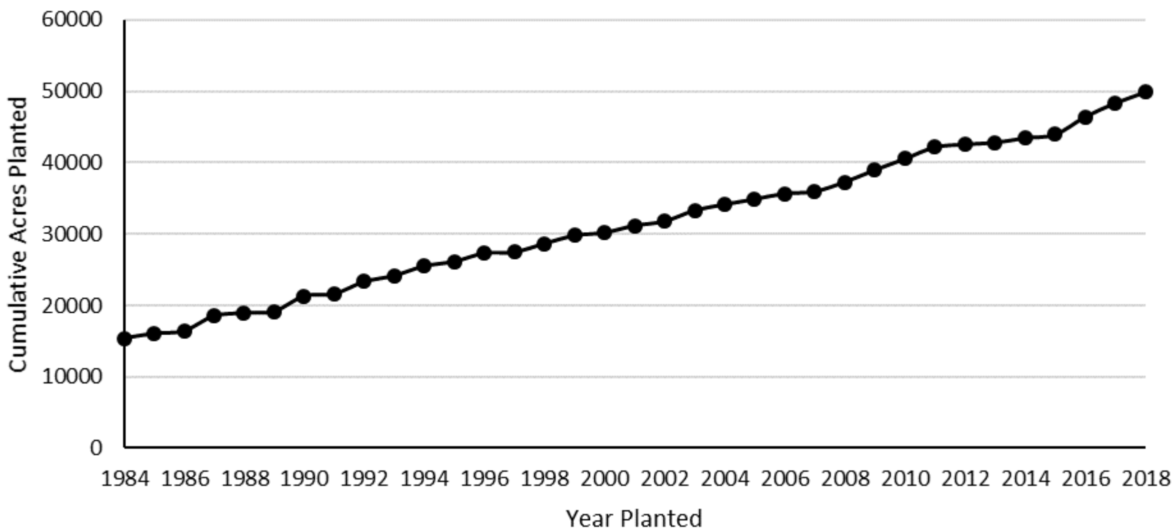

Exhibit 37. Cumulative Pecan Planted Acreage by Year from 2018-1984.

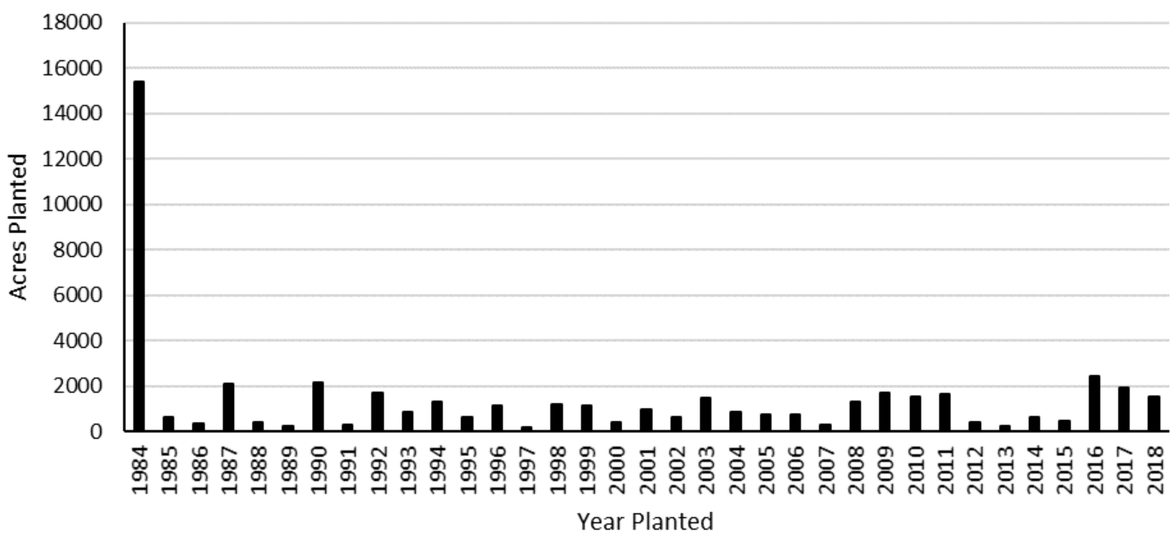

Exhibit 38. Pecan Planted Acreage by Year from 1984-2018.

Note: The year 1984 includes orchards planted in or prior to 1984.

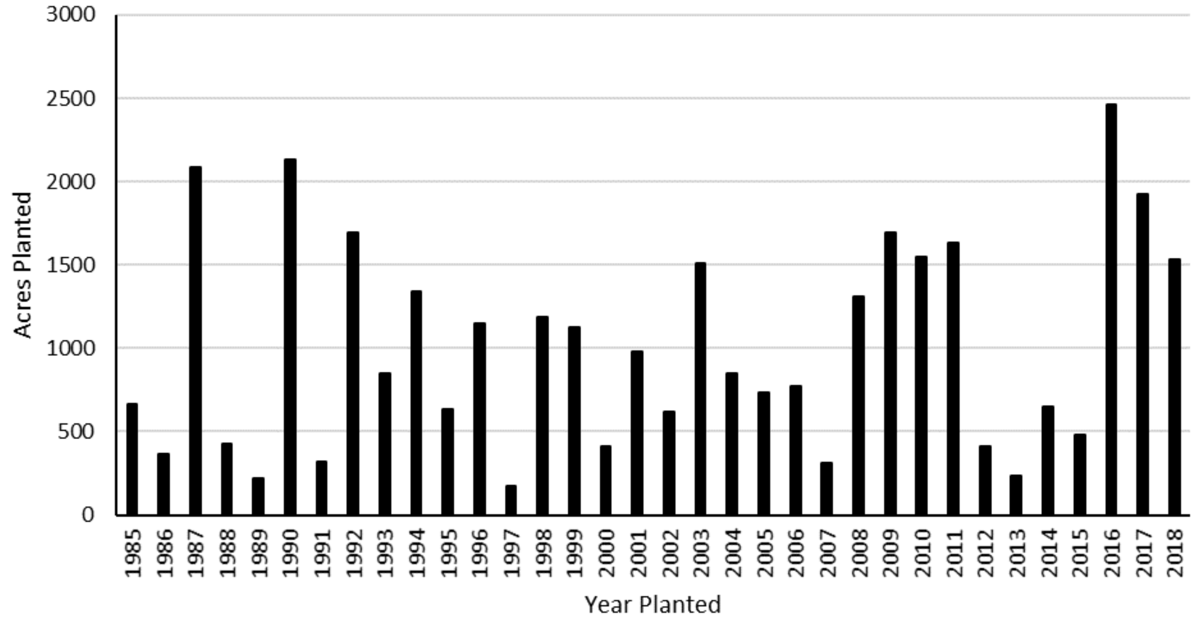

Exhibit 39. Pecan Planted Acreage by Year from 1985-2018.

Annual Land Use Interpolations and Area Determination by Valley

Methods

A detailed crop acreage report was used as one tool to determine annual crop acreages for calculating consumptive use. When suitable imagery resources were available, remote sensing and photo interpretation (coupled with other indicators and resources) were used to create spatial crop maps for multiple years. For years when this imagery did not exist, acreages had to be determined through other methods. Acreage values were assigned to each valley by use of the following data sources listed in descending order of importance:

- **i.** JIR spatial data.
- **ii.** Land IQ spatial crop mapping.
- **iii.** Area-specific crop report.
  - **1.** With or without In/Out Valley Distribution (IOVD) adjustment, depending on valley.
- **iv.** Calculated EBID acreage (CEA)–only valid for Rincon and Mesilla Valleys.
  - **1.** With or without IOVD adjustment, depending on valley.
- **v.** Linear interpolation between reliable values.

To assess time periods without spatial crop mapping, Project Histories of the Rio Grande Project documents written by the Bureau of Reclamation (crop reports) and other sources were consulted (Appendix A). Crop reports for the study area are aggregated to different levels. For the majority of the time period, the crop reports are aggregated to the irrigation district level. For certain periods of time, valley specific data were available and utilized. When valley level data was not available, assumptions had to be made about crop acreage. Due to the discrepancy between the valley boundary and the irrigation district boundary, some irrigated acreage falls outside the district boundary, but within the valley boundary. This acreage is not usually accounted for in the district service area and some project area crop reports. All irrigation district level crop reports were increased by the percent irrigated ground outside the irrigation district boundaries as applicable for Rincon and Mesilla Valleys respectively.

In years when a spatial dataset was available, an IOVD percentage was calculated for irrigated acreage within the valley boundary that was not inside the irrigation district boundary. A linear interpolation between spatial data years was used when no spatial data was available. The crop reports for the irrigation district can then be increased by the IOVD value, accounting for acreage outside the irrigation district boundary.

In years where there is no differentiation between Rincon and Mesilla Valleys (only reported as EBID), calculations and assumptions were used for a CEA. Distribution of total crop area was determined for 1989 and 1964 crop reports between Rincon and Mesilla Valleys (the only years EBID is broken down to valley level, otherwise they are reported on a project level); a relatively consistent 20/80 split between the two valleys. The distribution of crops within each valley also was calculated for 1989 and 1964 crop reports, and a linear interpolation of the 19 crop groups was calculated to provide acreage for 1988–1965. This provides a yearly crop distribution that is valley specific.

The EBID crop reports are given, but do not separate Rincon and Mesilla Valleys. The total EBID acreage is multiplied by the distribution between valleys (approximately 20/80 split) to arrive at the total acreage by year for each valley–distributing the total EBID acreage by year to the two valleys. Once the total acreage for each valley is calculated, this value is multiplied by the in-valley crop distribution linear interpolation, resulting in acreage by crop, by year, for each valley. These acreage distributions are then multiplied by the IOVD value to account for acreage outside district boundaries, but still within valley boundaries. During these years, pecans are not included in the CEA acreages because pecans are a permanent crop that do not change drastically from year to year. Therefore, a linear interpolation was calculated between the 1966 and 1976 spatial years, and the 1989 EBID crop report. The linear interpolation of this permanent crop matches known increases in pecan production over time from anecdotal resources and from years of spatial mapping results.

Acreage Disaggregation to Service Areas

The spatial extent of the project areas was distributed into 14 service areas (SA) over the Rincon and Mesilla Valleys (Exhibit 40) for project modeling through 2016. The results of spatial land use mapping were used to disaggregate the valley-wide annual land use datasets into land use acreage by SA (Appendix 3).

Exhibit 40. Service area distribution among valleys.

Service Area Number	Service Area Name	Valley
1	Arrey	Rincon
2	Eastside NM	Mesilla
3	Leasburg	Mesilla
4	Westside NM	Mesilla
5	Eastside TX	Mesilla
6	Westside TX	Mesilla
7	Outside Rincon N	Rincon
8	Outside Rincon W	Rincon
9	Outside Rincon E	Rincon
10	Outside Leasburg N	Mesilla
11	Outside Leasburg E	Mesilla
12	Outside East NM	Mesilla
13	Outside East TX	Mesilla
14	Outside West NM	Mesilla
99	Outside all Service Area Boundaries	Mesilla and Rincon

The Rincon Valley is comprised of four SAs and a small acreage outside the SA boundaries (SA 1 and 7–9). The Mesilla Valley is comprised of 10 SAs and a small acreage outside the SA boundaries (SAs 2–6 and 10–14) (Exhibit 41).

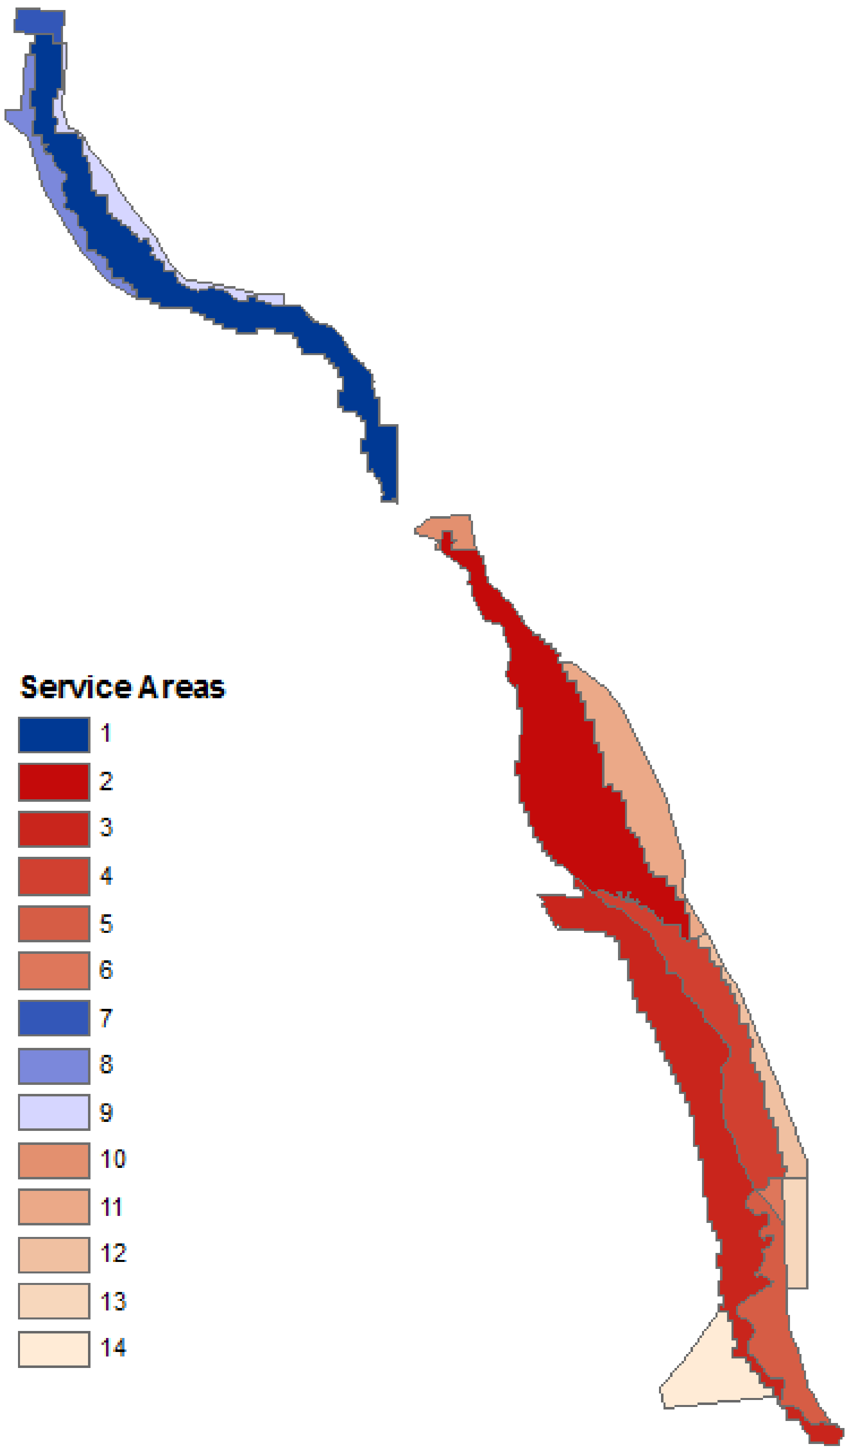

Exhibit 41. Service Areas in Rincon and Mesilla Valleys

Acreage Distribution

Remotely sensed crop mapping was completed in 2018, 2016, 2014, 2011, 2006, 1996, 1986, 1976/1975, 1966, and 1955 for the two valleys and in fewer years for the El Paso Valley. In 1936, there was a spatial map of crop types provided by the JIR (Appendix A). For Mesilla Valley, the 1975 crop mapping was not used because approximately 13,775 acres of agriculture was excluded from the southern portion of the imagery. The 1976 crop mapping was used for Rincon Valley. Spatial data from Land IQ crop mapping was digitally intersected with the SA boundaries (Exhibit 42). For fields situated within two SAs, the field acreage is split and each portion is assigned to one of the SAs (Exhibit 43). In some cases, small acreages fall outside the SA boundaries. These acreages were preserved and calculated as Service Area 99 (SA99) to reconcile total acreages.

The percent distribution of each crop within each service area (Service Area Crop Distribution–SACD) was calculated for years spatial data was available. For years that did not have spatial data, the crop distribution is unknown because the acreages are reported at the irrigation district level; they are never reported to the granularity of service areas. Therefore, a linear interpolation was used to calculate the percent distribution of each crop within each SA for non-spatial years:

- Rincon Valley
    - 2015
    - 2013-2011
    - 2010-2007
    - 2005-1997
    - 1995-1987
    - 1985-1977
    - 1975-1967
    - 1965-1956
    - 1954-1937
- Mesilla Valley
    - 2015
    - 2010-2007
    - 2005-1997
    - 1995-1987
    - 1985-1977
    - 1975-1967
    - 1965-1956
    - 1954-1937

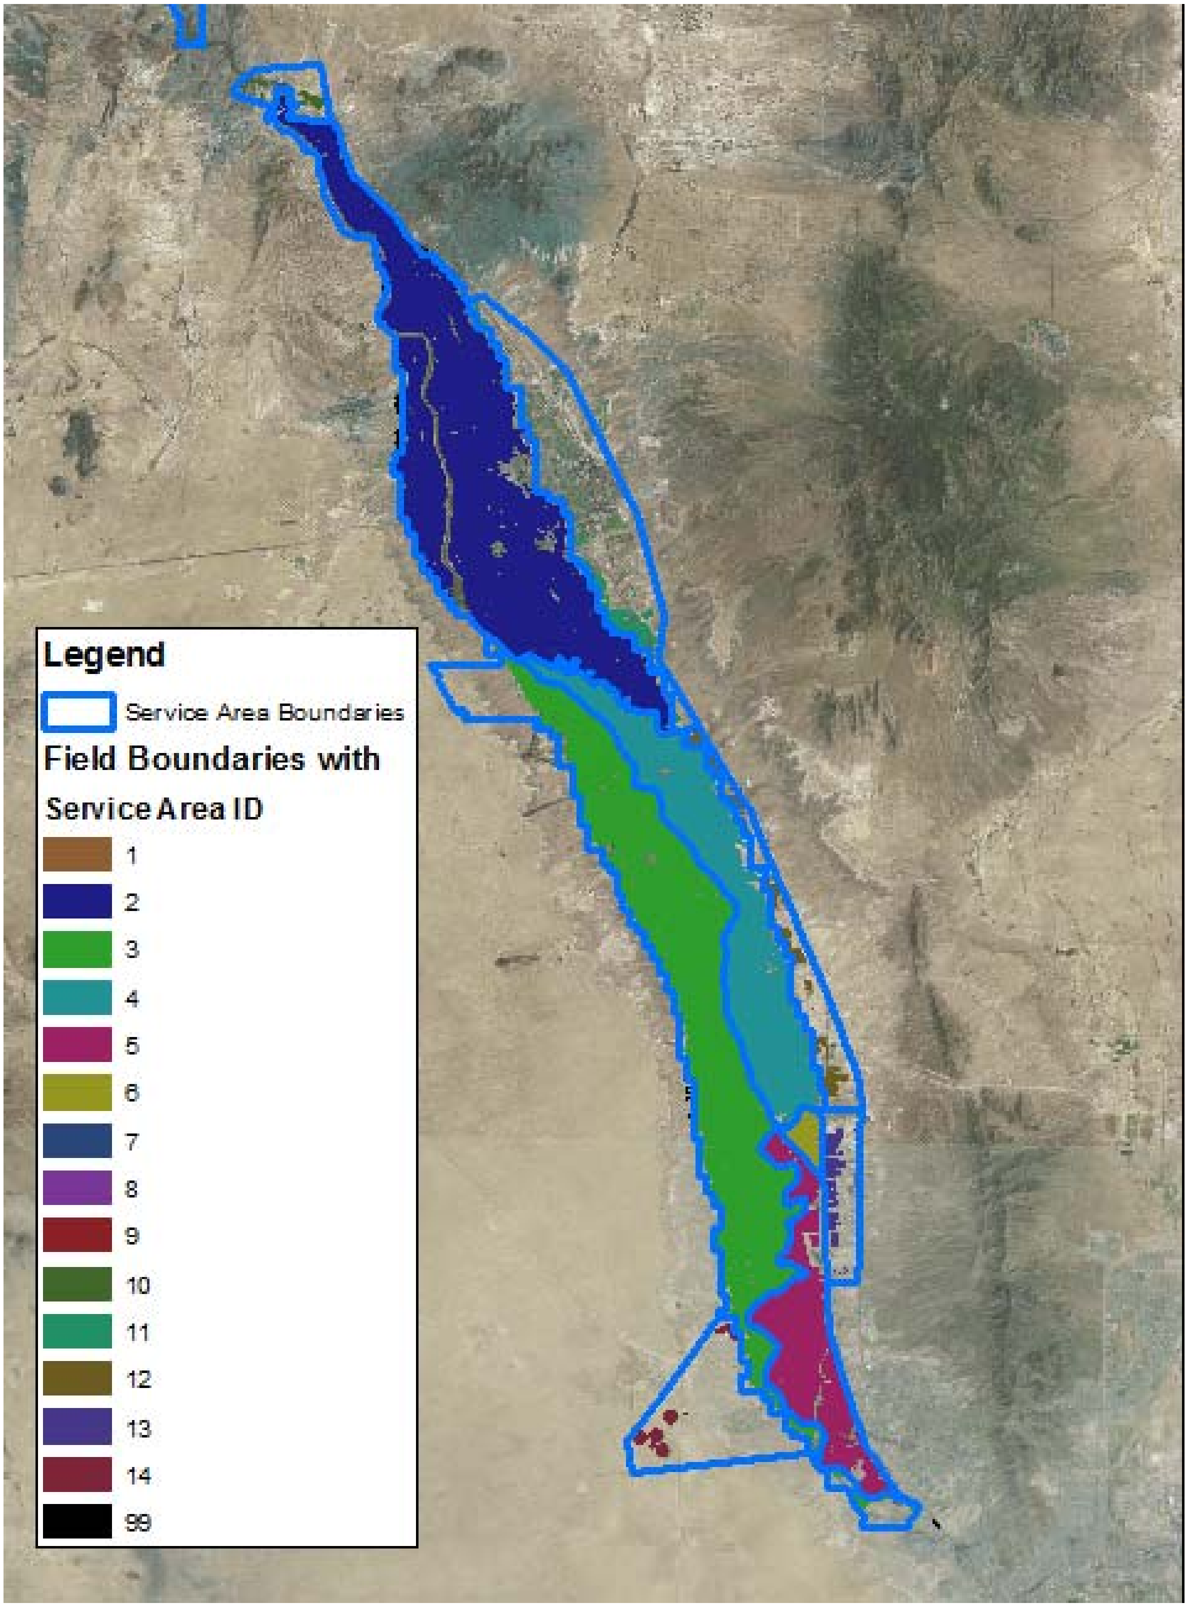

Exhibit 42. Results of Field Boundary spatial intersect with SAs, Mesilla Valley

Exhibit 43. Field intersection with SA boundaries; example of field overlapping service area boundary

Changes to the linear interpolation were made when acreage was present in the delivered acreages that were not present in one or both of the spatial years providing data for the linear interpolation. For example, if legumes are reported in the Rincon Valley crop report for 1963, but legumes are not present in the 1966 and/or 1955 crop mapping years, an assumption of distribution was made. The service area distribution for the closest year was applied. For the legume example, the 1963 crop distribution would be used from 1955 until 1966 as static values. These assumptions about crop distribution are listed (Exhibit 44).

Exhibit 44. Assumptions Made about Crop Acreage Service Area Distribution

Time Period	Crop	Valley	Distribution Assumption
2015-2018	All	Both	No distribution needed as 2015 was linearly interpolated between 2014 and 2016
2011-2014	Hay	Mesilla	2014 distribution used from 2012-2014
2011-2014	Irrig Annuals	Mesilla	2014 distribution used from 2012-2014

2006-2011	Legumes	Rincon	2011 distribution used from 2007-2011
2006-2011	Hay	Mesilla	2006 distribution used from 2006-2010
2006-2011	Irrig Annuals	Mesilla	2006 distribution used from 2006-2010
2006-2011	Legumes	Mesilla	2006 distribution used from 2006-2010
1996-2006	Chili	Rincon	1996 distribution used from 1996-2005
1996-2006	Legumes	Rincon	1996 distribution used from 1996-2005
1996-2006	Irrig Annuals	Mesilla	2006 distribution used from 2006-2010
1986-1996	Asparagus	Rincon	1986 distribution used from 1986-1995
1986-1996	Melon/Squash	Rincon	1986 distribution used from 1986-1995
1986-1996	Misc/Other	Rincon	1986 distribution used from 1986-1995
1986-1996	Root Crop	Rincon	1986 distribution used from 1986-1995
1986-1996	Tomatoes	Rincon	1986 distribution used from 1986-1995
1986-1996	Turf	Rincon	1986 distribution used from 1986-1995
1986-1996	Asparagus	Mesilla	1986 distribution used from 1986-1995
1986-1996	Irrig Annuals	Mesilla	1986 distribution used from 1986-1995
1986-1996	Misc/Other	Mesilla	1986 distribution used from 1986-1995
1986-1996	Root Crop	Mesilla	1986 distribution used from 1986-1995
1986-1996	Tomatoes	Mesilla	1986 distribution used from 1986-1995
1937-1954	Grapes	Rincon	100% are in SA1
1936-2014	Grapes	Mesilla	100% of grapes in SA2
1936-2014	Misc/Other	Mesilla	Assigned irrigated annuals distribution
1936-2014	Tomatoes	Mesilla	Assigned irrigated annuals distribution
1936-1955	Pecans	Rincon	1955 distribution used from 1936-1955
1936-1955	Pecans	Mesilla	1955 distribution used from 1936-1955

If there was no crop report for the given spatial year, a linear fill was calculated between the two adjacent years to provide acreages of the non-permanent crops. Using either the known crop report or the linearly-filled crop report, the distribution of other, non-permanent crops (excludes alfalfa, grapes, and pecans) was calculated for the spatial year. The large acreages were distributed based on the percent distribution calculated for each year. Acreages for all other years remained the same as the delivered values. The final delivered acreages were then multiplied by the SACD, producing acres of each crop in each area.

Calculated irrigated acres by crop and by SA were entered into a monthly consumptive use calculator. A separate iteration of the calculations was completed for each of the SAs and any acreage located outside the SA (i.e. SA 99).

All agricultural acreage summaries by valley, crop type, year, and SA are provided (Appendix 2).

Riparian Land Use

Opinions

- Phreatophytic or riparian vegetation exists within the study area, primarily along the edges of the Rio Grande. Riparian tree and shrub species depend on access to shallow groundwater for establishment and survival. Riparian vegetation group is small compared with agricultural production in the study area, but it consumes water directly from local riverine and groundwater sources, and thus is important to the overall assessment of consumption.
- Limited historical field survey information is available for riparian vegetation. The available information should be used to calibrate any remote or photo interpretation approaches.
- Total riparian vegetative cover decreased dramatically in the late 1930s due to clearing, decreasing from approximately 6,900 acres to approximately 350 acres between the Rincon and Mesilla Valleys. It remained at a similarly low level into the 1950s.
- Riparian vegetation has increased gradually since the 1950s to approximately 1,711 acres in 2018.

Methods

Riparian land cover was analyzed for Rincon and Mesilla Valleys. Because ground survey of native vegetation is highly intensive and was not available for much of the study period, previous studies informed by ground vegetation surveys were used. Qualitative ground observations of vegetation change in the study area were used in this analytical approach. Image resources could be analyzed with geospatial techniques to determine the relative cover of riparian vegetation classes. These results were then calibrated to the results of a historical study of vegetation cover change by Papadopulos (2008), which had similar assessment objectives and the benefit of ground survey data.

Papadopulos (2008) evaluated the years 2004, 1997, 1986, 1974, 1967, 1955, and 1936. Independent vegetative cover analyses were performed by Land IQ for two years (1955 and 2005) to evaluate Papadopulos' (2008) results to generate an annual riparian land use coverage. In addition, an analysis of riparian vegetation extent was conducted in 2014 to represent more recent conditions that could not be captured in the earlier study.

Riparian Area Delineation

Riparian corridors were delineated for 1955, 2005, and 2014 using digital mapping techniques and photo interpretation. The 2014 riparian land cover extent was delineated using photo interpretation of high-resolution, aerial images collected between August 13–20, 2014. Images used are summarized in Exhibit 45. The riparian boundary was further modified to exclude roadways, open-water features (e.g., river) and other land-use types (e.g., agriculture, urban). Complete riparian corridors were delineated and then segmented into areas with similar characteristics, such as vegetation cover, density of tree canopy, landscape features, and distribution of bare ground by visible elements in the image (e.g., color/tone, texture, shape, shadow) (Exhibit 46).

Exhibit 45. Imagery Used for Riparian Vegetation Mapping

Riparian Mapping Year	Image Source
1955	0.5 m Farm Service Agency aerial photography (June 1955)
2005	1 m NAIP (August 2005)
2014	1 m NAIP Aerial Imagery (June/July) 0.33 ft Aerial Imagery (August 13-20, 2014)
2016	1 m NAIP Aerial Imagery (May/June/August)

Vegetation Functional Group Classifications

The 2014 cover of riparian vegetation was assessed with NDVI, derived from the 2014 NAIP aerial imagery within the delineated riparian corridor areas. Using NDVI-based classification, the relative cover of three land cover classes, or plant functional groups (PFGs), was determined. Plant functional groups are groupings of plant species that exhibit similar growth and water use characteristics. The three PFGs assessed included:

1. Riparian Tree**:** Deep-rooted, woody riparian trees, including drought-intolerant phreatophytic trees that rely on shallow groundwater for establishment, growth, and transpiration.
2. Riparian Shrub: Phreatophytes with shallower rooting depths than riparian trees that also are reliant on shallow groundwater. One of the most common plant species in this group is *Baccharis* spp. (Mulefat).
3. Bare Ground**:** Includes areas that are bare year round and areas that may have seasonal vegetation cover (dominated by annual grasses and other herbaceous vegetation–the life cycle is driven by rainfall events and not to transpiration from deeper rooted perennials).

Papadopolus (2008) includes a fourth PFG for herbaceous riparian, which is relatively uncommon in the present day; however, it had significant historical extent as documented by Papadopolus (2008) for the year 1936, when it was estimated to be more than 57% (3,997 acres) of the riparian vegetation across the Rincon and Mesilla Valleys. Examples of common herbaceous riparian species include Curly Dock (*Rumex crispus*) and Deer Grass (*Muhlenbergia rigens*). For the purposes of this study, the Herbaceous Riparian PFG is insignificant from a consumptive water use perspective given its limited extent and relatively shallow rooting morphology.

For 2014, the relative cover of riparian trees, riparian shrubs, and bare ground was calculated for each delineated riparian polygon. This assessment was based on initial NDVI-analysis of cover groups in 2014 along with photo interpretative adjustments and calibration to the most recent 2004 results from Papadopulos (2008).

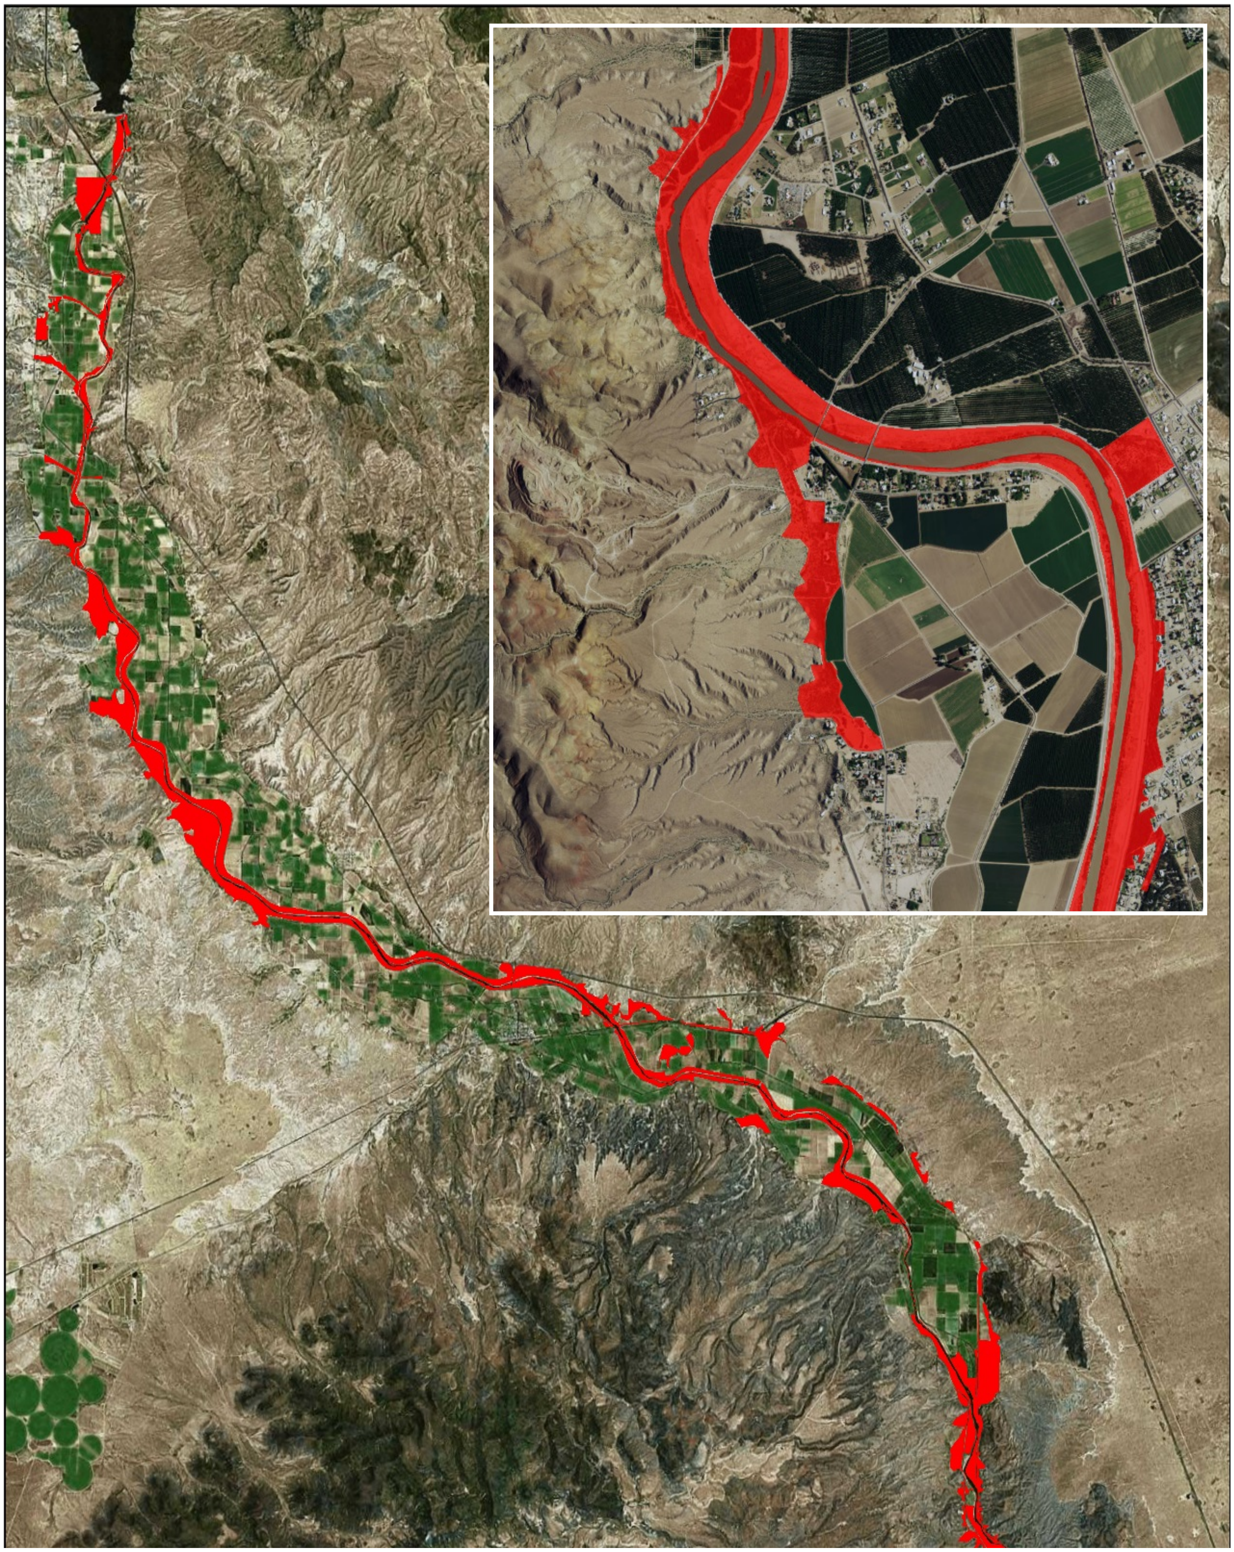

Exhibit 46. Example of Riparian Vegetation Mapping in 2014

The 4-Band June/July-2014 NAIP imagery was clipped to the Mesilla and Rincon Valleys, and used to generate NDVI using Image Analysis Model Builder in ArcGIS Desktop 10.2.2. Zonal statistics tools were used on the raster datasets to generate the number of pixels within the polygons for each riparian PFG, and were summed to determine fractional coverage (%) for each riparian PFG within each polygon.

Each 2014 riparian polygon was then reviewed using high resolution (0.3 ft) aerial imagery and Google Street View images (when available) to confirm the relative PFG cover for trees, shrubs, and bare ground in each polygon. Areas with misclassified vegetation were adjusted by photointerpretation to the appropriate PFG and cover value.

Relative change in riparian area extent and total vegetation versus bare ground between 2005 and 2014 was evaluated using retrospective photo-interpretive change analysis of the 4-band images. Cover of vegetation and bare ground were adjusted in increments of 5% to account for differences in canopy cover of trees or shrubs between the baseline year of 2014, derived from the NDVI and 2005.

Riparian Extent Comparisons and Calibrations

The accuracy of the following features of the Papadopulos (2008) report (Section 2.4 and Appendix K) were evaluated in two ways:

- By comparing the extent of the riparian area mapped by Papadopulos for 1955 and 2004 to the delineation of the years 1955 and 2005; and
- By comparing the amount of total vegetation and bare ground classified by Papadopulos in 2004 with the classification for the 2005 image.

NAIP 2005 imagery was used for comparative analysis with Papadopulos 2004 study year because it was the nearest suitable imagery available. The results of this comparison showed a 7% difference in total riparian area extent in 1955, and a 2% difference in 2004/2005 (Exhibit 47). These results were similar, indicating consistency in photo interpretative methods employed. Differences in delineated areas are likely attributable to the definition of the edge of riparian areas where they abut upland alluvial soils on the edge of the Rio Grande floodplain, and will not lead to significant differences in calculations of riparian plant cover area (as this excess will be classified as bare ground).

Exhibit 47. Comparison of Riparian Area Extent Mapped by Land IQ vs Papadopulos (2008) for 2004/2005 and 1955.

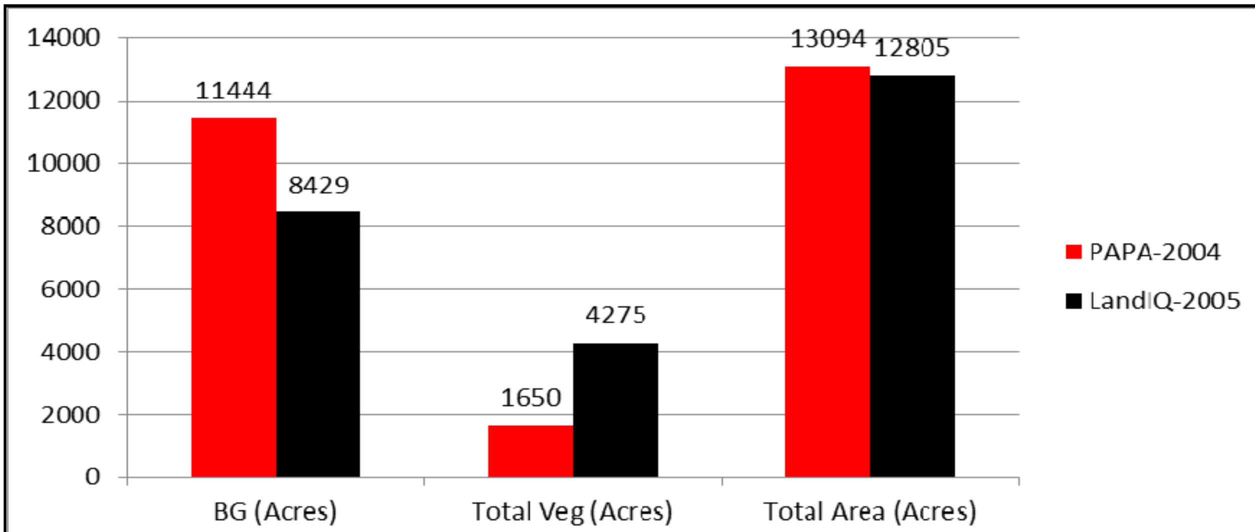
Comparison Year	Papadopulos Total Riparian Area (Acres)	Land IQ Check Total Riparian Area (Acres)	Difference (%)
2004/2005 [a]	13,094	12,805	2%
1955	13,160	12,186	7%

[a] Land IQ 2005 analysis was compared to Papadopulos 2004 analysis due to availability and suitability of aerial image resources.

The distinction between total vegetation and bare ground in both Papadopulos 2004 analysis and Land IQ 2005 analysis were compared. This comparison was made because 2004 was a year in which Papadopulos completed field vegetation surveys. The objective of this comparison was to establish scaling criteria to scale NDVI plant cover analysis to the Papadopulos 2004 results that were guided by ground surveys.

As discussed earlier, the 2014 NDVI-based total vegetation cover values were adjusted for 2005 by photointerpretation of differences in aerial cover of vegetation areas between the 2005 and 2014 imagery. The total vegetation cover calculated for 2005 was compared with the total vegetation result previously generated by Papadopulos in 2004. While total riparian extent was within 2% for these years, the Land IQ NDVI-based calculation of total riparian vegetation cover for 2005 was 159% greater than the Papadopolus (2008) total riparian vegetation cover calculated for 2004 (Exhibit 48). This difference is expected and due to the common overestimation of cover using NDVI values (pixel-based) compared with field survey data. The Papadopulos (2008) report had the benefit of field survey data to verify and measure riparian vegetation cover in 2004.

Therefore, the tabular 2014 total vegetation cover values were reduced by 159% to calibrate the 2014 NDVI-based cover observations to 2004 field-based observations in the Papadopulos (2008) report.



Comparison Year	Bare Ground (Acres)	Total Vegetation (Acres)	Total Riparian Extent (Acres)
2004 (Papadopulos)	11444	1650	13094
2005 (Land IQ)	8429	4275	12805
Difference used to generate scaling factor	-26%	159%	-2%

Exhibit 48. Comparison of 2004 Land IQ Analysis with 2004 Papadopulos Field-based Vegetative Cover.

Results

Results from both analytical efforts were used to compile a riparian land use dataset for the study period. Results of the comparative analysis showed similar relative change in vegetation cover. Therefore, cover values from Papadopulos (2008) were used for the years they were available and combined with the independent results for 2014 to comprise the riparian area dataset for consumptive use analysis purposes (Exhibit 49). The 2014 fraction of riparian tree, riparian shrub, and riparian herb based on Papadopulos 2004 report are values for the fraction of vegetated PFG cover, which are, in turn, based on field survey data (94.1% for tree; 5.6% for shrub; and 0.3% for herb). Photo-interpretation of the 2005 and 2014 high-resolution aerial images showed little to no detectable change in the relative PFG composition between 2005 and 2014 in the riparian areas.

Each analytical year was used to represent the approximate center point of the represented period between analytical years. For example, the values from the 1967 photo analysis were used for 1961 through 1970. Land IQ 2014 analysis results were used from 2014 back to 2010, and Papadopulos results were used for 2009 back to 1936. The completed annual riparian dataset is provided in Appendix 4.

Exhibit 49. Riparian PFG Cover for the Rincon and Mesilla Valleys.

Source	Year	Total Area (Acres)	Total Riparian Tree (Acres)	Total Riparian Shrub (Acres)	Total Riparian Herb (Acres)	Total Bare Ground (Acres)	Total Riparian Veg Area (Acres)	Riparian in Rincon[1](acres)	Riparian in Mesilla[1] (acres)
Land IQ	2016	12,882	1,619	96	5	11,161	1,721	1,149	572
Land IQ	2014	12,809	1,610	96	5	11,098	1,711	1,142	569
PAPA	2004	13,094	1,553	92	5	11,444	1,650	1,109	541
PAPA	1997	13,174	1,620	92	5	11,450	1,717	1,154	563
PAPA	1986	13,018	1,257	25	1	11,735	1,283	862	421
PAPA	1974	13,344	792	110	3	12,440	904	607	297
PAPA	1967	14,089	665	43	-	13,380	708	476	232
PAPA	1955	13,160	273	74	-	12,813	348	227	121
PAPA	1936	15,438	1,452	1,520	3,997	8,469	6,967	4,549	2,418

1. 1955 Fraction of Rincon-Mesilla Total Veg and PFGs is 0.653 of Total Riparian Veg in Rincon (based on Land IQ analysis of vegetation cover in 1955); 1935 to 1937, 1961 to 2014, assumed 0.672 of Total Veg and PFGs in Rincon (based on 2014 Land IQ analysis of vegetation cover)

Consumptive Use Evaluations

Extensive efforts were conducted to determine acreages of agricultural crops and riparian vegetation types for use in estimating consumptive use. Consumptive use for agriculture and riparian areas are presented below.

Agricultural Consumptive Use

Opinions

The following opinions are based on the results of the agricultural consumptive use determination as described below from 1936 through 2018. All crop consumptive use values are provided in Appendix D.

- The overall irrigated agricultural consumptive use in the Rincon and Mesilla Valleys increased from 238,870 acre-feet in 1936 to 275,162 acre-feet in 2018.
- The overall irrigated agricultural consumptive use in the Rincon Valley increased from 37,587 acre-feet in 1936 to 59,164 acre-feet in 2018.
- The overall irrigated agricultural consumptive use in the Mesilla Valley increased from 201,284 acre-feet in 1936 to 215,998 acre-feet in 2018.
- The increase in consumptive use can be attributed to the following:
    - Change in acreage to higher water use crops (e.g., cotton to pecans);
    - Development and production of higher yielding/larger biomass crops (e.g., new varieties of alfalfa developed since 1936);
    - Increase in double cropping and over-winter grain crops;
    - Improved farm management systems (e.g., land leveling, improved distribution uniformity, improved irrigation scheduling, etc.);
    - Incorporation of groundwater wells to provide an additional water supply and allow for a greater opportunity to meet crop water demand especially in years of limited surface water supplies; and
    - Higher density pecan plantings.

Methods

Modeling Approach

The CUP+ Evapotranspiration calculator model was used to determine the consumptive use of each crop per acre per year. The CUP+ was developed by Orang, Snyder, and Matyac, and calculates the potential daily evapotranspiration (PET) with weather and crop inputs. The CUP+ employs either the Hargreaves-Samani or the Penman-Monteith evapotranspiration model, depending on the amount of inputs available. The Penman-Monteith method was used when sufficient data were available. Potential evapotranspiration was calculated using CUP+ for the following 19 crop categories:

- Alfalfa
- Asparagus
- Chili
- Cole/Leafy Greens
- Corn/Silage
- Cotton
- Grain
- Grapes
- Hay
- Legumes
- Melons/Squash
- Misc/Other
- Onions
- Pasture
- Pecans/Other Trees
- Root Crops
- Tomatoes
- Turf
- Irrigated Annuals

Each of these crops has unique properties that influence consumptive use, including Kc values (PET modifier, based on crop and growth stage), percentage of the growing season in each development stage, rooting depth, allowable depletion factor, planting date, and harvest date (Appendix E).

Water Use of Mesilla Valley Crops

Crops

Chilis

Chili acreage in New Mexico peaked in the mid-1990s at about 35,000 acres. Although acreage has declined to approximately 10,000 acres, production has not decreased since that time (Western Farm Press, NASS). According to historical yield records, chili yield has increased from about 15,000 lb/ac in the mid-1990s to roughly 17,000 lb/ac in the Mesilla Valley. Akinbile and Yusoff (2011) demonstrated that chili grown at 50% ET (calculated using an energy balance model) yielded as much as chili irrigated at full ET, indicating that high yields can be achieved with less water than might have been previously used.

According to Bosland and Walker (2014), chilis require 48 to 60 inches of irrigation per season. Assuming that this value refers to applied water and that irrigation efficiency is less than 100%, chili consumptive use is some value lower than this amount. Skaggs and Samani (2005) reported that irrigation efficiency on chili in the Elephant Butte Irrigation District ranges from 83 to 94%; therefore, consumptive use of chili is estimated at 40 to 46 irrigation inches using this information.

Using standard methods to determine potential evapotranspiration (Penman-Monteith, when data was available, and Blainey-Criddle for other years in the study period) and crop coefficients from the New Mexico Climate Center (1996), and adjustments for historically lower yields, average consumptive use for chili from 1936 to 2016 was calculated at 32 inches. The study referenced for these crop coefficients was from Saddiq (1983).

Gencoglan et al. (2006) demonstrated that when chilis were deficit irrigated the crop water production function was linear, meaning that yield declines proportionally and at the same rate when water is decreased, regardless of how much water is applied.

The information above indicates:

- The crop coefficient from 1996 represents relatively high yielding crops compared to today's crops;
- Current crops are even higher yielding, but may also be more water efficient and likely don't need more water; and
- Historical crops within the study period yielded much lower.

Therefore, adjusting the crop coefficient downward going back in time is a reasonable approach to estimate consumptive use throughout the study period (Appendix G).

Onion

According to Cramer (2000), acreage, per acre yield, total production, and total value for the New Mexico onion crop increased from 1980 to 2000, which could be attributed in part to improved varieties and improved cultural practices. Yields have continued to increase until present day. Cramer (2000) documented yields in 2000 at approximately 460 cwt/ac, or 46,000 lb/ac. Current regional yields are approximately 900 bu/ac or 51,300 lb/ac.

Seasonal water use was documented at 23.3 inches by Erie et al. (1982). Walker et al. (2009) reported that the average yield for New Mexico (approximately 800 sacks/acre) was obtained with an efficiency of 80% and the application of 32 inches of water, implying that the crop used about 26 inches of water. Hall et al. (undated) estimated onion water use at 25 to 30 inches per season in Texas. Calculated crop ET using standard methods to calculate potential ET and crop coefficients from the New Mexico Climate Center (1999) resulted in an average estimated crop ET of 28.8 inches per growing season for the Mesilla Valley. Elsewhere, recent onion crop ET was documented at 27 inches per season (Hammond Conservancy 2011). These sources indicate that onion consumptive use is in the range of 26 to 29 inches of water. Onion ET in the Mesilla Valley is likely near the top of this range.

New Mexico State University (undated) cited the work of Al-Jamal et al. (1999) that provided the data for the water production function shown in Exhibit 50. Al-Jamal et al. (2001) investigated irrigation efficiencies of drip, sprinkler, and furrow irrigation on onion in the Mesilla Valley and concluded:

"The IWUE using the sprinkler system was higher compared to the subsurface drip and furrow irrigation methods, which indicates that if you are trying to conserve water, then a sprinkler irrigation system should be used with some form of irrigation scheduling. If you are trying to maximize yield, then this will be achieved by using a drip irrigation system."

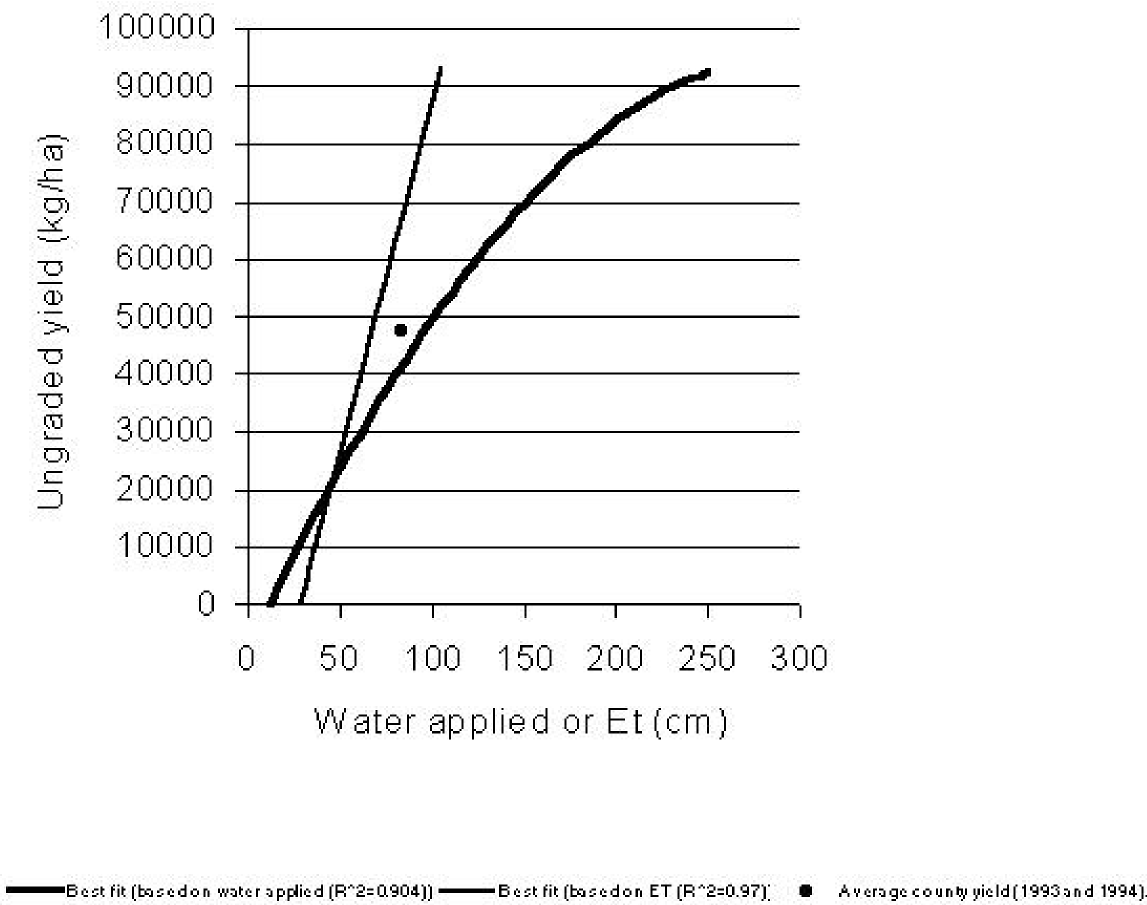


Exhibit 50. Onion Water Production Function. (Source: New Mexico State University. https://aces.nmsu.edu/aes/irrigation/onions.html)

De Oliveira's et al. (2002) Arizona study demonstrated that when Kc was measured on lettuce irrigated with drip, water use was significantly lower than previous crop coefficients (from 1965) indicated. The information above indicates:

- The crop coefficient from 1999 represents relatively high yielding crops compared to today's crops;
- Current crops may be higher yielding, but may also be more water efficient, and likely don't need more water; and
- Historical crops within the study period yielded much lower.

Therefore, adjusting the crop coefficient downward going back in time is a reasonable approach to estimate consumptive use throughout the study period.

Lettuce

Average seasonal crop water use estimated for the study period is 18 inches. While New Mexico State University documented the crop water production function and crop coefficients for chili and onion, there is no similar documentation for leafy greens or specific leafy greens such as lettuce. Therefore, calculations to estimate crop ET for the study period used crop coefficients from FAO Irrigation and Drainage Paper 56 (Allen et al. 1998) or California varieties.

Leafy greens vary widely in their water requirements, as shown in Exhibit 51.

Exhibit 51. Water Requirements of Leafy Greens in Texas (Source: Dainello, 2003)

Type of leafy green	Seasonal water requirement (inches)
Cabbage	20-30
Collards, kale	12-14
Lettuce	8-12
Mustard greens	10-15
Spinach	10-15

Using the water requirements in Exhibit 51 as a guideline, the calculated ET of 18 inches is representative as an average of recent cabbage and lettuce water requirements (the main leafy green crops in the Mesilla Valley).

Seasonal water use of lettuce was documented at 8.5 inches by Erie et al. (1982). This value does not differ from the value in Exhibit 51, indicating that the water requirement of lettuce may not have increased proportionally to yields, which have a little more than doubled during the study period. Martin et al. (2009) reported that head lettuce in Arizona uses 9 to 12 inches of water per season, which is also within the same range. However, De Oliveira et al. (2005) reported that lettuce irrigated with subsurface drip methods use less water than the surface irrigation that was studied in Erie et al. (1982).

The information above indicates:

- The crop coefficients used to estimate lettuce and cabbage ET are likely applicable; and
- Current crops may be higher yielding, but likely don't use much more water than crops grown during the time period when crop coefficients were developed.

Therefore, adjusting the crop coefficient downward going back in time is a reasonable approach to estimate consumptive use throughout the study period (Appendix G).

Climatic Data

Many climatic data resources were evaluated; however, only those resources with reliable climatic data spanning the historical period within the project area were chosen. When a station within a valley offered suitable data, those data were used for that valley. The three primary sources of climatic data identified were:

- NCDC/NOAA (National Climatic Data Center/National Oceanic and Atmospheric Administration);
- WRCC (Western Regional Climate Center); and
- Texas ET Network.

The following criteria were used to evaluate suitability of weather stations and data:

- Location/distance to agriculture fields;
- Immediate surroundings (e.g., irrigated surface vs. vacant lot);
- Measured values (preference for stations that have variables supporting Penman Monteith calculations); and
- Data reliability and consistency.

Weather stations were ranked on these criteria and any data gaps were filled with the next station meeting the selection criteria (Exhibit 52). Through the data evaluation process it was determined that data originating from weather stations located in each valley were sufficient for representing each of the three valleys, respectively. These included:

- Rincon and Mesilla Valleys
- EPCWID1/Hudspeth

Exhibit 52. Weather station ranking over time according to suitability of data.

Date Range	Valley	Most Desirable Data --------------------------------------Least Desirable Data				
2012-2016	EPCWID1/Hudspeth	Tornillo	Ysleta	Fort Hancock	-	-
2011-2012	EPCWID1/Hudspeth	Art Ivey	Tornillo	Ysleta	Fort Hancock	-
2007-2011	EPCWID1/Hudspeth	Tirres	Art Ivey	Tornillo	Ysleta	Fort Hancock
2004-2007	EPCWID1/Hudspeth	Art Ivey	Tornillo	Ysleta	Fort Hancock	-
2002-2004	EPCWID1/Hudspeth	Tornillo	Ysleta	Fort Hancock	-	-
1981-2002	EPCWID1/Hudspeth	Tornillo	Ysleta	Fort Hancock	El Paso International Airport	El Paso, TX
1977-1981	EPCWID1/Hudspeth	Ysleta	Fort Hancock	El Paso International Airport	El Paso, TX	-
1962-1977	EPCWID1/Hudspeth	Fabens	Ysleta	El Paso International Airport	El Paso, TX	-
1950-1962	EPCWID1/Hudspeth	Ysleta	El Paso International Airport	El Paso, TX	-	-
1936-1950	EPCWID1/Hudspeth	Socorro	Ysleta	El Paso International Airport	El Paso, TX	-
2001-2014	Rincon/Mesilla	Fabian Garcia	NMSU Main Campus	NMSU Turf Grass	Leyendecker PSRC	-
1944-2000	Rincon/Mesilla	Las Cruces, NM	State University, NM	La Tuna S, Tx	-	-
1936-1943	Rincon/Mesilla	State University, NM	La Tuna S, TX	-	-	-

Two potential ET calculation methods were evaluated and included the Penman-Monteith Method and the Hargreaves-Samani method. Climate data variables needed for ET calculation differ for each method.

Penman-Monteith variables required:

- Maximum temperature
- Minimum temperature
- Solar radiation
- Wind speed
- Dew point
- Precipitation

Hargreaves-Samani variables required:

- Maximum temperature
- Minimum temperature
- Precipitation

The available climate data did not include the data required for the Penman-Monteith ET calculation method for part of the time period. As a result, the Hargreaves-Samani ET calculation method was used when the Penman-Monteith parameters were not complete. In years that Penman-Monteith data were available, however, both methods were calculated to compare methods and generate adjustment factors for earlier years when only Hargreaves-Samani could be used (Appendix F).

Monthly Adjusted Agricultural Consumptive Use

A crop calculator was created to adjust PET values produced by the CUP+ program. The PET results from the CUP+ program are in acre-feet of consumptive use per acre of planted acreage (acre-feet/acre). These PET values were adjusted due to difference in ET calculation methods. An average monthly adjustment factor was calculated for each of the two ET zones (Rincon/Mesilla and EPCWID1/Hudspeth) when data was available to compare the two ET methods.

PET was also adjusted for irrigation and production differences across time. This adjustment factor takes into account improvements in irrigation efficiency, land leveling, and increased yields/biomass. This factor reduces the PET of crops in historical years because the overall yield, vigor, density, and consistency of growth were proven (through historical yield records and image analysis) to be less in previous years. As a result, the consumptive use was correspondingly less. An adjustment factor was employed for many of the crop types (dominated by cotton and alfalfa) based on yield records and image analysis. These values were based on information obtained from various resources, including comparison of reported yield in the JIR and crop reports. Visual evidence of these crop growth differences also are seen when comparing image resources from different decades (Exhibit 53).

Once the final adjusted PET is calculated (CUP+ PET number * ET Adjustment Factor * Irrigation and Production Factor), it is then multiplied by the total number of acres of each crop on a monthly time step. This value is final consumptive use, by crop, by service area, by year.

Effects of Salinity and Specific Ion Toxicity on Crop Yield in the El Paso, Mesilla, and Rincon Valley

Introduction

The following technical literature review summarizes the current available literature on the direct and indirect impacts of salinity on the crops with the highest acreage in the El Paso, Mesilla and Rincon Valleys (study crops). Various sources have been consulted and the most current and/or established research available has been summarized. The review provides general information on salinity, sodicity (caused by sodium [Na^+]), and chloride (Cl^-) effects on soils and plants. General guidelines, relative tolerance thresholds and rankings are provided for the study crops. Finally, a brief review of scientific literature related to salinity and specific ion tolerance is provided for each study crop.

Summary

Excess soil salinity occurs when salts accumulate in the root zone, or upper layers of soil. Salts accumulate from natural soil conditions and from long-term irrigation, which precipitates salts when water evaporates from soil and transpires from plants. In many cases, crop growth and yield are reduced in saline conditions because plants need more energy to take up water from salty soil than from non-saline soil. This is called the osmotic effect. One of the most common salts in the environment is sodium chloride (NaCl), which separates into Na^+ and Cl^- ions. These ions, in excess, can also accumulate to toxic levels in plants, which is called specific ion toxicity. Sodium chloride, through all of these effects, is typically thought of as having the most impact on crops compared to other salts, such as calcium chloride (CaCl2).

To manage salinity stress, plants use physiological and biochemical responses and ecological strategies to either avoid or tolerate the stress. Some common strategies include (other) ion uptake by roots, ion exclusion from roots, ion accumulation in vacuoles of root or shoot cells, regulation of ion transport from root to shoot, increased tolerance to high concentrations of toxic ions, and accumulation of compatible solutes (Sandhu et al. 2017). These mechanisms have been studied to a great degree in some crops, such as alfalfa, and little in other crops, such as pecan.

The study crops include alfalfa, cabbage, chile pepper, corn, cotton, grains, lettuce onion and pecan. These crops differ in their tolerance to salinity and Na^+ and Cl^- ions specifically, and in some cases, exhibit a wide variety of tolerance between varieties within the same crop. In general, however, crops that are sensitive to salt are also relatively sensitive to one or both of these salt ions. Crops are only as tolerant as their lowest specific ion tolerance. For example, alfalfa is tolerant of Na^+, but much less tolerant of Cl^-, resulting in its moderate tolerance of salinity. Corn, on the other hand, is moderately sensitive to salinity largely because of its sensitivity to Na^+, even though it can tolerate Cl^- fairly well. Onions are neither tolerant of Na^+ nor Cl^-, and chili pepper tolerance differs so widely between varieties that a single ranking of relative salt tolerance is difficult to determine.

Adding sulfur (S) to soil achieves multiple benefits. First, the S will react with oxygen and water in the soil to produce sulfuric acid (H_2SO_4). This acid will reduce and better balance the pH in soils that may be alkaline (basic) in nature. The sulfuric acid will then react with any lime ($CaCO_3$) in the soil to produce gypsum ($CaSO_4$). Lastly, the $CaSO_4$ then reacts in a sodic soil to produce (tie up) sodium sulfate ($NaSO_4$) which then becomes mobile and is able to leach beyond the root zone. This creates a relative increase in the proportion of Calcium (Ca) and Magnesium (Mg) which tend to aid in soil flocculation, water penetration, and overall improved soil health. The ratio of Sodium (Na) to Ca and Mg is critical to keep in balance and thus one reason why growers will apply S and/or $CaSO_4$ to their fields.

Background Information

The following section summarizes general information on salinity, Na, and Cl^- and their effects on soil and crop growth and yield.

SALINITY

Excess soil salinity occurs when salts accumulate in the root zone, or upper layers of soil. Salts accumulate from natural soil conditions and from long-term irrigation, which precipitates salts when water evaporates from soil and transpires from plants. In many cases, crop growth and yield are reduced in saline conditions because plants need more energy to take up water from salty soil than from non-saline soil. This is called the osmotic effect. Ions that form salt compounds, such as Na^+ and Cl^-, can also accumulate to toxic levels in plants, which is called specific ion toxicity. In addition to these two main impacts of salinity, nutritional imbalances and oxidative stress also result from salinity stress.

To manage salinity stress, plants use physiological and biochemical responses and ecological strategies to either avoid or tolerate the stress. Some common strategies include (other) ion uptake by roots, ion exclusion from roots, ion accumulation in vacuoles of root or shoot cells, regulation of ion transport from root to shoot, increased tolerance to high concentrations of toxic ions, and accumulation of compatible solutes (Sandhu et al. 2017).

Crops vary in their ability to withstand and/or mitigate the multiple effects caused by salinity stress, and though the exact thresholds of salinity where crop yields are impacted are published, these values should only be viewed as guidelines. Actual salinity tolerance in the field may fluctuate or diverge from these values as a result of site specific conditions such as climate, soil type, and management practices, and/or improvements in crop salinity tolerance resulting from crop breeding aimed at increasing salt tolerance. Therefore, some assumptions and considerations associated with crop salt tolerance thresholds should be understood.

- Salinity threshold studies for some crops are more prevalent than others. Availability of salinity research depends on the degree of research funding and efforts conducted on the individual crop.
- Salinity impacts often occur over the period of several years, which demands multi-year studies to better assess the changes in and variability of these conditions.
- Yield factors such as nutrition are impacted by salinity, which has indirect and usually compounding effects on crop growth and production.

- Saline irrigation water affects soil quality as well as crop health, and it can be difficult to separate out these impacts, although the saline irrigation water is the main exacerbating issue to begin with.
- Field and farm management conditions and actions affect impacts of soil salinity.
- Salinity threshold studies can be exacerbated by specific ion toxicity, or the impacts of specific salt ions on plant growth.
- There is a variety of salinity tolerance among cultivars of crops, but in general the information contained in this document addresses the main production systems and should be considered representative.
- Seedlings are generally more sensitive to salt than later growth stages of a crop.
- Obvious injury symptoms usually don't appear unless salt stress is extreme, however impacts on production usually do occur prior to visual indicators.
- There are several parameters that influence crop response to salt stress, including:

  - Salt constituents and existing salt distribution in the soil profile
  - Soil water content, microorganisms, physical conditions, and fertility
  - Climate and air quality
  - Varieties, rootstocks, and stage of growth
  - Cultural practices such as irrigation methods, seed bed arrangements, and plant population density

The most recent data from Maas and Grattan (1999) (reproduced in Tanji and Kielen, 2002) is currently considered some of the best information available on crop salinity tolerance with a few exceptions for specific crops and varietals included. These thresholds are published in international publications such as the Irrigation and Drainage Papers published by the Food and Agriculture Organization of the United Nations (FAO), and aside from specific studies on particular crop varietals, they are considered the best crop salinity tolerance information available and are based on decades of thorough scientific research. Since these data were published, salinity tolerance research has focused on the following areas:

- Crop breeding/rootstock development to increase salinity tolerance.
- Determination of specific ion toxicity of salt constituents, such as Na^+, Cl^-, and sulfate.
- Salinity tolerance in crops for which no salinity threshold and/or impact function has been previously published.

These new studies coupled with the industry standard research results were considered in reviewing the salinity thresholds for the crops in the area.

Irrigation water salinity is often measured as total dissolved solids (TDS) in parts per million (ppm), however literature often describes soil and water salinity as electrical conductivity (EC) in decisiemens per meter (dS/m). A simple conversion for irrigation water from TDS in ppm to EC in dS/m is as follows (Equation 1):

EC = TDS/640 (up to an EC of 5 dS/m) **(EQUATION 1)**

When EC > 5.0 dS/m, research recommends dividing by 800 instead of 640.

This technical memorandum will discuss salinity in terms of irrigation water salinity (ECw) and soil salinity (ECe), which are both expressed in units of dS/m. ECe is the electrical conductivity of a soil saturated paste and is the standard method of measuring salinity in the soil. Crop salt tolerance thresholds are described as ECe thresholds and provide the maximum ECe of the soil at which 100% of crop yield can still be achieved. ECe thresholds are representative of crop salt tolerance at maturity. It is known that crop salt tolerance varies throughout different crop growth stages and is usually less tolerant during germination and seedling stages. In addition to the crop threshold ECe, a slope is often calculated which explains how quickly yield will decrease once the crop threshold ECe is reached per every 1 dS/m increase above the ECe threshold.

The following equation can be used to estimate soil salinity based on irrigation water salinity.

$$\mathbf{ECe = (ECw)(X)} \qquad \textbf{(Equation 2)}$$

Where: ECe = soil salinity

ECw = irrigation water salinity

X = soil concentration factor (a soil concentration factor of 1.5 is assumed by Maas and Grattan, 1999)

For reference, crops are generally categorized by their salinity tolerance, as shown in Exhibit 54.

Exhibit 54. Crop Salt Tolerance Generalized Categories (Adapted from Ayers and Westcot, 1994)

Crop Salinity Tolerance Category	Upper Limit Soil Salinity (ECe) Threshold (dS/m)	Irrigation Water Salinity (ECw) Threshold[a] (dS/m)
Sensitive	3.0	1.0 – 2.0
Moderately sensitive	5.0	1.7 – 3.3
Moderately tolerant	8.0	2.7 – 5.3
Tolerant	12.0	4.0 – 8.0

[a] Assuming 1.5 soil concentration factor, and 1 dS/m EC = 640 mg/L TDS.

Agricultural salinity impact functions are used to estimate the crop yield that results from soils possessing a specific salinity. The slope coefficient is the percentage decline in yield for every unit increase in soil salinity. In general, the more salt-sensitive a crop, the higher its slope coefficient. In other words, the lower the ECe threshold, the more crop damage will occur if salinity is increased above the threshold. The formula for a salinity impact function generally follows this format:

$$\mathbf{y = 100 - b(x - ECe\ Threshold)} \qquad \text{(Equation 3)}$$

Where: y = yield potential (%)

b = slope coefficient (%)

x = actual soil salinity (dS/m)

ECe Threshold = crop soil salinity threshold (ECe)

SODICITY

Typically, the most detrimental salt ion in a soil-plant-water system is Na^+ (Na). Na^+-specific ion toxicity can result in soil degradation and crop yield decline. The Na^+ adsorption ratio (SAR) is the ratio of Na to Ca (Ca) and magnesium (Mg) ions. This relationship is important because it is an indication of the potential impact Na can have on the soil. The SAR is determined by the following formula where ion concentrations are in meq/L:

$$SAR=\frac{[Na]}{\sqrt{\frac{1}{2}([Ca]+[Mg])}}$$

To manage the amount of salt ions in the root zone, excess irrigation water is often applied to leach salt ions lower in the profile. The amount of additional water needed to sufficiently remove the salts is termed the leaching requirement. However, in heavier soils (soils with more clay) with poor drainage, sufficient leaching is more difficult to achieve and salt accumulation can occur in the upper portion of the soil profile.

Sodicity is usually not a concern when the SAR is between 0 and 3 as long as the water salinity is greater than 0.7 dS/m (Ayers and Westcot, 1994). If the SAR is between 3 and 6, the ECw needs to be greater than 1.2 dS/m to ensure that soil degradation will not occur due to excess Na. A high SAR with a relatively low water salinity suggests that Na is the dominant salt forming cation which would likely result in degradation of soil structure, decreased infiltration, etc. Within the soil environment, Na^+ hazard is measured as the exchangeable Na^+ percentage (ESP). The relationship between the SAR and ESP is roughly linear, meaning water with a SAR of 2 will result in soil with an ESP of around 2. As long as soil ESP is below 15 there is unlikely to be any impact to soil drainage or structure.

SPECIFIC ION TOXICITY OF SODIUM AND CHLORIDE

As introduced previously, the two main responses of plants to salinity are the osmotic effect, which inhibits water uptake, and the specific ion effect, which results from accumulation of salt ions to toxic levels. Nutrient imbalance is another effect of excess salinity. The osmotic effect occurs within minutes to days of exposure to saline conditions, and results in oxidative stress and water and nutrient imbalances in the plant. The ion-dependent response to salinity, however, develops over days to weeks as a result of build-up of ions to toxic levels, such as Na^+ (Na) and Cl^- (Cl^-) in the shoots of plants. Both of these effects cause premature senescence of leaves (leaf drop), reduced yield, and ultimately plant death (Negrao et al. 2017). Though Cl^- is an essential plant nutrient and is required in small amounts, Na is not an essential nutrient but is often present in high concentrations, especially in irrigated agriculture.

Multiple mechanisms have been identified that plants use to survive saline conditions: 1) ion exclusion, or the ability of the plant to exclude ions like Na and Cl from the shoot; 2) tissue tolerance, or the compartmentalization of toxic ions in specific tissues; and 3) osmotic adjustment – the maintenance of growth and water uptake even when toxic ions accumulate in the shoot. However, Bartha et al. (2015)

cite multiple studies, including their own, that demonstrate that "*Although the ability to exclude Na^+ or Cl^- from the shoot is often a primary determinant of variability in salinity tolerance within a species, there is not necessarily an inverse relationship between shoot Na^+ or Cl^- concentration and salinity tolerance. There is rather a difference in the ability of ion homeostasis maintenance in the root, in the xylem sap and in the leaves*." Therefore, very specific parameters need to be measured to determine which effect, or which ion, ultimately causes yield reduction in each crop type.

SODIUM

Excess Na^+ is potentially problematic for both soils and plants. Na^+ is not an essential plant nutrient, so it is not required in any way for plant function, though too much Na^+ results in plant water and nutrient imbalances. As described above, excess Na^+ also causes dispersion of soil aggregates and inhibits water infiltration.

Most of the salinity tolerance studies conducted to determine thresholds were executed using Na^+ Cl^- (NaCl) as the imposed salt. Maas and Grattan's work (199…) is an example of such a study, where tolerance was determined but no attempt was made to compare salt species. However, scientific literature on salt ion tolerance in specific crops is sparse, because of the complexities of salinity tolerance and the difficulties in determining cause and effect relationships.

CHLORIDE

Chlorine is an essential plant nutrient that is required in small amounts. Chlorine converts to Cl^- in the soil, which is taken up by plants. Because it is a negatively charged ion, Cl^- moves readily with water similar to nitrate, and is easily consumed by plants. Because it is present in many salt compounds (eg. NaCl, KCl, $CaCl_2$), Cl^- can accumulate in amounts above what is needed by the plant and become toxic. Cl^- toxicity occurs when too much Cl^- accumulates in plant shoots, causing leaf chlorosis (yellowing) and necrosis (death), both of which are sometimes described as leaf "scorch" or "burn".

Again, because most salinity tolerance studies have been carried out using NaCl, it has not always been obvious which impacts to plant growth were caused by the osmotic stress induced by salinity, or by Cl toxicity. Even if Cl^- toxicity symptoms were present, few studies have compared the effects of different salts under the same saline conditions.

White and Broadley (2001) reported on a system of categorizing crops by growth responses to Cl^- as follows:

1. Halophytes – native flora of saline soils, in which 200 mM Cl^- (in external media, not tissue)
    a. Stimulates growth
    b. Affects growth very little
2. Halophytes and non-halophytes (glycophytes) whose growth is reduced substantially by 100 mM Cl^-
    a. Tolerant
    b. Intermediate
    c. Sensitive
3. Very salt-sensitive glycophytes

White and Broadley use (2001) this categorization system for salinity as well, and do not differentiate between Cl^- sensitivity and salt sensitivity. They state that sensitive and tolerant species have tissue Cl^- threshold ranges of 4 to 7 and 15 to 50 ppm dry weight, respectively; however, tissue concentration depends entirely on how well the plant can restrict Cl^- from roots to shoots, and cannot easily be related to specific Cl^- concentrations in irrigation water or soil.

Summary Exhibits of Salinity, Sodium and Chloride Tolerance

The following section provides exhibits of thresholds and guidelines found in the literature related to salinity, sodicity and chloride tolerance for the study crops. These sources do not all have information for each of the study crops; however, they represent the most complete information available.

SALINITY

Crop salinity impact functions have a zero slope until they reach their ECe threshold. Once the ECe threshold has been reached a linear relationship is assumed between ECe and crop yield percentage. Exhibit 55 summarizes the ECe thresholds, slope coefficients, and their resultant salinity impact functions for the most widely grown crops in the area. Additionally, Exhibit 55 shows each of the salinity impact functions. (Salinity thresholds for each crop are reviewed individually in the next section.) Onions are the most sensitive to salinity, while cotton and grains are the least sensitive (Exhibit 56).

Exhibit 55. Crop Salinity Impact Functions of the mostly widely grown crops in the El Paso, Mesilla and Rincon Valleys

Crop	Soil Salinity Threshold, ECe (dS/m)	Salinity Slope (%)	Salinity Impact Function
Alfalfa / Pasture	5	7.3	y = 100 - 7.3(x - 5.0)
Cabbage	1.8	9.7	y = 100 - 9.7(x - 1.8)
Chile Pepper	1.5	14	y = 100 - 14.0(x - 1.5)
Corn	1.8	7.4	y = 100 - 12.0(x - 1.7)
Cotton	7.7	5.2	y = 100 - 5.2(x - 7.7)
Grains	5.9	3.8	y = 100 - 3.8(x - 5.9)
Lettuce	1.3	13	y = 100 - 13.0(x - 1.3)
Onion	1.2	16	y = 100 - 16.0(x - 1.2)
Pecan	2.5	11.4	y = 100 - 11.4(x - 2.5)

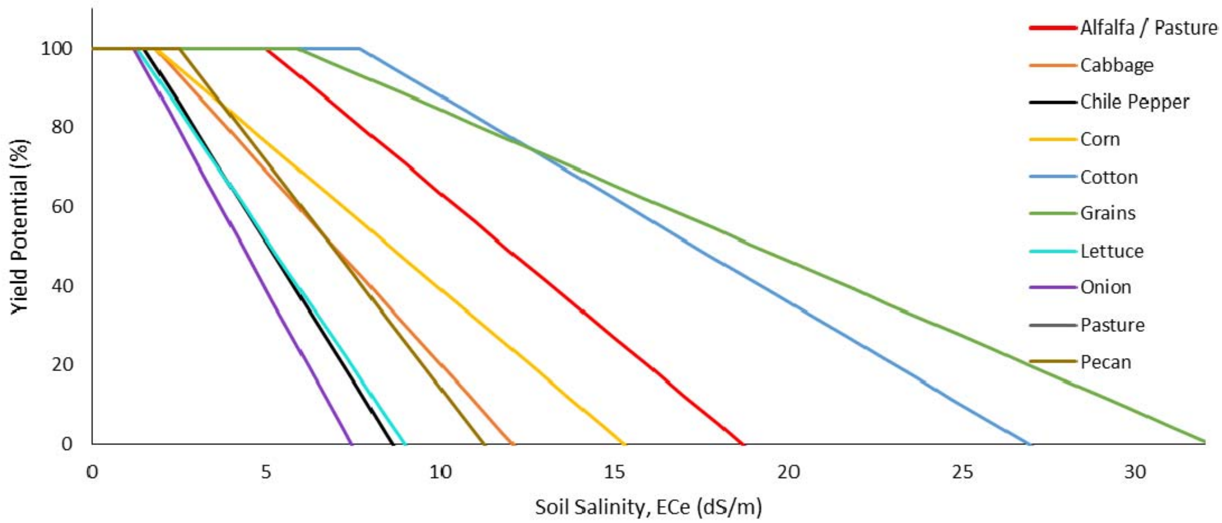

Exhibit 56. Crop Salinity Impact Functions of the mostly widely grown crops in the El Paso, Mesilla and Rincon Valleys

SODIUM

There are no specific thresholds published for Na tolerance, because Na excess typically causes soil infiltration problems long before Na ion toxic effects occur in agricultural fields. For this reason, The Food and Agriculture Organization (FAO) published relative Na tolerances for selected crops, with corresponding exchangeable Na^+ percentage (ESP) ranges (Exhibit 57).

Exhibit 57. Sodium (as ESP) tolerance of the mostly widely grown crops in the El Paso, Mesilla and Rincon Valleys.

Crop	Sensitive (< 15 ESP)	Semi-Tolerant (15-40 ESP)	Tolerant (>40 ESP)
Alfalfa / Pasture			X

CHLORIDE

Some Cl tolerance thresholds or relative tolerance concentrations have been published for various crops, but is it unknown if these have been peer reviewed. For example, K&S Fertilizer ranks cereals, corn, cabbage and cotton as Cl^- tolerant crops, whereas chili pepper, onion, and lettuce are listed as Cl^- sensitive crops (ref). Alfalfa and pecan were not rated. Similarly, Spectrum Analytic lists Cl^- thresholds for selected crops as summarized in Exhibit 58. Some crops, such as alfalfa, cabbage, lettuce, and small grains, respond well to Cl^- fertilizer, while others are susceptible to toxicity.

Other sources rank irrigation water Cl^- concentration in terms of general safety for crops. An example from a fertilizer company (not peer reviewed) is shown in Exhibit 59.

Exhibit 58. Chloride tolerance of the mostly widely grown crops in the El Paso, Mesilla and Rincon Valleys

Crop	Relative Chloride Tolerance[1]	Soil Chloride Threshold (ppm)	Percent Yield decrease for every ppm above threshold (slope)
Alfalfa / Pasture	MT	700	0.020
Cabbage	MT	525	0.028
Chile Pepper	-	-	-
Corn	MT	525	0.034
Cotton	T	2,625	0.014
Grains (durum wheat)	T	1,925	0.014
Lettuce	S	350	0.037
Onion	S	350	0.046
Pecan	-	-	-

Crops

The following section summarizes information on salinity and ion toxicity for each of the widely grown crops in the area. The amount of information available varies for each crop depending on how common it is and its economic importance. Therefore, this information is not necessarily conclusive; rather, it is included to provide more insight on crop specific tolerances and yield potential for each crop, and how these tolerances might be affected by environmental factors such as soil type and water quality, and cultural practices such as varietal selection and irrigation method.

ALFALFA

Alfalfa has been considered a crop that is moderately sensitive to salinity (threshold ECe=2 dS/m) with a slope of 7.3% since the 1960s (Tanji and Kielen 2002). However, in recent years researchers have demonstrated that alfalfa is more tolerant than previously thought (up to ECe=8 dS/m) (Putnam, pers. comm.). In addition, researchers in Arizona and California have been working on breeding more salt tolerant alfalfa varieties for the last 30 years (Sanden and Sheesley, 2007).

In some cases, field studies have demonstrated that low leaching fractions that result in soil salinity higher than the conventional threshold do not necessarily harm alfalfa growth and yield (Leinfelder-Miles, 2016), although these studies were conducted in a dissimilar climate to that of southern California and Arizona and have not been validated again in the research. Central Arizona alfalfa growers have also demonstrated that alfalfa grows without symptoms of salt stress in highly saline soils (ECe = 8 dS/m) (Land IQ, 2014). This is site specific, however and may or may not be applicable to southern New Mexico. Until repeated verification of these results occurs, the standards presented in this documentation memorandum should be used.

The irrigation water salinity threshold that would result from using the conventional soil salinity threshold of 2 dS/m and a soil concentration factor of 1.5 (as assumed by Mass and Grattan, 1999) would be 1.3 dS/m or 832 mg/L TDS. Salinity experts acknowledge that due to newer varieties, the conventional salinity threshold for alfalfa may be too low and a new one needs to be developed, but no official update to the alfalfa threshold or impact function has been developed to date (Putnam, 2018). However, recent studies performed in sand tanks, greenhouses, and field stations all corroborate a salinity threshold for alfalfa between 5 and 8 dS/m ECe, assuming that water management optimizes alfalfa growth and salinity mitigation (Benes et al., 2015; Putnam et al., 2014). Therefore, a threshold of 5 dS/m is recommended for alfalfa, which represents the minimum of this range.

According to Sanden and Sheesley (2007), alfalfa and other crops are 10 to 20 percent more tolerant of Ca and sulfate salts compared to NaCl. Al-Khateeb (2006) corroborated this perception for Ca by demonstrating that shoot and root growth declined under increasing treatments of NaCl, while the addition of Ca mitigated those effects.

However, Henning et al. (2004) found no difference between Cl uptake in the forms of ammonium Cl^-, calcium Cl^- or a mix of the two. Soltanpour et al. (1999) found no difference between Cl^- and sulfate salts, which both reduced alfalfa dry matter equally; however the slope (or impact function) they calculated was much lower (-3.37 percent) than that of Maas and Hoffman (1977) (-7.3 percent). Interestingly, they did not observe a salinity threshold. Potassium chloride (KCl), a commonly used fertilizer, has long been known to cause leaf burn and shoot death (Smith and Struckmeyer 1977). These authors showed that high Cl uptake caused thickened, yellowed and deformed shoots. Meyer and Matthews (1995) found that Cl^- application could prevent some disease, but large amounts applied as KCl caused toxicity.

Sandhu et al. (2017) tested 12 genotypes of alfalfa for salinity tolerance using different salt compounds, and also investigated mechanisms of salt tolerance in the most tolerant varieties. They found that Na exclusion was an important mechanism in the most tolerant alfalfa varieties. This may be the reason alfalfa is considered tolerant to Na (Ayers and Westcot 1994).

CABBAGE

The cabbage ECe threshold is cited at 1.8 dS/m with a 9.7% slope, being considered moderately sensitive (Tanji and Kielen, 2002). Varieties differ in their salt sensitivity. Sanoubar et al. (2016) found that Savoy cabbage was more tolerant of NaCl than white cabbage, likely because of greater concentrations of antioxidant enzymes accumulated in Savoy that mitigate oxidative stress. This mechanism results in better water relations and tissue adjustment/tolerance than that of white cabbage. The authors identified two thresholds – one at 100 millimoles (mmol)/L and one at 200 mmol/L where morphological and physiological changes took place. These values are similar to those found by Pavlovic et al. (2019), who reported a salinity threshold of 180 mmol/L, which is consistent with previously published values of Shannon and Grieve (1999) and others. These authors also investigated the salinity tolerance mechanisms of cabbage, but focused on Na^+ ion relations and biological responses, and did not study Cl^-. Maggio et al. (2005) found relatively high tolerance to NaCl in cabbage. They reported that despite some observed physiological responses, cabbage could still be grown in low to moderate saline soils up to 4.4 dS/m.

CHILE PEPPER

The published ECe threshold for pepper is 1.5 dS/m with a slope of 14% being considered moderately sensitive (Tanji and Kielen, 2002). Recent pepper salinity research has focused on the relative salinity tolerance of different varieties of peppers and seedling emergence (Niu and Sun, 2013; Niu et al., 2010).

Several studies have documented that chili peppers differ considerably between and within species in their salinity and ion tolerance. For example, habanero peppers exhibit a combination of stress tolerance mechanisms, but varieties range from sensitive to tolerant in their salinity tolerance overall (Bojorquez-Quintal et al. 2014). Iroka et al. (2016) also found that pepper varieties differ in their tolerance even at the germination stage from tolerant to highly sensitive.

CORN

The ECe threshold for corn is 1.7 dS/m with a 12% slope and is considered moderately sensitive (Tanji and Kielen, 2002). However, the salinity threshold for corn grown specifically for forage has been published as 1.8 dS/m ECe with a slope of 7.4% (Tanji and Kielen, 2002). It is recommended to use the corn, forage salinity impact function as corn is commonly grown for forage.

Eaton (1942) conducted outdoor sand tank and indoor greenhouse water culture experiments to evaluate the tolerance of corn to Cl^- and sulfate salts. The results of this experiment showed that corn was susceptible to Cl^- toxicity at relatively low concentrations. Parker et al. (1985), however, conducted greenhouse and field research to investigate the effect of Cl^- on one variety of corn (Trojan), and found that it was not very susceptible to Cl^- toxicity; they were not successful inducing Cl^- toxicity symptoms using imposed Cl^- treatments. One explanation for the difference in these results is the difference in corn varieties that were used, given that one study took place almost 80 years ago, whereas the other was fairly recent.

Farooq et al. (2015) contend that in the second phase of salt stress, when accumulation of Na and Cl^- has potential to become toxic, Cl^- is not as problematic as Na for corn. They also cite a study (Isla and Aragues 2010) the demonstrated that as salinity increased, Na accumulation was much higher than Cl−in maize, and maize productivity was more sensitive to Na accretion than Cl^- (Isla and Aragues2010). Farooq et al. (2015) also observed multiple exclusion and compartmentalization mechanisms that corn uses to mitigate the effects of Na, but no similar mechanisms for Cl^-. Therefore, corn is likely not very sensitive to Cl^-. This is supported by the fact that a positive response to Cl^- has been documented in numerous studies on corn in the Midwestern US, and application of low amounts of Cl^- is becoming part of a complete corn fertilization program (Kansas State University Extension). Ayers and Westcot (1994) also suggest that corn is sensitive to Na. The differences in corn tolerance to Na and Cl^- are reflected in Exhibits 57 and 58.

COTTON

Cotton is tolerant to salinity and has a relatively high salinity threshold. Therefore, the salinity threshold for cotton has not been challenged by new research. Sources agree on the threshold, published by Tanji and Kielen (2002) of a 7.7 dS/m ECe threshold with a slope of 5.2%.

White and Broadley (2001) list cotton as an example of a tolerant glycophyte. This assessment is corroborated by other sources that rank cotton as tolerant or moderately tolerant of salinity (Maas 1990), Na and Cl^- as well (Exhibits 57 and 58). However, varieties differ in their salt tolerance (Ashraf 2010), and these differences, which are largely genetic, are exploited in breeding programs designed to generate more salt tolerant cotton varieties (Akhtar 2010). Ayers and Westcot (1994) recommend that cotton is sensitive to Na during germination but tolerant as a mature crop.

GRAINS

Salinity thresholds and slope vary greatly between different types of grains, with barley being the most salt tolerant. Durum wheat is a representative variety grown in the area because it is the most widely grown grain. It is considered moderately tolerant to salinity and has a published ECe tolerance of 5.9 dS/m and a slope of 7.3% (Mass and Grattan, 1999).

However, Royo and Abio (2003) concluded, from their study of 17 durum wheat genotypes and their tolerance to salinity, that varieties differ in their salinity tolerance, and commonly accepted literature values are likely too high. While Ayers and Westcot (1985) list the salinity at which durum yield is reduced by half (ECe_{50})at 15 dS/m, Royo and Abio (2003) found that this value was, on average for several different varieties including some that were very tolerant, 11.3 dS/m. The maximum ECe_{50} they found in the most tolerant variety they tested was 16.6 dS/m, while the lowest was 7.5 dS/m. They also observed increasing Cl^- and Na in leaf sap with increasing salinity in the irrigation treatments. While the increase in Cl^- correlated to yield in six varieties, no correlation was found for Na. This led the authors to believe that Cl^- toxicity is more problematic than Na toxicity; however, the effects of Na could have been mitigated by Ca in the treatments and growth media.

Contrasting results were reported by Borrelli et al. (2011), who also tested several durum wheat varieties for salinity tolerance and Na uptake. In their case, little Na accumulation was observed, even in plants exposed to high salinity treatments. The authors concluded that low Na accumulation coupled with osmotic adjustment allowed durum wheat to resist ion toxicity and salinity effects.

During the last 10 years, crop breeders have improved salinity tolerance of durum wheat even more by an estimated 25 percent (CSIRO 2010). Interestingly, Genc et al. (2015) found that when durum varieties were bred with a Na exclusion gene in an attempt to develop more salt tolerant varieties, these varieties out-yielded others under sodic conditions. However, under saline conditions, and even though leaf Na was very low, the osmotic effect of salinity negated any benefits afforded the plant by Na exclusion. This research indicates that plants with an exclusion mechanism can tolerate sodicity alone, but may not be able to tolerate overall saline conditions.

LETTUCE

The ECe threshold for lettuce is 1.3 dS/m with a slope of 13% and is considered moderately sensitive (Tanji and Kielen, 2002). There is considerable variability in salt tolerance between varieties (Shannon and Grieve 1999; Xu and Mou 2015), but for the most part the values suggested here are considered reasonable. Unlukara et al. (2010), for example, observed a threshold salinity value of 1.1 dS/m but a slope of 9.3 percent in a study that included five varieties. However, in their study, they used a mixture of NaCl, MgSO4 and CaCl2, rather than NaCl alone, which likely accounts for the difference in slope. Cahn and Ajwa (ref date?), in their study of lettuce salinity tolerance in the Salinas Valley in California, found that the published thresholds may be overestimated because of their findings indicating that yield can be impacted before salinity symptoms are observable. At the published thresholds, a 10 percent reduction in marketable yield was observed (on average for two varieties). However, they noted that the response of lettuce to salinity can depend on other factors such as the weather regime, species of salts, irrigation practices, and varietal tolerance to salinity. Because of these factors, the published salinity threshold is still considered valid.

Ayers and Westcot (1994) list lettuce as semi-tolerant of exchangeable Na^+. Cahn and Ajwa (undated) also found that increased tissue Cl and Na was correlated with increasing soil salinity and SAR respectively, but not correlated to yield. Similarly, Bartha et al. 2015 found that the most salt tolerant lettuce variety they tested (with NaCl) also had the highest amount of Na in the shoot, whereas as the lowest amount of Na was found in the least tolerant variety. These findings indicate that in lettuce, Na^+ exclusion is not a main strategy for salt tolerance. They further concluded that lettuce is an example of a crop in which salinity tolerance is related not to ion exclusion, but to inclusion of Na in the shoot system. They also observed that for salt tolerant varieties, the marketable yield has a higher dry biomass percentage, and that leaves of plants grown under high salinity were crispier and darker green. Unlukara et al. (2010) also found that dry matter content increased with increasing salinity.

In their study of 178 lettuce varieties, Xu and Mou (2015) observed that in general, varieties with high growth potential were relatively salt sensitive based on the percentage of growth reduction, while those with relatively high salt tolerance commonly had low growth potential under control condition. This finding indicates that salt sensitivity is not necessarily related to lower yield when genetic potential is considered. They further submit that growers may choose high yielding potential over salt tolerance.

ONIONS

The published ECe threshold for onions is 1.2 dS/m with a 16% slope and is considered salt sensitive (Tanji and Kielen, 2002). Salt tolerance of onion varies during crop development, being the most sensitive to salinity during seedling growth. Chang and Randle (2004) observed that though onion is considered a salt sensitive vegetable, it is grown in saline soils throughout the world. However, they observed similar threshold values in their study of onion salinity sensitivity using NaCl. Sta-Baba et al. (2010) also corroborated this threshold value in their greenhouse study on onion salt sensitivity. Ayers and Westcot (1994) list onion as a semi-tolerant of exchangeable Na^+.

Shannon and Grieve (1999) reported that little genetic variability in salinity tolerance exists between onion varieties. Correa et al. (2013) found some differences in salt tolerance between varieties, and Sivritepe and Sivritepe (2007) found that when onion seeds were primed with NaCl, seedlings developed from them were more salt tolerant than their unprimed counterparts. However, study findings are consistent in finding that increasing NaCl tissue concentrations are related to decreased plant viability and vigor. Specifically, Correa et al. (2013) observed that antioxidant enzyme activity increased with these high ion concentrations. These findings indicate that onion is likely not able to exclude or compartmentalize Na and Cl, which may be the reason for its low salinity tolerance.

PASTURE

Because pasture crops are of relatively low-value, recent salinity research has not been focused on pasture. There is a wide variety in salt tolerance between various pasture and grain crops, ranging from about 640 mg/L TDS to more than 3,242 mg/L TDS (Tanji and Kielen, 2002). These crops include grains, forages, grasses, and legumes. Finding a representative average threshold for this group of crops would require specific information about pasture mixes and grains grown in the region, which is not available to that level of detail. We recommend using alfalfa as the representative crop for this pasture, as it is a common component of pasture mixes and is widely used.

PECANS

Tanji and Kielen (2002) did not publish a salinity tolerance for pecans, citing only that they are moderately sensitive to salinity. However, Miyamoto et al. (1986) conducted pecan salinity research in the El Paso Valley, finding that the ECe tolerance varied from 2.0 to 3.0 dS/m with a slope varying from 9.5% to 14.5% when correlated to tree trunk diameter and cross-sectional area. However, no studies have been found that describe the decrease in yield associated with increase in salinity. The slope in Exhibit 55 was derived by considering the change in growth parameters with salinity documented by Myamoto (1986), and by reviewing slope values for other deciduous woody crops. The most recent pecan salinity tolerance research has focused on relative salinity tolerance of pecan rootstocks and varieties, along with salinity management measures.

Walworth (undated) interpreted Miyamoto's work more conservatively, as a threshold of 2.0 to 2.5 dS/m, but also suggested that salinity thresholds for pecans depends on soil type, rationalizing that clay soils are more difficult to leach and warrant a lower salinity threshold. Though Walworth acknowledges that pecan varieties differ in their salt tolerance and that data is lacking for most cultivars, he recommends the guidelines shown in Exhibit 60.

Exhibit 60. Pecan Salinity Tolerance Guidelines

	Salinity Threshold	
Soil Texture	**ECe (dS/m)**	**mg/L (ppm)**
Clay, clay loam	< 1.0	<640
Loam	1.0-2.0	640-1,280
Sand, loamy sand	2.0-2.5	1,280-1,600

Source: Walworth undated.

Deb et al. (2013) investigated salinity tolerance on one rootstock/scion combination with a CaCl and NaCl mixture, and found that salinity tolerance was between 0.89 and 2.71 dS/m ECe. This range encompasses that of Walworth (undated), shown in Exhibit 60; however, they based their conclusion on leaf scorch symptoms, which occurred within this range of salinity, and did not measure yield. Deb et al. (2013) the accumulation of Cl^- in leaves and observed leaf burn with increasing salinity treatments. Myamoto (2006) states that pecan is especially sensitive to Na and Cl^-, and that these salts are potentially more harmful and calcium or sulfate salts.

Riparian Consumptive Use

Opinions

- Riparian vegetation can be categorized into plant functional groups (PFGs) that have similar water use and plant growth characteristics. The vegetation within the study areas was represented by three plant functional groups: dominantly riparian trees, and to a lesser extent riparian shrubs and riparian herbaceous. Evapotranspiration rates are available from literature resources and studies relevant to the study area for the three PFGs.

- Riparian consumptive use in the Rincon and Mesilla Valleys was highest at the start of the study period when historical reports and studies document that total riparian vegetation was much higher along the Rio Grande prior to anthropogenic activities and development. Consumptive use at this time was estimated to be approximately 17,975 acre-feet. Efforts to clear riparian vegetation in the late 1930s, and resulted in dramatic declines in vegetative cover and associated consumptive use by the 1940s to approximately 720 acre-feet in Rincon and Mesilla Valleys combined.

- Since the 1950s, total riparian vegetation cover has increased gradually from this level, resulting in similar increasing trends in riparian consumptive use with the total riparian consumptive use for Rincon and Mesilla Valleys increased to approximately 4,371 acre-feet.

Methods

Riparian consumptive use was calculated using riparian land use areas and average ET rates for the three evaluated PFGs–riparian shrub, riparian herbaceous, and riparian tree. Riparian consumptive use calculations focused on phreatophyte vegetation and do not address bare ground. Evapotranspiration rates depend on several factors, including the characteristics of the plant community species identification, height and age, vegetation health), stand densities, site conditions such as depth to groundwater, salinity, temperature, and precipitation (Tamarisk Coalition 2009, Johns 1989).

Estimated ET rates for the three functional groups were generated from available literature sources. The ET rates for riparian shrub and riparian herbaceous PFGs were taken from Papadopulos (2008) (Exhibit 61). Riparian ET rates were estimated for the dominant PFG type; riparian trees, by selecting published ET rates for the three most common tree sub-types in this group: Tamarisk, Mesquite, and Cottonwood-Willow. Using relative tree cover estimates from Papadopulos (2008) for those three tree groups for each year of analysis, an average riparian tree ET was developed. Due to changes over time in vegetative composition of this PFG, riparian tree group ET values also change slightly over time.

The selected riparian tree ET rates used in this analysis are shown (Exhibit 62). A summary of literature resources for the relevant tree sub-types is provided below.

Exhibit 61. Annual Consumptive use Rates for Riparian Shrub and Riparian Herbaceous Functional Groups (From Papadopulos 2008)

Riparian Plant Functional Group		Annual Consumptive Use	
Shrubs			
0.01	ft/day	3.65	ft/year
Herbaceous			
0.006	ft/day	2.19	ft/year

Exhibit 62. Annual Consumptive use Rates for Riparian Tree Subcategories.

Riparian Tree Type		Annual Consumptive Use	
Tamarisk			
0.94	m/year	3.08	ft/year
Mesquite			
0.47	m/year	1.54	ft/year
Cottonwood/Willow			
1300	mm/year	4.27	ft/year

Tamarisk ET

Estimates of ET for typical dense stands of Tamarisk are presented in Exhibit 63 (Tamarisk Coalition 2009). In general, lower density stands and stands experiencing water and salinity stress (such as stands on upper floodplain terraces) have lower ET rates (~0.7 m/year), while healthy, well-watered stands, such as those along water courses with access to groundwater, can use up to 1.45 m/year. The mean value of these reported literature references was selected for this study (0.95 m/year).

Cottonwood/Willow ET

In the riparian floodplain zone, phreatophytic tree community vegetation (primarily Cottonwood-Willow) in western river systems, exhibit ET rates that are comparable to Tamarisk that has reached maturity (woody stems) and full canopy closure (Tamarisk Coalition 2009). Tamarisk vegetation cover has lower ET rates where it invades upper floodplain terraces, which are out of the mesic riparian fringe that supports Cottonwood-Willow riparian vegetation. Consequently, across a broad floodplain with a mix of upper and lower floodplain terraces, such as in the Lower Rio Grande Basin, the average ET for Tamarisk is expected to be lower than Cottonwood-Willow, assuming both are relatively mature stands. Younger stands of these communities, especially Tamarisk, will have higher ET rates, reflected by greener (photosynthesizing) plant material. The ET rates decrease to a relatively stable water consumption rate–assuming weather conditions are stable between years–as the biomass becomes woodier.

Annual ET rates for the Cottonwood-Willow riparian vegetation community were selected by reviewing Allen et al. (2005), which calculated average annual ET (mm) for Cottonwood (1380 mm) and Willow (1283 mm) for a study area in the Middle Rio Grande River Basin, with 2002 imagery and a satellite-based energy balance calculation method using Landsat imagery. The selected rate was 0.47 m/year.

Mesquite ET

The vegetation community of Bosque Mesquite in the Lower Rio Grande River Basin includes species such as Honey Mesquite and Velvet Mesquite. Examples of Mesquite ET rates are provided in research from Tamarisk Coalition (2009) (Exhibit 64). An ET rate of 0.5 m/year was selected for Mesquite.

++ Growing season only.

Riparian Tree ET

Using the fractional cover of Mesquite, Tamarisk, and Cottonwood in the riparian area as reported by Papadopulos (2008), a compound ET value for riparian tree was calculated. The percent cover of riparian tree species presented in this report accounts for approximately all of the tree cover reported in the Riparian Tree PFG from 1955 to 2004. The year 2014 was assumed to have the same tree composition as documented in the 2004 field surveys. The 1936 tree composition was estimated. The tree distribution was used to weight relative tree type ET rates and generate a weighted ET for the Riparian Tree PFG in each evaluated timeframe. Exhibit 65 shows the resultant ET estimations that were used for consumptive use calculation in the riparian tree areas.

Exhibit 65. Riparian Tree Plant Functional Group relative tree type distribution and Resultant Consumptive Use Assumptions

Year	**Mesquite** Fraction of Riparian Tree PFG	**Tamarisk** Fraction of Riparian Tree PFG	**Cottonwood-Willow** Fraction of Riparian Tree PFG	**Annual Riparian Tree CU*** **(Acre-Feet/Acre)**
2016	38.8%	59.0%	1.7%	**2.49**
2014	38.8%	59.0%	1.7%	**2.49**
2004	38.8%	59.0%	1.7%	**2.49**
1997	40.7%	57.7%	1.6%	**2.48**
1986	62.1%	36.2%	2.1%	**2.16**
1974	59.0%	37.1%	4.2%	**2.23**
1967	73.1%	25.4%	1.7%	**1.98**
1955	96.3%	0.0%	3.9%	**1.65**
1936	63.8%	0.0%	36.3%	**2.53**
Annual Consumptive Use (Acre-Feet/Acre)	1.54	3.08	4.27	---

*based on mix of dominant species over time

In the analysis year, the selected annual ET rates were multiplied by the corresponding riparian plant functional group acreage to generate the annual consumptive use by category. The years of analysis– 2014, 2004, 1997, 1986, 1974, 1967, 1955, and 1936–were used as the condition for intervening years; with the analyzed year used as the center point (i.e., year 1986 was used for 1987–1991 and 1982–1985). The results are presented in Appendix 5, including total riparian area, PFG area, PFG ET rate, and PFG water consumption by year from 2014-1936.

Results

Riparian consumptive use was highest at the start of the study period when historical reports and studies document that total riparian vegetation was much higher along the Rio Grande (Papadopulos 2008). Efforts to clear this vegetation occurred in the late 1930s and 40s and resulted in significant declines in vegetative cover and associated consumptive use. Since the 1950s, total riparian vegetation cover has increased gradually, resulting in similar increasing trends in riparian consumptive use (Exhibit 66).

Complete annual consumptive use results are presented in Appendix 4, including total riparian area, PFG area, PFG ET rate, and PFG water consumption by year from 2014-1936.

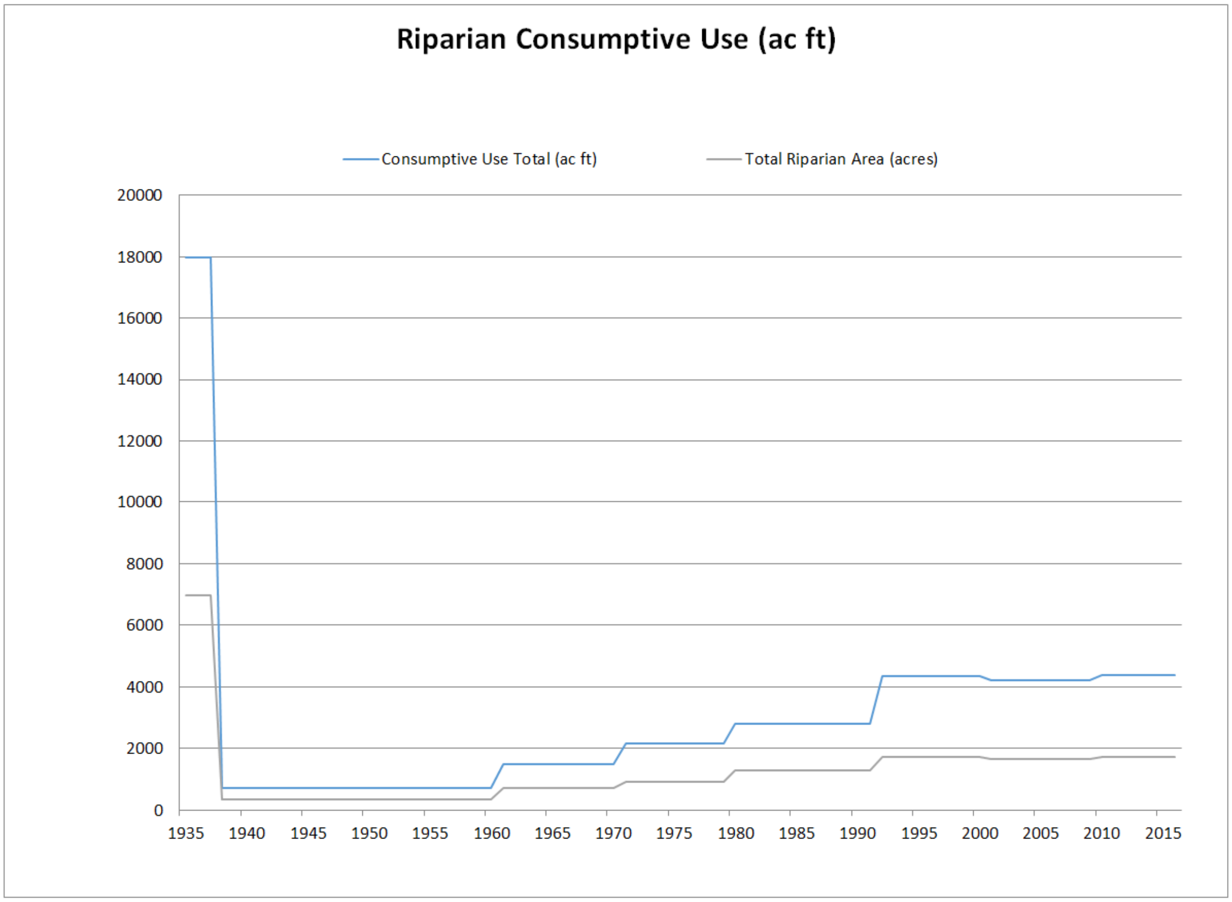

Exhibit 66. Riparian vegetation acreage and consumptive use from 1926 to 2016.

Notes/Assumptions

1 Dates for which analysis is available were used as the midpoints of the years for which ET Consumption by Riparian Veg was to be calculated

2 2014 fraction of Riparian Tree, Riparian Shrub, Riparian Herb and Bare Ground are based on 2004 Papadopulos(2008) report values for fraction of vegetated cover - which are in turn based on field surveys (94.1% for Tree; 5.6% for Shrub; and 0.3% for Herb)

3 2014 Vegetation by NDVI-based method was divided by 2.59 (aka reducing it by 159%) to calibrate to survey-based method in Papadopulos (2008) report

4 1955 Fraction of Rincon-Mesilla total vegetation and Plant Functional Groups (PFGs) is 0.653 of total vegetation in Rincon (based on Land IQ analysis of vegetation cover in 1955); 1935 to 1937, 1961 to 2014, assumed 0.672 of Total Veg and PFGs in Rincon (based on 2014 Land IQ analysis of vegetation cover)

* Note: PAPA 2008 = Papadopulos & Associates (Papadopulos). 2008. Summary Documentation of the Calibrated Groundwater Flow Model for the Lower Rio Grande Basin, LRG_2007. November 2008. Prepared for New Mexico Office of the State Engineer.

Appendix 6

Joel Kimmelshue, PhD.

Resume

Joel Kimmelshue, Ph.D., CPSS
Principal Agricultural and Soil Scientist
jkimmelshue@landiq.com

Education

Ph.D., Soil Science (Water Resources concentration), North Carolina State Univ., Raleigh, 1996
M.S., Soil Science (Ag Engineering concentration), North Carolina State Univ., Raleigh, 1992
B.S., Soil Science (Crop Sci. concentration), California Polytechnic State Univ., San Luis Obispo, 1990

Professional Registrations and Organizations

Certified Professional Soil Scientist (CPSS - #18204) – American Registry of Certified Professionals in Agronomy, Crops and Soils; American Society of Agronomy; Soil Science Society of America

Distinguishing Qualifications

Expert/Specialist in the following areas:

- Land use assessments and crop identification
- Production agricultural systems
- Soil/water/plant relations in arid climates
- Irrigation and drainage management
- Crop consumptive use estimates
- Expert witness testimony
- Soil and land use evaluations for the implementation of irrigation systems and crop production
- Water resources
- Soil nutrient interactions and environmental issues in soils
- Agricultural land application and reuse systems for various liquid and solid byproducts
- Soil and water salinity management for agriculture
- Dust and Erosion Control
- Water quality for irrigated agriculture
- Regulatory support and negotiation for agriculture
- Policy, regulatory, and environmental influences on agricultural production systems
- Soil and water conservation
- Agricultural research

Relevant Experience

Dr. Kimmelshue is a Principal Soil and Agricultural Scientist for Land IQ. Dr. Kimmelshue is also a founding Owner in the firm. He has experience in agricultural and water resources consulting in the western United States (especially California), and agricultural research and crop production throughout the United States. This experience stretches to various locations in Europe and the Middle East. Dr. Kimmelshue has performed technical leadership and/or managed numerous projects and tasks of nearly $15 million dollars over the past 19 years.

Dr. Kimmelshue's consulting experience includes practical and applied solutions for development of water/soil management systems and agricultural systems, specifically with irrigated agriculture. This technical expertise also includes expert witness testimony, crop consumptive use estimates, erosion and dust control, regulatory support and negotiation, water resources science and planning, land reclamation, soil/plant nutrient dynamics, irrigation and drainage in arid and humid climates, soil classification, crop production, land application of municipal and agricultural wastes, and revegetation/reclamation efforts.

Predominantly, the objective scientific work that Dr. Kimmelshue performs is driven by ever-changing policy, legislative and environmental pressures on production agricultural systems. Dr. Kimmelshue thoroughly understands these drivers and applies sound scientific results to help his clients address these challenges.

Select Representative Projects – Domestic

(Complete work experience includes efforts in the states of: Alabama, Arizona, California, Colorado, Florida, Georgia, Idaho, Iowa, Louisiana, Montana, Nevada, New Mexico, North Carolina, Oklahoma, Oregon, Texas, Utah, Washington, and Wisconsin.)

- **Principal in Charge and Technical Lead – Nationwide Mapping of Pecans – American Pecan Council.** As a result of successful mapping of various other tree crops for multiple years primarily in California, the American Pecan Council contracted with Land IQ to map pecans nationwide. This ongoing project spans the states of California, Arizona, New Mexico, Texas, Oklahoma, Louisiana, Alabama, and Georgia. The mapping years currently are for 2017 and 2018 and also contain an orchard by orchard age analysis. The orchards are mostly classified as improved or organized plantings, however some of the pecan production consists of native areas. Applications of these efforts also focus on the impact of Hurricane Michael on losses of orchards in Georgia in late 2018.
- **Principal in Charge and Technical Lead – Statewide Crop and Land Use Mapping – California Department of Water Resources.** Land IQ is contracted by the state of California to conduct statewide crop mapping of approximately 50 different crop types on over 9.4 million acres of agricultural land for fields of 2.0 acres and larger (sometimes smaller depending on crop type – (e.g. avocados)). The entire dataset amounted to over 350,000 individual polygons and an average field size of 34 acres. The mapping spanned the entire state from the Mexico, Nevada, and Arizona borders to the Pacific Ocean. The ultimate accuracy of the 2014 mapping based on thousands of miles of ground truthing was 96.6%. The 2016 accuracy was 97.6%. Land IQ is now mapping multi-cropping systems throughout the state in addition to the main season cropping systems.
- **Principal in Charge and Technical Lead – Statewide Avocado Mapping – California Avocado Commission.** For the California Avocado Commission, Dr. Kimmelshue leads a technical team in mapping avocados statewide although primarily in southern California. The mapping is highly accurate (>97%) and ranges down to fields of 0.5 acres. The California avocado industry is a relatively small in the global market, however produces high quality fruit for a premium price. The purpose of this annual mapping is to always be aware of not only the number of acres in production for also the condition of each orchard (e.g. producing, young, stumped, abandoned).
- **Principal in Charge and Project Manager – Monthly Remotely Sensed Crop Consumptive Use – Semitropic Water Storage District, North Kern Water Storage District, Shafter Wasco Irrigation District.** As a part of the California Sustainable Groundwater Management Act (SGMA) regulatory requirements, highly accurate and timely evapotranspiration measurement are a key input to

hydrologic models and overall efficient water management. For these 3 irrigation districts spanning approximately 400,000 acres, a monthly remotely sensed ET field by field measurement is performed and delivered to the districts within 30 days following the end of the previous month. The results are created with a remotely sensed regression approach that integrates nearly 40 simple ground truthing stations that measure the climatic variables necessary to calculate actual ET. These calibration points are then used in the model to estimate ET from every irrigated and non-irrigated field, as well as native areas. The ground truthing stations are also used for validation datasets.

- **Project Manager and Technical Lead–Cold Water Rice Yield Loss Determination; Western Canal Water District, Richvale Irrigation District, Biggs West Gridley Irrigation District; Cold Water Influences on Rice Yield; Nelson, Richvale, and Gridley, CA.** This project centered on the development and implementation of Settlement Agreement technical protocols between the three Districts (approximately 100,000 acres) and the California Department of Water Resources. The implementation of this Agreement will result in payment by the State of California to the growers within the Districts for loss of rice yield due to cold water diversion from the State Water Project at Oroville Dam and the Thermalito afterbay. The determination of yield loss is being conducted using aerial, satellite and other remote sensing techniques. This approach is being correlated to field measured yield losses utilizing grower owned and operated, combine-equipped GPS yield monitors. Also, in-canal temperature measurements were taken at 125 locations throughout the Districts for a period of up to 90 days. A temperature interpolation map and equation has been developed and is a third method of estimating yield loss determination. These three methods are being correlated against each other for an ultimate yield loss estimate. This work involves consistent contact and interaction with Districts' managers and staff, representatives from the California Department of Water Resources in Sacramento and Red Bluff, cooperating growers, and sub-consultants.
- **Principal In Charge/Technical Specialist – Statewide Spatial Mapping of Almonds, Walnuts, Pistachios, and Dried Plums; Almond Board of California, California Walnut Commission, California Pistachio Research Board, California Dried Plum Board; Modesto/Sacramento/Fresno, CA.** Dr. Kimmelshue is currently leading an intensive state-wide, field by field mapping product of all almonds, walnuts, pistachios, and dried plums across the entire state of California. Due to the rapid expansion of these tree crops, understanding of actual acres, age, and location in comparison to water sources, environmentally sensitive areas, transportation corridors, other crop types, and many other attributes are increasingly important to these four commodity organizations. The resultant work is a highly accurate, timely, and cost-effective crop mapping product. The technology employed for this work is a combination of inherent agronomic knowledge of cropping systems in California, remotely sensed attributes, and use of multiple additional lines of evidence.
- **Technical Lead and Project Manager – Kern River Watershed Coalition Authority, Sub Basin Review of Agricultural Irrigation and Drainage Practices and Crop Impacts; Bakersfield, CA.** Dr. Kimmelshue was retained by the KRWCA as an expert in providing sound technical agronomic information related to the unique irrigation and crop production practices of the Kern Sub Basin area within the Southern San Joaquin Valley Water Quality Coalition. This work involved understanding and interpreting changes in cropping patterns, irrigation methods, salinity management, fertilization practices and overall water and nitrogen use efficiency. A portion of this work included intensive ground truthing for development of remotely sensed crop mapping products. Those ground truthing data included permanent crop irrigation method documentation for use in irrigation method change over time.

- **Technical Lead – San Joaquin River Restoration Program, Seepage Management Plan, Expert Review Panel Member; United States Bureau of Reclamation; Sacramento, CA.** Dr. Kimmelshue was retained as a salinity, agricultural production, and irrigation and drainage expert to review a completed current version of the Seepage Management Plan for seepage impacts to agriculture including acceptable water table depths, salinity management, yield decline, remotely sensed solutions and irrigation and drainage management considerations. This work will result in completion of a comprehensive management document offering a review of thresholds, solutions and mitigation opportunities as a result of future increased flows in the San Joaquin River.

- **Project Manager and Technical Lead–Historical and Present Crop Evaluation and Water Use Estimate; Brownstein, Hyatt, Farber, Schreck – Water Law Firm – representing a Confidential Client; Bakersfield, California.** This project involved the historical and present quantification of water use at a confidential site near Bakersfield. Historical remote sensing imagery was acquired to determine the irrigated area changes over time as well as the cropping pattern shifts from the early 1950s to present day. Water use estimates were determined for the current cropping patterns as well as diverted water quantities. A comprehensive site evaluation was performed with the client and area grower/owner to determine soil type, water conveyance, irrigation methods and management, storage, crop types, etc. This work was used to facilitate a potential substantial land purchase and water rights quantification.

- **Expert Witness and Technical Lead–Prepared Testimony for United States District Court – Eastern District of California; Judge Oliver W. Wanger; Tehama Colusa Canal Authority Water Deficit Evaluation; Willows and Fresno California.** Dr. Kimmelshue was retained to prepare a detailed evaluation of the influence of regulated deficit irrigation on a variety of crops including almonds, grapes, walnuts, rice, olives, alfalfa, tomatoes and a variety of other permanent and annual field and row crops. The preparation of this testimony was conducted to determine the influence of a deficit of irrigation water at predetermined periods of the growth cycles of the crops mentioned above – predominantly focusing on perennial crops such as almonds. The results of this work indicate the extreme detrimental influence of insufficient irrigation during key growth stages of the crop.

- **Expert Witness and Technical Lead–Prepared Testimony for Santa Clara County Superior Court; Judge Jack Komar; Crop Water Demand and Estimation of Return Flows in Irrigated and Nonirrigated Areas; Southern California Water Company; Santa Maria, California.** This project involved expert witness testimony, both in deposition and in trial settings, based on an 8-month effort to assess crop water use for an historical 58-year period over a 164,000-acre basin. The work focused on pumped water and return flows to groundwater under irrigated and nonirrigated areas. Crop and native vegetation evapotranspiration and soil storage modeling was conducted. Water was assessed to ensure adequate quality for sensitive crop production. The expert witness testimony included 2 days of deposition and 2 additional days of trial testimony, including cross-examination. The work was conducted as a component of a groundwater basin assessment focusing on the potential for overdraft. This was a multi-stakeholder case, which included agricultural, urban and local, state, and federal agencies.

- **Expert Witness and Technical Lead–Preparing Testimony for Los Angeles County Superior Court; Judge Jack Komar; Crop Water Demand and Estimation of Return Flows in Irrigated and Non-irrigated Areas; Antelope Valley Groundwater Agreement Association; Lancaster, California.** This work centered on the quantification of a water right adjudication of the Antelope Valley. Dr. Kimmelshue represented the agricultural interests in the Valley and conducted a detailed and comprehensive assessment of crop water use, irrigation methods and efficiencies, return flows, and other parameters to ultimately assess a component of the safe yield of the groundwater basin based on agricultural pumping. This work was prepared for expert witness testimony in early 2011. Modeling was conducted to assess not only a variety of crop types in irrigated agricultural, but also irrigated urban areas.

- **Project Manager and Technical Lead–Blending of Saline Mine Water with Central Arizona Project (CAP) Water for Irrigation to Cotton, Alfalfa, and Sod; Rio Tinto Mining Company – Resolution Copper; Superior and Queen Creek, Arizona.** Dr. Kimmelshue is leading an effort to create an acceptable blended water quality for irrigation to alfalfa, cotton and sod on approximately 5,500 acres of land within the New Magma Irrigation and Drainage District (NMID). This project involves direct working efforts with the USBR, the state of Arizona Lands Department, NMID, the University of Arizona Soil, Water and Environmental Science Department, and the Resolution Copper Company. Many of these multi-stakeholder meetings were for the purpose of obtaining permitting documents and satisfying the discharge requirements. The work involves real-time monitoring of treated mine water, CAP water, and the blended result. This monitoring network comprises in-canal Total Dissolved Solids (TDS), temperature, and pH probes. A web-based portal will be used for instantaneous water quality assessment and tracking. Also, a comprehensive soil, water, and tissue sampling program will take place at least quarterly during this 5-6 year project. Crop growth stages and tracking will also be conducted. The dewatering of this mine is necessary to make copper ore available from the largest copper mine in North America.

- **Technical Lead and Task Manager–Blackfeet Indian Reservation Water Right Adjudication; Bureau of Indian Affairs/Department of Justice; Browning, Montana.** Technical expert since 1997 leading efforts related to the establishment of a water rights claim for the Blackfeet Indian Tribe. These efforts have and continue to include determination of practicably irrigable acres, detailed land classification for the determination of arable and irrigable lands, present and historical irrigation delineations, water demand estimates of both agricultural and urban uses, drainage evaluations for the purpose of avoiding salinization of lands, and overall task management for nearly $1.7M of labor, sub consultants, and expenses.

- **Technical Specialist – Owens Lake Dust Control; Los Angeles Department of Water and Power; Los Angeles/Lone Pine, CA.** For more than a decade Dr. Kimmelshue has provided senior technical expertise on a large variety of dust control efforts on the Owens Lake Dust Control Project. Historically, this area was one of the largest dust emission sources in the western hemisphere. Over time, Dr. Kimmelshue has provided objective scientific leadership on development, testing and large-scale (thousands of acres) implementation of various dust control technics and methodologies. These efforts specifically focus on analysis of various environmental conditions including soil type, climate, seasonality of emissions, water quality, and relative land disturbance. Based on those analyses, various methodologies to control source areas and challenging surface emissions in harsh environmental conditions have been achieved. Control methodologies include source control, soil binders, revegetation, shallow flooding and various tillage operations.

- **Project Manager and Technical Lead–Irrigation Water Reuse – Water Demand Estimates and Water Quality Suitability; City of Hollister and San Benito County Water District; Hollister, California.** This project involved the quantification of water needs assessment from both a quantity and quality perspective for irrigation with treated wastewater. Dr. Kimmelshue led multiple public education sessions related to the water quality and worked closely with both the City and Water District to ensure acceptance by the farming community. Water quality and quantity estimates were determined and were coupled with appropriate crop types and practices. A key portion of this work involved an update of the Recycled Water Master Plan for approval by the Regional Water Quality Control Board and other entities.

- **Project Manager and Technical Lead–Santa Clara River Watershed Total Maximum Daily Load (TMDL) Collaborative Process; Agricultural Irrigation Thresholds for Chloride and Salinity; Los Angeles County Sanitation Districts; Fillmore, California.** This project included the development of a detailed literature review and evaluation for determination of the potential threshold of irrigation water quality constituents of concern, specifically chloride, on sensitive crops as a basis of a TMDL process in working with the California Regional Water Quality Control Board. This collaborative process included work with a multitude of stakeholders including the California Avocado Commission, the California Strawberry Commission, Nursery Crop Growers, Ventura County Farm Bureau, and Los Angeles County Sanitation Districts. A multitude of crops were evaluated for their individual tolerances to specific constituents of concern. Only the most susceptible crops were further evaluated and included avocados, strawberries, and nursery stock. This work involved detailed assessment of water quality, irrigation practices, cultural practices and drainage management for the overall determination of acceptable irrigation water quality. The work also included comprehensive public notification efforts with stakeholder groups, public officials, researchers, and farm managers. The ultimate outcome of the work has been highly influential in establishing a chloride TMDL for irrigation of sensitive species in the Santa Clara River Basin.

- **Principal In Charge/Technical Specialist – Dust Control in Almonds; Almond Board of California/California Department of Food and Agriculture, Modesto/Sacramento, CA.** Dr. Kimmelshue is currently providing senior technical expertise on a state-wide dust control testing project through the Almond Board of California as funded by the California Department of Food and Agriculture Specialty Crop Block Grant Program. This project is being conducted to ascertain the effectiveness of application of $MgCl_2$ as a dust suppressant in almond production. Different rates of application are being tested to assess relative dust suppression coupled with agronomic suitability and environmental protection. This project began in October of 2012 and will continue through June of 2015. Environmental testing including air emissions and comprehensive soil testing, analysis and interpretation. Expected results include determination of an acceptable range of application rates as related to soil type, irrigation method, and orchard floor management.

- **Technical Lead–Land Application of Former Fertilizer Processing Solids; ChevronTexaco; Fort Madison, Iowa.** This $1.2 million project included the land application of fertilizer pond wastewater (1.5 million gallons) and solids (16,000 cubic yards) to approximately 2,200 acres of suitable farmland in Lee County, Iowa. Roles and responsibilities included management of site suitability analysis, pilot testing with Iowa State University, and request for subcontractor proposal development, contract negotiations, and regulatory requirements.

- **Project Manager and Technical Lead–Detailed Nitrogen Balance Model as a Component to a Required Plan of Study (POS); Anheuser-Busch; Jacksonville, Florida.** This POS evaluated the nitrogen dynamics resulting from multiple-year application of brewery processing waters to more than 300 acres of sod grass through center-pivot irrigation systems. Products included the development of a detailed nitrogen balance historical and predictive model for improvement of site irrigation management. An assessment report and findings were presented to the Florida Department of Environmental Protection and approved for permit extension.

- **Project Manager and Technical Lead–Pilot Study and Full-scale Reuse Program; ChevronTexaco; Richmond, California.** This water quality effort included agricultural reuse of approximately 11 million gallons of processing rinse water from a former nitrogen fertilizer manufacturing facility. The processing rinse water was registered with the State of California Department of Food and Agriculture as an agricultural mineral and labeled as Nitro One. Nitro One contains approximately 4 percent total nitrogen. A pilot study was conducted on a cooperating farmer's land that evaluated the effects of different application rates, injection protocols, and handling techniques on corn production. A public relations campaign was conducted to educate the area farmers about the benefits of using Nitro One and the management considerations of the product.

- **Project Manager and Technical Lead–Coalbed Methane Produced Water Discharge and Irrigation Suitability; Petroglyph Operating Company; La Veta, Colorado.** Dr. Kimmelshue evaluated the suitability of highly concentrated sodium-rich water from a coalbed methane operation for discharge and irrigation to corn and alfalfa near Walsenburg, Colorado. This work involved evaluating soil and water amendments to compensate for the high sodium concentrations. This challenging project involved public presentations at local community forums as well as ongoing collaboration with Colorado State University and the Colorado Cooperative Extension Service.

- **Technical Lead–Nutrient Management for the City of Los Angeles Biosolids Land Application Farm; City of Los Angeles Bureau of Sanitation; Bakersfield, California**. Over the past 8 years, Dr. Kimmelshue has been the lead technical consultant for the City of Los Angeles biosolids land application program at Green Acres Farms. This project involved a multitude of nutrient management programs and land application recommendations including irrigation, crop and overall farm management (including a Comprehensive Farm Management Plan) for the 5,000-acre site. The farm receives and beneficially reuses Class A biosolids from multiple municipal treatment plants in the Los Angeles Basin. Recent work involved the refinement of soil and plant tissue monitoring plans, a phased soil amendment schedule, crop fair market value assessment, and customized biosolids database and agronomic loading rate calculation tool Cybersolids™ for use at Green Acres Farm.

- **Technical Lead–Feasibility Study to Determine the Chemical and Hydraulic Effects of Irrigating 420,000 Gallons per Day of Saline Wastewater to an 80-acre Orchard and 75 Acres of Landscaping; IBM; San Jose, California.** This evaluation included a detailed cost estimate of modifying the existing irrigation system and management plan to accept the reuse irrigation water. It also included a comprehensive water quality evaluation that reviewed different blending ratios to ensure adequate water quality according to plant species receiving this irrigation water.

- **Technical Lead–Soil Salinity Evaluation; Glenn Colusa Irrigation District (GCID); Willows, California.** This soil salinity evaluation took place over approximately 200,000 acres of within GCID and some neighboring Districts. Dr. Kimmelshue managed and worked with GCID staff to sample the entire District and adjacent areas for soil salinity within the root zone. Sampling and analysis results were compared with historical measurements by the U. S. Bureau of Reclamation (USBR). The trend of salinization was analyzed for its relationship to long-term irrigation management, including a regulatory drought during which irrigation was curtailed throughout the District.

- **Technical Lead; Water Resources Plan–Oakdale Irrigation District; Oakdale, California.** This effort involved detailed assessment of historical land use and projections for future trends based on agricultural market conditions and urban and environmental pressures. This project also involved the development of a comprehensive water resources planning model. Main inputs to this dynamic model were crop water use estimates, water storage and conveyance, deep percolation, losses, recycled water use, and overall long-term water management options for both agricultural and urban uses.

- **Technical Lead and Manager–Clark County Water Reclamation District Biosolids Management Study: Market Assessment; Las Vegas, Nevada.** This effort included a diverse evaluation of potential end-use for Exceptional Quality (EQ) biosolids (in pelletized and bulk form) in the Las Vegas area for the Clark County Water Reclamation District. A key end-use included land application to alfalfa in an arid environment. The end result included recommendations for loading, crop rotations, soil sampling and analysis, tissue sampling and analysis, and potential economic return.
- **Technical Lead–Central Utah Water Resources and Land Classification Project; Central Utah Water Conservancy District; Roosevelt, Utah.** Successfully mapped nearly 10,000 acres of lands slated for supplemental irrigation and drainage improvements. Responsibilities included quality control for soil sampling and data interpretation. Co-authored a report to the USBR for final project approval and certification by the United States Congress.

Select Representative Projects – International Work

(Complete work experience includes efforts in the countries of: Turkey, Malaysia, Germany, Egypt, Israel, Jordan, and The West Bank) Representative projects listed here include:

- **Project Manager and Technical Lead–Development of a Reuse Feasibility Assessment for Irrigation of Conventionally Treated Wastewater; Adana, Turkey**. This project was stimulated by the need to conserve on-base water supplies at the Incirlik Air Base. The feasibility study evaluated the needs associated with the conversion of some on-base irrigation water sources from potable water to treated wastewater. This $100,000 project limited the reliance on off-base water supplies through irrigation with treated wastewater and other conservation practices associated with landscape and crop irrigation. The use efficiency was maximized in this project because storage was limited. A nutrient and hydraulic management plan was constructed for this work to ensure that no over-application of treated wastewater takes place.
- **Project Manager and Technical Lead–Development of Evaluation Strategy for Agricultural Reuse at 19 Wastewater Treatment Plant Sites throughout the Country of Jordan; Amman, Jordan.** These efforts included a technical strategy development for agricultural reuse for the currently operating 19 wastewater treatment plants in Jordan. This involved an evaluation of influencing factors such as soils, climate, and crop production in the area, market conditions, cultural acceptance, wastewater quality, and crop recommendations. The technical report was used to preliminarily prioritize agricultural reuse development for specific areas.
- **Technical Lead–Development of a Feasibility Assessment for Agricultural Reuse of Treated Wastewater for the Hebron Wastewater Treatment Plant Improvements Project; Hebron, West Bank.** This project involved initial development and site location options for reuse of treated wastewater from the anticipated wastewater treatment plant serving Hebron and surrounding communities. Four main sites were evaluated according to land suitability; climatic regimes; proximity to markets; available land area; wadi discharge, potential storage areas and sizing; and impacts to the surrounding environment. Preliminary hydraulic and nutrient balance modeling was conducted for each site and for projected increases in treated wastewater production. This included development of water and nutrient balances for agricultural reuse with local cropping patterns.
- **Technical Lead–Development of a Master Planning Document for the Hebron Wastewater Treatment Plant Improvements Project; Hebron, West Bank.** This project involved a detailed hydraulic and nutrient loading modeling effort for the agricultural reuse component initially proposed in a previous Feasibility Assessment effort. This work was a component of an overall

wastewater master planning effort and was driven by environmental and economic concerns of the region.

- **Technical Lead–Development of a Feasibility Study for the Mafraq Wastewater Treatment Plant Improvements Project; Mafraq, Jordan.** This project involved development of water and nutrient balances for beneficial agricultural reuse of treated wastewater based on various scenarios of different cropping patterns, storage sizing, and wadi discharge for forecasted wastewater flows to 2025. Managing climatic influences and the seasonality of application were optimized to maximize the land base available for application.

Previous Experience

Before co-founding Land IQ, LLC, Dr. Kimmelshue spent over 11 years with CH2MHILL. During that time, Dr. Kimmelshue was the firm-wide leader for Agricultural Services Technology, which represented nearly 70 people throughout the firm. Dr. Kimmelshue was also the Business Development Lead for all water resources related projects for a 7-state southwestern region. Prior to that, Dr. Kimmelshue worked as a research associate at North Carolina State University and managed portions of an irrigated agricultural farm in northern California, producing a variety of tree, field, and row crops.

Professional Responsibilities and Accomplishments

State Committee Member – California Department of Food and Agriculture – Specialty Crop Block Grant Advisory Committee – A 6-year appointment for review and selection of proposals for up to $16M in United States Department of Agriculture funding annually. Sacramento, CA

Fellow – California Agricultural Leadership Program – Class 37 – a 2-year, intensive leadership development program designed for the advancement of current and future leaders in California agriculture. Sacramento, CA

National Committee Member – American Society of Agronomy Career Placement and Professional Development, Minneapolis, MN

Participant – California Water Education Foundation Tours – Sacramento Valley and Central Valley Tours.

Board Chair and Member – Advisory Board for California Polytechnic State University Earth and Soil Sciences Department, San Luis Obispo, CA

Board Member – Advisory Board for California State University Geosciences Department, Chico, CA

Board Member – Shasta Land Trust, Redding, CA

Joel Kimmelshue, PhD.

Legal/Expert Witness Experience

Client	Dates of Work	State	Specific Location	Study Analysis Duration	Size of Area (approximate acres)	Crop Consumptive Use	Irrigability Land Classification	Ag Management Aspects Considered	PET/ET	Crop Coefficients	Estimation of Return Flow to Groundwater	Nutrient and/or Salinity Component	Image Analysis	Image Analysis Summary	Crops Analyzed	Degree of Legal Support	Judge	Law Firm/Entity	Project Description
Southern California Water Company	2004-2005	CA	Santa Maria Valley	1946-2004	165,000	Y	N	Y	Y	Y	Y	Y	Y	Photo interpretation as additional verification of CA DWR irrigated area crop mappings for cropped versus idle lands. Determination of boundaries of developed versus native areas.	Leafy Greens, Cole Crops, Strawberries, Berries, Grains, Fruit Trees, Grapes	Legal Preparation, Deposition, Court Testimony	Jack Komar	(Then) Hatch and Parent	This project involved expert witness testimony, both in deposition and trial settings, based on an 8-month effort to assess crop water use for an historical 58-year period over a 164,000-acre basin. The work focused on pumped water and return flows to groundwater under irrigated and nonirrigated areas. Crop and native vegetation evapotranspiration and soil storage modeling was conducted. Water was assessed to ensure adequate quality for sensitive crop production. The expert witness testimony included 2 days of deposition and 2 additional days of trial testimony, including cross-examination. The work was conducted as a component of a groundwater basin assessment focusing on the potential for overdraft. This was a multi-stakeholder case, which included agricultural, urban and local, state, and federal agencies.
Tehama Colusa Canal Authority	2010	CA	Sacramento Valley - West Side	1955-2010	155,000	Y	N	Y	Y	Y	N	Y	N	N/A	Almonds, Walnuts, Pistachios, Olives, Grapes, Alfalfa, Pasture, Tomatoes, Safflower, Beans, and various other crops	Legal Preparation, Attended Court, however Testimony Unnecessary	Oliver Wanger	Downey Brand	Dr. Kimmelshue was retained to prepare a detailed evaluation of the influence of regulated deficit irrigation on a variety of crops including almonds, grapes, walnuts, rice, olives, alfalfa, tomatoes and a variety of other permanent and annual field and row crops. The preparation of this testimony was conducted to determine the influence of a deficit of irrigation water at predetermined periods of the growth cycles of the crops mentioned above – predominantly focusing on perennial crops such as almonds. The results of this work indicated the extreme detrimental influence of insufficient irrigation during key growth stages of the crop.
Antelope Valley Growers	2011-2012	CA	Antelope Valley	1940-2011	1,600,000	Y	N	Y	Y	Y	Y	Y	Y	Aerial photo and satellite interpretation of irrigated urban areas (e.g. parks, playgrounds) and ag reuse sites.	Cherries, Peaches, Apricots, Alfalfa, Cotton, Pasture, Carrots, Potatoes, Tomatoes, and a variety of other annual row and field crops	Legal Preparation, Deposition, Court Testimony	Jack Komar	Brownstein Hyatt Farber Schreck	This work centered around the quantification of a water right adjudication of the Antelope Valley. Dr. Kimmelshue represented the agricultural interests in the Valley and conducted a detailed and comprehensive assessment of crop water use, irrigation methods and efficiencies, return flows, and other parameters to ultimately assess a component of the safe yield of the groundwater basin based on agricultural pumping. This work was prepared for expert witness testimony in early 2011. Modeling was conducted to assess not only a variety of crop types in irrigated agricultural, but also irrigated urban areas.
Los Angeles Department of Water and Power	2012-present	CA	Owens Valley	1913-2010	300,000	Y	Y	Y	Y	Y	N	Y	Y	Photo Interpretation for the assessment of supply infrastructure, irrigated area, and native vegetation extent.	Pasture, Alfalfa, Grains, Cherries, Peaches, Apricots, Potatoes and other historic fruit and row crops	Legal Preparation Only To Date	TBD	Internal LADWP Counsel, Various External	Dr. Kimmelshue was retained as the lead technical expert on estimating monthly and annual potential historic consumptive use as far back as the early 1900's for the Owens Valley if the aquaduct had not but constructed. This work involved the acquisition, review and interpretation of historic documentation as far back as 1904. The work resulted in a reasonable estimate of irrigable land based on USBR and USDA reports, local knowledge of the area and soils and past experience. The work then focused on estimation of consumptive use of likely crops to be grown as compared to other high desert valleys in California and Nevada that actually were developed. Crop evapotranspiration and crop coefficients were calculated where necessary based on historic climatic conditions and some CIMIS and LADWP information.
United States Department of Justice - Bureau of Indian Affairs	1998-2008	MT	Blackfeet Indian Reservation	1950-2006	1,500,000	Y	Y	Y	Y	Y	N	Y	Y	Detailed photo interpretation for current and historic irrigation, crop type, native vegetation, water supply infrastructure, and soil and irrigation suitability classification on over 1.5M acres.	Pasture, Alfalfa, Rangeland, Grain	Legal Preparation, Settled	N/A	USDOJ Legal	Technical expert from 1998 to 2008 leading efforts related to the establishment of a water rights claim for the Blackfeet Indian Tribe. These efforts determined practicably irrigable acres, detailed land classification for the determination of arable and irrigable lands, present and historic irrigation delineations, water demand estimates of both agricultural and urban uses, drainage evaluations for the purpose of avoiding salinization of lands, and overall task management for nearly $1.7M of labor, subconsultants, and expenses.
Kern River Watershed Coalition Authority	2012-present	CA	Kern Sub-Basin	1930-2012	900,000	Y	N	Y	Y	Y	Y	Y	Y	Evaluated satellite image resources to assess crop type and overall irrigated land extent. Detailed field delineations and crop identification	Cotton, Almonds, Pistachios, Citrus, Walnuts, Pomegranates, Persimmons, Cherries, Carrots, Potatoes, Corn, Sorghum, Sudan Grass, Grains, and other fruit, nut, row and field crops	Legal Preparation Only To Date	TBD	Young Wooldridge	Dr. Kimmelshue was retained by the KRWCA as an expert in providing sound technical agronomic information related to the unique irrigation and crop production practices of the Kern Sub Basin area within the Southern San Joaquin Valley Water Quality Coalition. This work involved understanding and interpreting changes in cropping patterns, consumptive use, irrigation methods, salinity management, fertilization practices and overall water and nitrogen use efficiency. A portion of this work included intensive ground truthing for development of remotely sensed crop mapping products. Those ground truthing data included permanent crop irrigation method documentation for use in irrigation method change over time.
United States Bureau of Reclamation	1996-1997	UT	Uintah Basin	1960-1995	10,000 (select areas of much larger basin)	Y	Y	Y	Y	Y	N	Y	Y	Detailed aerial photo interpretation for historic irrigated lands, supply infrastructure and irrigation suitability classification. Photo interpretive differentiation of crop type.	Pasture, Alfalfa, Rangeland, Grain	Legal Preparation, Certified	Certified by United States Congress	USBR Legal	Dr. Kimmelshue successfully mapped nearly 10,000 acres of lands slated for supplemental irrigation, drainage improvements, consumptive use estimates, etc. Responsibilities included quality control for soil sampling and data interpretation. Co-authored a report to the USBR for final project approval and certification by the United States Congress.
Confidential Client	2008	CA	Kern County, CA Area	1950-2008	15,000	Y	N	Y	Y	Y	Y	N	Y	Interpreted both aerial photo and satellite resources from 1950's to present day for the purposes of irrigated area delineation and crop type differentiation.	Pasture, Alfalfa, Rangeland, Grain	Legal Preparation, Settled	N/A	(Then) Hatch and Parent	This project involved the historic and present quantification of water use at a confidential site near Bakersfield. Historic remote sensing imagery was acquired to determine the irrigated area changes over time as well as the cropping pattern shifts from the early 1950s to present day. Water use estimates were determined for the current cropping patterns as well as diverted water quantities. A comprehensive site evaluation was performed with the client and area grower/owner to determine soil type, water conveyance, irrigation methods and management, consumptive use, storage, crop types, etc. This work was used to facilitate a potential substantial land purchase and water rights quantification.
Los Angeles Department of Water and Power	2000-present	CA	Owens Valley	1947-present	110,000	Y	N	Y	Y	Y	N	Y	Y	Interpreted both aerial photo and satellite resources from 1947 to present for evaluation of land cover including vegetation characterization, soil assessment and historic infrastructure	Native Saltgrass and other salt-tolerant vegetative communities	Technical Support of Multiple Legal Settlements and Regulatory Negotiations	N/A	City of Los Angeles	Efforts have included playa-wide soil and vegetation classification, monitoring of vegetation and wetness cover, and historic evaluation of anthropogenic activities and natural processes affecting the Owens Lake Playa and Keeler Sand Dunes. This project has involved several photo and satellite image analysis efforts for characterization and evaluation of playa surfaces for management, modelling and design purposes. Performed detailed photo interpretive evaluation of all infrastructure and activities on the playa from 1947 to present (e.g., water conveyance, mining, transportation, stormwater management, evaporation basins, structures).

Appendix 8

Statement of Compensation

Dr. Kimmelshue's compensation rate for deposition, trial preparation, and testimony is $500/hour.

Color Code

<table>
<tr><td>Valley specific crop report</td><td rowspan="5">Modified EBID Acreage (MEA) – In order to determine the distribution of crop acreages by valley, in the years where valley specific crop acreages were not provided in the crop reports, the following approaches were used: (1) the percentage of irrigated crop land present in each valley in spatially mapped years was used and linear interpolations of the ratios between valleys were applied in the intermediate years. (2) total acreage by valley was distributed into crop categories by linear interpolation between spatially mapped years and reliable crop reports using the percentage distribution by crop in those spatial mapping years and crop reports.</td></tr>
<tr><td>Valley specific crop report- adjusted by Inside/Outside Valley Distribution (IOVD) - see note below</td></tr>
<tr><td>** Spatial year not fully complete. Image did not encompass the entire AOI. Approximately 13,775 acres could not be classified. The same distribution that had been in the classified acres was applied to the non-classified acres</td></tr>
<tr><td>Land IQ Spatial year</td></tr>
<tr><td>Linear interpolation</td></tr>
</table>

Note:

Valley specific crop report- adjusted by Inside/Outside Valley Distribution (IOVD). IOVD accounts for the irrigated acreage that is inside the valley boundary but outside the district boundary and is not accounted for in district crop reports. In spatial mapping years, the percentage of irrigated acreage located outside the district boundary however inside the valley boundary was calculated. A linear interpolation of these percentages was implemented in the intermediate years when necessary.

Valley specific crop report	Modified EBID Acreage (MEA) – In order to determine the distribution of crop acreages by valley, in the years where valley specific crop acreages were not provided in the crop reports, the following approaches were used: (1) the percentage of irrigated crop land present in each valley in spatially mapped years was used and linear interpolations of the ratios between valleys were applied in the intermediate years, (2) total acreage by valley was distributed into crop categories by linear interpolation between spatially mapped years and reliable crop reports using the percentage distribution by crop in those spatial mapping years and crop reports.
Valley specific crop report- adjusted by Inside/Outside Valley Distribution (IOVD) - see note below	
** Spatial year not fully complete. Image did not encompass the entire AOI. Approximately 13,775 acres could not be classified. The same distribution that had been in the classified acres was applied to the non-classified acres	
Land IQ Spatial year	
Linear interpolation	

Note:

Valley specific crop report- adjusted by Inside/Outside Valley Distribution (IOVD). IOVD accounts for the irrigated acreage that is inside the valley boundary but outside the district boundary and is not accounted for in district crop reports. In spatial mapping years, the percentage of irrigated acreage located outside the district boundary however inside the valley boundary was calculated. A linear interpolation of these percentages was implemented in the intermediate years when necessary.

Appendix E

Table E-1: Crop Variables Used in CUP+ Modeling

	Planting Date	Harvest Date	KcAB	KcCD	KcE	% Season in Stage B	% Season in Stage C	% Season in Stage D
Alfalfa	3/1	12/1	0.95	0.95	0.95	25	50	75
Asparagus	3/1	10/31	0.50	0.95	0.30	12	25	95
Chili/ Peppers	4/1	10/1	0.30	1.20	0.50	25	65	82
Cole/ Leafy Greens	2/1	6/1	0.80	0.80	0.80	25	63	88
Corn/ Silage	5/1	11/15	0.20	1.05	0.60	20	45	75
Cotton	4/15	11/30	0.35	1.00	0.50	15	25	85
Grain	11/1	5/1	0.33	1.10	0.15	20	45	75
Grapes	4/1	11/1	0.45	0.80	0.35	0	25	75
Hay	3/1	12/1	0.85	0.85	0.85	25	50	75
Legumes	6/15	9/30	0.20	1.00	0.10	24	40	91
Melons/ Squash	4/1	8/14	0.75	1.05	0.75	21	50	83
Misc/ Other	4/1	10/1	0.30	1.20	0.50	25	65	82
Onions	11/1	6/1	0.55	1.20	0.55	10	26	75
Pasture	3/1	10/31	0.90	0.90	0.90	25	50	75
Pecans/ Other Trees	3/1	11/30	0.20	1.10	0.35	0	45	90
Root Crop	4/15	8/15	0.80	1.10	0.70	20	45	78
Tomato	4/1	8/31	0.30	1.10	0.65	25	50	80
Turf	4/1	10/31	0.60	0.60	0.60	25	50	75
Irrigated Annuals	4/1	10/1	0.30	1.20	0.50	25	65	82

	Source(s)
Alfalfa	Kc estimated from FAO24 and CA research
Asparagus	FAO56
Chili/ Peppers	NM Climate Center estimated from figure (https://aces.nmsu.edu/aes/irrigation/documents/crop-coefficient.pdf)
Cole/ Leafy Greens	Lettuce California
Corn/ Silage	Adjusted CUP+ value, lowered KcE to FAO56 value
Cotton	Adjusted FAO 56- not as high as 1.15-1.2, not as low as CUP+ (0.95); Evaluating on-farm irrigation efficiency across the watershed: A case study of New Mexico's Lower Rio Grande Basin Rasool Ahadi a,1, Zohrab Samani b,∗, Rhonda Skaggs b,2 (Says 904 mm avg cotton use)
Grain	CUP+
Grapes	CUP+
Hay	Dates same as alfalfa - Kc 0.1 < Alfalfa
Legumes	CUP+
Melons/ Squash	CUP+
Misc/ Other	Based on chili peppers
Onions	(NMSU CE CR 563) Plant: 15 Sep-1 Feb Harvest: 9 May - 10 Aug (Split the difference of fall planting dates sept/Jan)
Pasture	For dry climate FAO 24
Pecans/ Other Trees	(Sammis, Mexal, Miller, 2004); (Samani et al., 2012)
Root Crop	CUP+, Based on potato (CA)
Tomato	CUP+
Turf	CUP+
Irrigated Annuals	Based on chili peppers

Color Code
CUP+ value used
Rick Snyder communication
Specific Reference
Same as Chili/ Peppers

Appendix F

Table F-1: Reference Evapotranspiration Adjustment Factors

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Rincon & Mesilla Valleys	1.09	1.14	1.15	1.15	1.08	1.03	1.03	1.01	1.02	0.98	1.00	1.04
El Paso Valley	1.28	1.34	1.31	1.26	1.14	1.03	1.02	0.95	0.99	1.01	1.12	1.26

Notes:

- For Rincon and Mesilla Valleys:
  - Factors were used to scale ETo calculated using the Hargreaves-Samani method when data required to compute ETo using the Penman-Montieth method was unavailable. The evapotranspiration adjustment factors were applied in all months for the years 1936 through 1999.
- For El Paso Valley:
  - Factors were used to scale ETo calculated using the Hargreaves-Samani method when data required to compute ETo using the Penman-Montieth method was unavailable. The evapotranspiration adjustment factors were applied in all months for the years 1936 through 2003 and 2013 through 2018. Additionally, the factors were applied to December 2005, 2006, and 2008, and January 2007 through April 2007.

1 INTRODUCTION

1.1 Statement of Qualifications for Staffan W. Schorr

1. My name is Staffan W. Schorr. I am a principal hydrogeologist and partner at Montgomery & Associates in Tucson, Arizona, where I have been employed since 2006. I have 19 years of professional experience as a hydrogeologist and geospatial data analyst.
2. My education includes a Bachelor of Science degree in Geosciences from the University of Arizona, and a Master's of Science degree in hydrogeology from the University of Arizona.
3. Prior to working for Montgomery & Associates, I was employed by Pima Association of Governments in Tucson, Arizona where I worked as a watershed planner from 1998 to 2006.
4. In December 2010, I became a shareholder at Montgomery & Associates.
5. I have developed more than a dozen conceptual hydrogeologic models for regional and local scale characterization projects and numerical groundwater models.
6. Montgomery & Associates is being compensated for my work on this assignment at a rate of $146 per hour.
7. My professional resume, including publications authored in the previous 10 years, is included in Appendix H.

1.2 Statement of Qualifications for Colin P. Kikuchi

1. My name is Colin P. Kikuchi. I am a groundwater hydrologist at Montgomery & Associates in Tucson, Arizona. I have 10 years of professional experience as a hydrologist.
2. My education includes a Bachelor of Arts degree in Environmental Studies and Geography from Middlebury College and Master of Science and Doctoral degrees in Hydrology and Water Resources from the University of Arizona.
3. From September 2009 through August 2014, I was employed by the U.S. Geological Survey in Tucson, Arizona and Anchorage, Alaska.
4. From August 2014 through present I have been employed by Montgomery & Associates in Tucson, Arizona.
5. Montgomery & Associates is being compensated for work on this assignment at the rate of $117 per hour.
6. My professional resume, including publications authored in the previous 10 years, is included in Appendix H.

1.3 Assignment and Summary of Opinions

We were asked by counsel to prepare multiple products in support of expert analyses related to New Mexico's compliance with the Rio Grande Compact:

1. We developed water budgets for Rincon and Mesilla basins over the period from 1938 through 2016. We refer to this period of time as the study period. A major component of the water budget assignment was to develop a farm soil water balance model for estimating agricultural groundwater pumping, deep percolation, and return flows related to crop operations in the basins. The water budgets were developed in part to characterize changes in groundwater storage and streamflow depletions over time in the basins. Details of these water budgets are described in the body of this report.
2. We developed and implemented a web-based database for basic hydrologic data obtained from public sources for all experts to use, if needed, for their respective analyses. The database serves as an archive of raw public data used to prepare the water budgets and other expert analyses. The database is summarized in Appendix D of this report.
3. We provided technical support to William R. Hutchison for developing a numerical groundwater flow model for Rincon and Mesilla basins. We prepared model input datasets from the associated water budgets. We also prepared the streamflow routing package for model input. Datasets prepared for model input are described in Appendix E of this report. In addition, we prepared a hydrogeologic framework for Rincon and Mesilla Basins to define aquifer layering for the groundwater model. Source data and methods used for developing the aquifer framework are described in Appendix F of this report.
4. We developed a farm water budget for El Paso Valley for estimating agricultural groundwater pumping in the valley for economic analysis by David Sunding and water quality analyses by Lydia Dorrance. The El Paso Valley farm water budget is described in Appendix G of this report.

Opinions by Staffan Schorr on Non-Farm Water Budgets, Surface Water Budgets, and Groundwater Budgets

For any water budget, the sum of inflows minus the sum of outflows equals changes in storage. For the water budgets described herein, I use a simple "bucket" model approach, which provides useful insight on the general functional behavior of the system. A bucket model approach considers all inflows and outflows during a time step (monthly in for this water budget) and computes a change, if any, in water stored within the system. Complex interactions and feedback loops between water budget components are not included in this bucket water budget, such phenomenon are better handled by distributed parameter simulations.

5. The water budgets presented herein are prepared to the basin scale for aggregating inflows and outflows. I used a basin scale approach because important components of the water system, such as surface water deliveries to farms and groundwater exchange between sub-areas within the basins, could not be estimated on a localized monthly scale for the entire study period. Although this basin scale water budget ignores the spatial distribution of individual components, it does provide useful insight on the general functional behavior of the system.

6. I prepared separate water budgets for Rincon Basin and Mesilla Basin because the basins are separated by a bedrock constriction, which limits the hydrologic connection between the basins.

7. The overall water budget for each basin comprises three types of budgets: Land-Surface Water Budget, Surface Water Budget, and Groundwater Budget. I used this approach to facilitate budget development by compartmentalizing common components.

8. The Land-Surface Water Budget comprises a Farm Water Budget and Non-Farm Water Budget. The Non-Farm Water Budget was prepared for lands outside farm lands. Water inflows to the Non-Farm Water Budget include precipitation and groundwater withdrawals. The Non-Farm Water Budget is split into three sub-budgets to account for the source of water supply and land use. An Urban Applied Water Budget was prepared for urban use of applied groundwater. An Urban Precipitation Water Budget was prepared for urban use of precipitation. An Upland Watershed Water Budget was prepared for all native or undeveloped lands in the upland portions of the watershed, outside farm and urban lands. Although the Non-Farm Water Budget could be prepared as a single water budget, I used this approach to facilitate budget development by compartmentalizing components based on water supply and land use.

9. The number of groundwater production wells located in Rincon and Mesilla basins has increased since 1938, shown on Figures 4.6 and 4.7. I obtained well databases from the states of New Mexico and Texas for water product well information and well installation history. In 1939, less than 60 New Mexico wells existed in the basins, with vast majority used for domestic purposes and five wells for irrigation purposes. By 2016, the number of New Mexico wells located in the basins increased to more than 7,700, with about 465 wells for municipal and industrial purposes, 1,300 for irrigation purposes, and majority still for domestic purposes. A substantial number of well records in the New Mexico wells database are missing installation dates and are not included in these well counts; these undated wells may or may not exist. The number of water production wells located in Texas portions of Mesilla Basin increased from 3 wells in 1938 to 239 wells in 2016, with about half being used for irrigation purposes.

10. Historic groundwater withdrawals from water production wells in Rincon and Mesilla basins have been estimated for previous groundwater flow models for the basins. We relied heavily on pumping model input datasets from the groundwater model developed by S.S. Papadopolus & Associates in 2007 for the New Mexico Office of the State Engineer. Pumping rates specified in that model are based on pumping records from Las Cruces and El Paso, metered pumping, and estimates by a USGS study by Frenzel and Kaehler in 1992. The USGS study estimated pumping in the basins using pumping records and per capita water use and population data. In the absence of another data source, we used the Papadopolus model input dataset to represent pumping in the Groundwater Budget described herein.

11. Groundwater is exported from Mesilla Basin as treated wastewater discharged downstream from the basin outlet at the Rio Grande at El Paso streamflow gage and as pumped groundwater conveyed to Ciudad Juarez from a municipal wellfield located in the southern portions of the basin in Mexico. The treated effluent that is discharged from the El Paso Hickerson Wastewater Treatment Plant originates as groundwater pumped from El Paso wells. I assigned the treated effluent as exported groundwater simply because the discharge point is downstream from the Rio Grande at El Paso streamflow gage, which is the outlet point along the river for the Mesilla Basin water budget.

12. Watershed runoff models require detailed streamflow data and information on physical characteristics for drainages and sub-watersheds. The lack of streamflow gages on the majority of drainages to the Rio Grande within the study area prevents the use of surface water modeling for determining tributary runoff. Instead of using a runoff model, I specified runoff to be 3 percent of monthly precipitation, which is consistent with the results of a runoff study for a smaller watershed in the adjacent Jornada del Muerto Basin. I made an attempt at estimating runoff using daily streamflow data from gages located at the upstream and downstream ends of Rincon Basin. That evaluation resulted in runoff estimates that could not be accommodated by the water budgets, as indicated by unrealistic surface water-groundwater exchanges and groundwater storage changes. It is my opinion that the approach that specifies runoff as percentage of precipitation provides reasonable estimates for the regional water budget analysis.

13. The only source of reported data for surface water deliveries to farms in the area is crop reports and water distribution tables compiled by the U.S. Bureau of Reclamation (USBR). It is my opinion that the USBR data are generally reliable based on information learned from interviews with Bert Cortez at USBR.

14. A net loss of surface water to the groundwater system in Mesilla Basin occurred during most years since 1950. This loss of surface water coincides with the timing of substantial increase in groundwater pumping in the basin. The net surface water-groundwater interactions were more variable in Rincon Basin and fluctuated around net exchange of zero.

15. I used the Hearne-Dewey equation for estimating mountain-front/mountain-block recharge for the groundwater budget because natural recharge is not measured in the basins. It is my opinion that the Hearne-Dewey equation is a reasonable method to use for the groundwater budget because (1) it was developed to estimate basin water yield based on hydrologic data from basins in northern New Mexico and (2) the same method was previously used in the groundwater model developed for Rincon and Mesilla basins by S.S. Papadopulos & Associates for the New Mexico Office of the State Engineer.

16. When groundwater inflows are not equal to outflows there is a change in the amount of groundwater stored in the aquifer. For this analysis, changes in groundwater storage were estimated as the quantity required to close the Groundwater Budget. Changes in groundwater storage were used as a calibration metric for this analysis. Calibration of the water budgets was accomplished by adjusting components, such as tributary runoff inflows, until the estimated changes in groundwater storage were in reasonable agreement with simulated changes in groundwater storage from the calibrated numerical groundwater flow model developed by William Hutchison for this litigation project. My water budget results indicate that there has been a steady cumulative loss of groundwater in storage in both Rincon and Mesilla basins since the early 1950s. The rate of decline in cumulative groundwater storage in Mesilla Basin increased after 2010 when the Ciudad wellfield began pumping from the Conejos-Medanos wellfield in Mexico.

17. My water budget analysis included evaluating and comparing patterns during wet and dry time periods in Rincon and Mesilla basins since 1938. Agricultural groundwater pumping in both basins increased during dry periods when surface water deliveries to farms were small. This occurs even though total crop consumptive use remained generally constant during the wet and dry periods. In my opinion, supplemental agricultural groundwater is used by farmers to maintain agricultural production when surface water allotments are small.

18. In forming my opinions, I have relied in part on findings by William R. Hutchison. Dr. Hutchison simulates riparian evapotranspiration in his numerical groundwater flow model. Riparian evapotranspiration varies with changes in depth to groundwater at a location. Our water budget does not include changes in groundwater levels over time. I

used his preliminary model results for riparian evapotranspiration as input to the Groundwater Budget.

Opinions by Colin Kikuchi regarding Farm Water Budgets

19. In forming my opinions, I have relied in part on the findings of Dr. Joel Kimmelshue. In his report, Dr. Kimmelshue developed historical estimates of crop consumptive use, and changes in consumptive use that have occurred due to improvements in irrigation water management and crop variety. As an example, Dr. Kimmelshue determined that in 1938, consumptive use of alfalfa, cotton, and pecans in the Rincon and Mesilla Basins was about 70% of consumptive use of the same crops in 2016.

20. In this report, I present Farm Water Budget analyses that provide a complete accounting for all water entering and leaving the maximum extent of agricultural lands – meaning lands on which irrigated crops are grown. I provide separate Farm Water Budgets for the Rincon and Mesilla Basins. Water inflows to agricultural lands consist of precipitation, surface water deliveries, and groundwater applied to the land surface. Water outflows from agricultural lands consist of crop consumptive use, consumptive use from fallow lands, surface water return flows of applied irrigation water, and agricultural deep percolation which ultimately becomes groundwater recharge. Agricultural deep percolation includes percolation along on-farm conveyance structures and percolation beneath irrigated fields.

21. An important consideration in the preparation of any water budget is determination of the spatial scale at which to aggregate inflows and outflows of water. The Farm Water Budgets presented in this report have been prepared at the basin scale. The spatial resolution of historical surface water delivery data is the primary reason for deciding to prepare Farm Water Budgets at the basin scale. Specifically, official records of Rio Grande Project and similar records of EBID do not consistently resolve surface water deliveries to the scale of the EBID divisions served by the main canals, namely the Leasburg Division, Mesilla Eastside Division, and Mesilla Westside Division. The same official records do, however, consistently resolve surface water deliveries to the basin scale.

22. Some of the Inflow and Outflow components in the Farm Water Budgets are readily calculated from available datasets. Procedures for calculating these components are described in this report:
    a. The section ‘Precipitation Routing’ describes datasets and procedures used to quantify precipitation on farms.
    b. The section ‘Surface Water Deliveries to Farms’ describes datasets and procedures used to quantify surface water deliveries to farms.

c. The section ‘Surface Runoff of Applied Water’ describes datasets and procedures used to quantify farm tailwater.
d. The section ‘Surface Runoff of Precipitation from Agricultural Lands’ describes datasets and procedures used to quantify precipitation runoff from agricultural lands.
e. The section ‘On-Farm Conveyance Losses’ describes datasets and procedures used to quantify on-farm conveyance losses.
f. The section ‘Crop Evapotranspiration’ describes datasets and procedures used to quantify crop consumptive use. Crop consumptive use in the Farm Budget is calculated by a soil water balance model that I describe in this report. Therefore, exact values of crop consumptive use as reported in Dr. Kimmelshue’s report are not used directly as input in the Farm Water Budget. However, crop consumptive use datasets provided by Dr. Kimmelshue form the basis for model calculations of crop consumptive use, and crop consumptive use in the Farm Water Budget is very similar to crop consumptive use calculated by Dr. Kimmelshue.

23. Some of the Inflow and Outflow components in the Farm Water Budgets cannot be quantified from available data over the full study period. For example, the New Mexico Office of the State Engineer currently reports irrigation pumping volumes that are measured under the authority of the Lower Rio Grande Water Master. However, reliable historical records of irrigation pumping volumes extend only as far back as 2010. Agricultural deep percolation at the basin-scale cannot be measured directly. The two quantities listed above must be estimated. I estimate agricultural groundwater pumping and agricultural deep percolation over the study period using a soil water balance model.

24. The soil water balance model is a set of mathematical equations that describe the average soil moisture in the root zone of agricultural lands in the Rincon and Mesilla Basins. A soil water balance model is an appropriate way to calculate agricultural groundwater pumping, deep percolation, and crop consumptive use because these Farm Water Budget components depend on soil moisture content in the root zone. The model equations calculate crop consumptive use, the groundwater that must be applied to sustain crop consumptive use, and the agricultural deep percolation beneath the root zone, as a function of simulated soil moisture conditions.

25. In both the Rincon and Mesilla Basins, a portion of the total agricultural land is located outside EBID and EPCWID boundaries. These lands outside the District boundaries do not receive surface water deliveries. The agricultural lands within each basin therefore fall into one of two zones: inside and outside the Districts. Corresponding to these zones, two soil water balance models are developed for each groundwater basin: one model representing land inside District boundaries and the other representing land outside the

District boundaries. Simulated agricultural groundwater pumping and deep percolation from the two models are summed to provide totals by groundwater basin.

26. Crop consumptive use in the Rincon and Mesilla Basins is satisfied by precipitation and applied irrigation water. For lands within District boundaries, applied irrigation water consists of surface water deliveries to farms and supplemental groundwater pumping. For lands outside District boundaries, groundwater pumping provides applied irrigation water.

27. During certain times of the year throughout the study period, a portion of the agricultural lands within each basin were fallow, or non-cropped. During the winter, for example, any lands cultivated exclusively during the growing season will be fallow. However, soil moisture conditions within seasonally fallowed land determine in part the consumptive use and irrigation requirements during the subsequent growing season. Furthermore, irrigation water applied to crops near the end of the growing season may not be completely consumed by crops, and instead is consumed as soil evaporation after the growing season, when the land is again fallow. For these reasons, a complete accounting of the Farm Water Budget requires tracking soil moisture both on lands that are actively cultivated, and lands that are fallow. The soil water balance model developed for the Farm Water Budget accounts for both cropped and fallow land areas.

28. Nearly all acreage within the Rincon and Mesilla Basins is irrigated using surface irrigation methods. However, irrigation water management and by extension, soil moisture uniformity, have both improved substantially over the study period due to development and adoption of technologies such as high precision land leveling. Based on these two factors – the widespread use of surface irrigation and the long historical period of interest – the most appropriate approach for estimating agricultural groundwater pumping and deep percolation is to explicitly represent changes in soil moisture uniformity through time, as described in the section 'Non-uniform moisture distribution'.

29. It is not possible to directly measure some of the parameters of the soil water balance model that control moisture distribution at the basin scale. Such parameters must therefore be estimated. The process of estimating these parameters is called model calibration, and consists of adjusting the parameter values in such a way as to most closely match both historical data and qualitative historical trends. The section 'Soil Water Balance Model Calibration' in this report describes the calibration process in detail.

30. In his report, Dr. Kimmelshue quantifies increases in crop consumptive use due in large part to improvements in irrigation water management. The soil water balance model

explicitly represents those improvements in irrigation water management through time as more uniform moisture distribution and farm tailwater reductions. The soil water balance model also accounts for the effects of water stress on crop consumptive use based on a mathematical relationship defined in the section, 'Crop Evapotranspiration'. Consequently, the soil water balance model is simulates the effects of improvements in irrigation water management on crop consumptive use. Crop consumptive use simulated using the soil water balance model matches crop consumptive use reported in Dr. Kimmelshue's report very closely, with average percent discrepancy less than 0.01%.

31. The portion of crop consumptive use satisfied by precipitation varies from year to year. Over the study period, precipitation satisfied about 20% of consumptive use in the Rincon Basin, and 19% of consumptive use in the Mesilla Basin, on average. The remaining portion of crop consumptive use is satisfied by applied irrigation water.

32. Average surface water deliveries to farms within EBID boundaries in the Rincon Basin were about 36,000 acre-feet per year over the study period. Average surface water deliveries to farms within EBID and EPCWID boundaries in the Mesilla Basin were about 169,000 acre-feet per year.

33. Some of the surface water delivered to farms is lost to percolation along on-farm conveyance structures between the farm headgate and the field inlet. Average on-farm conveyance losses were about 17,000 acre-feet per year over the study period. Most of the remaining surface water delivered to farms is applied to the field and replenishes soil moisture in the crop root zone. A percentage of surface water entering the field is lost as tailwater leaving the end of the field, and ultimately re-enters the surface water network. However, this percentage has declined with time due to improvements in irrigation management.

34. Groundwater pumping supplies a portion of applied irrigation water in both the Rincon and Mesilla Basins, and the groundwater portion varies from year to dependent primarily on the availability of surface water. From 1951 through 2016, average groundwater pumping for irrigation supply was about 29,000 acre-feet per year in the Rincon Basin, and 265,000 acre-feet per year in the Mesilla Basin. Over the same time period, groundwater contributed on average about 46% and 43% of the total irrigation water supply in the Rincon and Mesilla Basins, respectively.

35. A portion of irrigation water applied to cropped field is lost to deep percolation below the root zone. From 1938 through 2016, average field losses were about 9,000 acre-feet per year in the Rincon Basin and 39,000 acre-feet per year in the Mesilla Basin.

36. From 1938 through 2016, on-farm irrigation efficiency was about 70% in both the Rincon and Mesilla Basins. This represents the percentage of the irrigation water supply that ultimately sustains crop consumptive use.

1.4 Objective and Scope for Water Budget Analysis

Montgomery & Associates developed monthly, basin-wide land-surface water, surface water, and groundwater budgets for Rincon and Mesilla basins for 1938 through 2016. Water budgets were developed to provide conceptual inputs to a numerical groundwater flow model being developed separately by William R. Hutchison, as well as inputs to other expert analyses. Monthly time steps. This report summarizes the data sources, methodology, and results of this water budget analysis.

Rincon Basin refers to the southern portion of the Palomas Basin from below Caballo Reservoir in the north to Selden Canyon in the south. Selden Canyon is part of Rincon Basin for this analysis. Mesilla Basin extends southward from Selden Canyon in the north to the El Paso Narrows in El Paso, Texas in the south. Las Cruces, New Mexico is located in the northern portions of Mesilla Basin. The southern portion of Mesilla Basin extends southward across the international border with Mexico; this portion of the basin is referred to as the Conejos-Medanos Aquifer and is hydraulically connected to the Mesilla Basin north of the border. The Rincon and Mesilla basins comprise alluvial valleys along the Rio Grande, regional groundwater basins, and the surrounding watershed. The study areas for this water budget analysis are shown on **Figure 1.1**.

Water budgets are described by the basic mathematical relationship:

$$[\text{Inflow}] - [\text{Outflow}] = [\text{Storage Change}] \quad (1)$$

A change in storage occurs when inflows are not equal to outflows during a specific time period. Changes in inflows and outflows through time generally result in changes in storage through time. The inflow and outflow terms in this analysis comprise multiple components.

A diagram of the water budget components of this analysis and their relationships is shown on **Figure 1.2**. Each component of the water budgets is summarized in subsequent chapters of this report. The land-surface water budget represents the agricultural and urban lands within the basins, as well as the surrounding upland watershed. The principal land-surface water budget components include water supply, consumptive use, and deep percolation. The surface water budget represents the Rio Grande, irrigation canal network, and drains within the basins. The principal surface water budget components include Rio Grande inflows and outflows, surface water deliveries to farms (farm deliveries), and groundwater-surface water exchanges. The groundwater budget represents the groundwater systems in the basins. The principal groundwater budget components include groundwater-surface water exchanges, groundwater withdrawals (pumping), and deep percolation from land surface.

A number of components link among the three water budgets. Deep percolation outflows (irrigation, urban, and mountain-front recharge) from the land water budget are inflows to the groundwater budget. Return flows (runoff) from urban lands, agricultural lands, and tributary arroyos, as well as wastewater discharges, are outflows from the land water budget and inflows to the surface water budget. Farm delivery outflows from the surface water budget are inflows to the land water budget. Groundwater-surface water exchanges are inflows and outflows between the surface water budget and the groundwater budgets. Groundwater withdrawal outflows from the groundwater budget are inflows to the land water budget.

Volume units of acre-feet are used for all of the terms defined in the land water budget, surface water budget, and groundwater budget. One acre-foot is equal to the volume of water required to cover one acre of land to a depth of one foot; it is also equal to 325,851 gallons. For general reference, **Figure 1.3** provides a graphical depiction of the meaning of the term acre-foot.

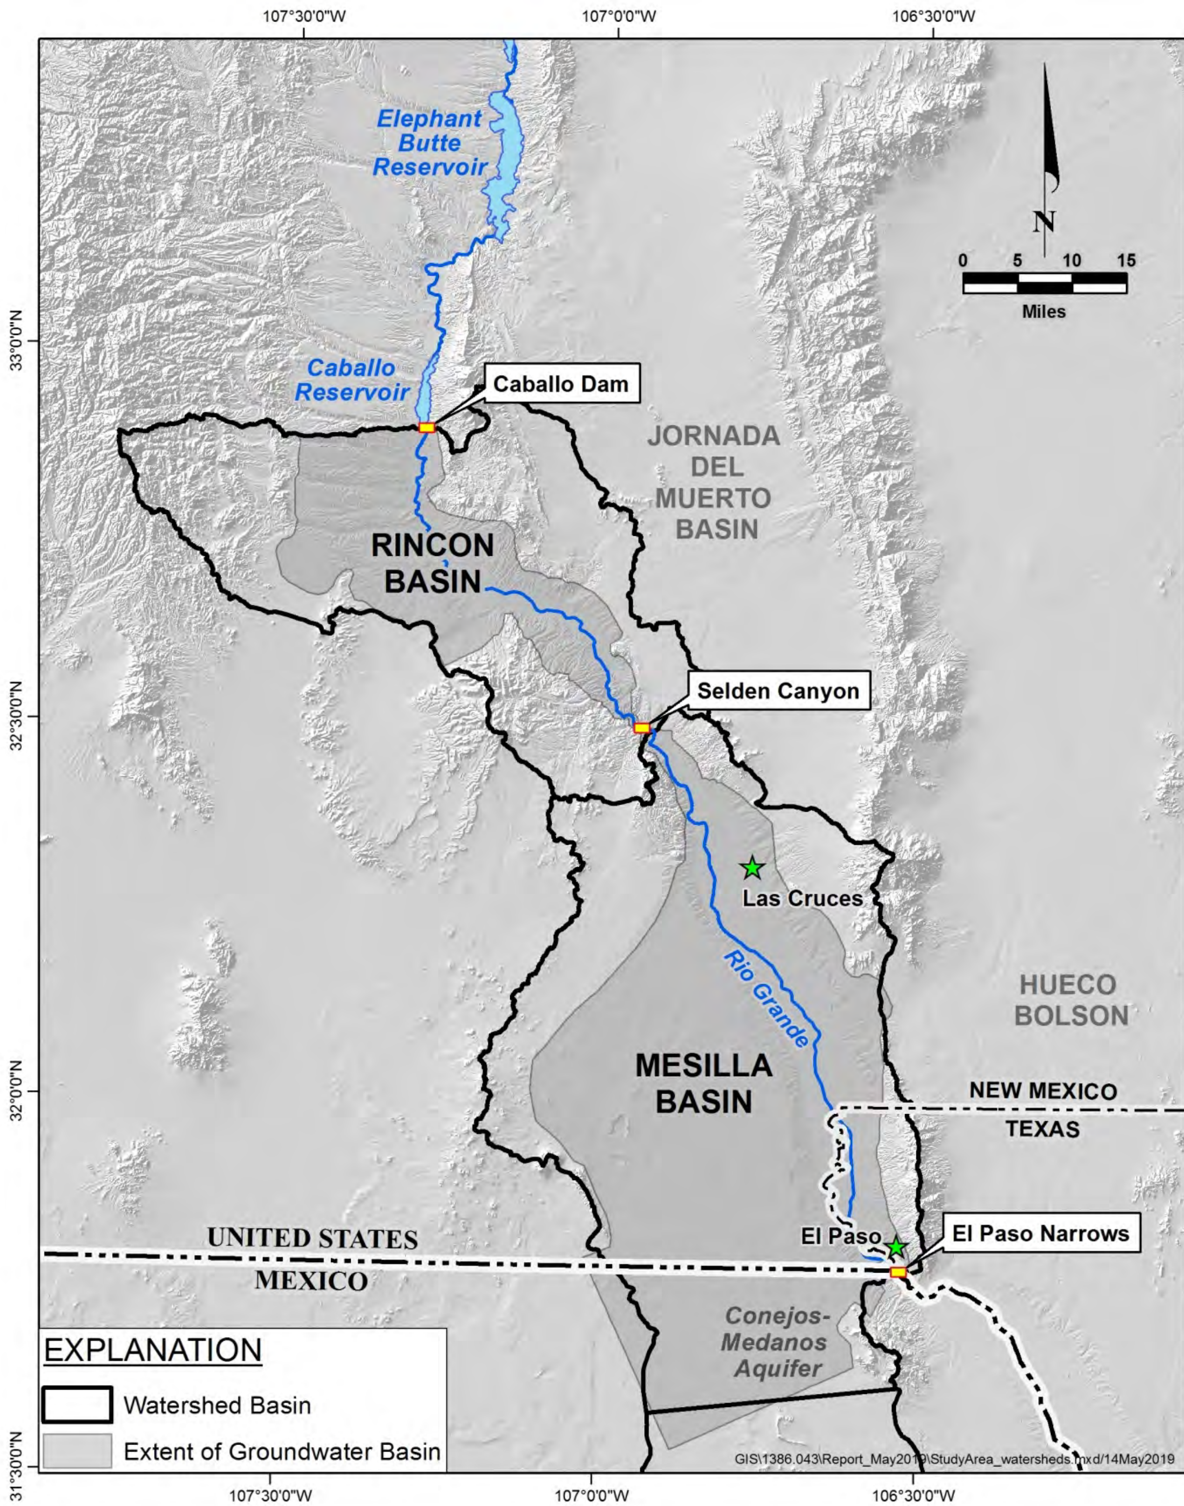

Figure 1.1. Locations of Rincon and Mesilla Basins

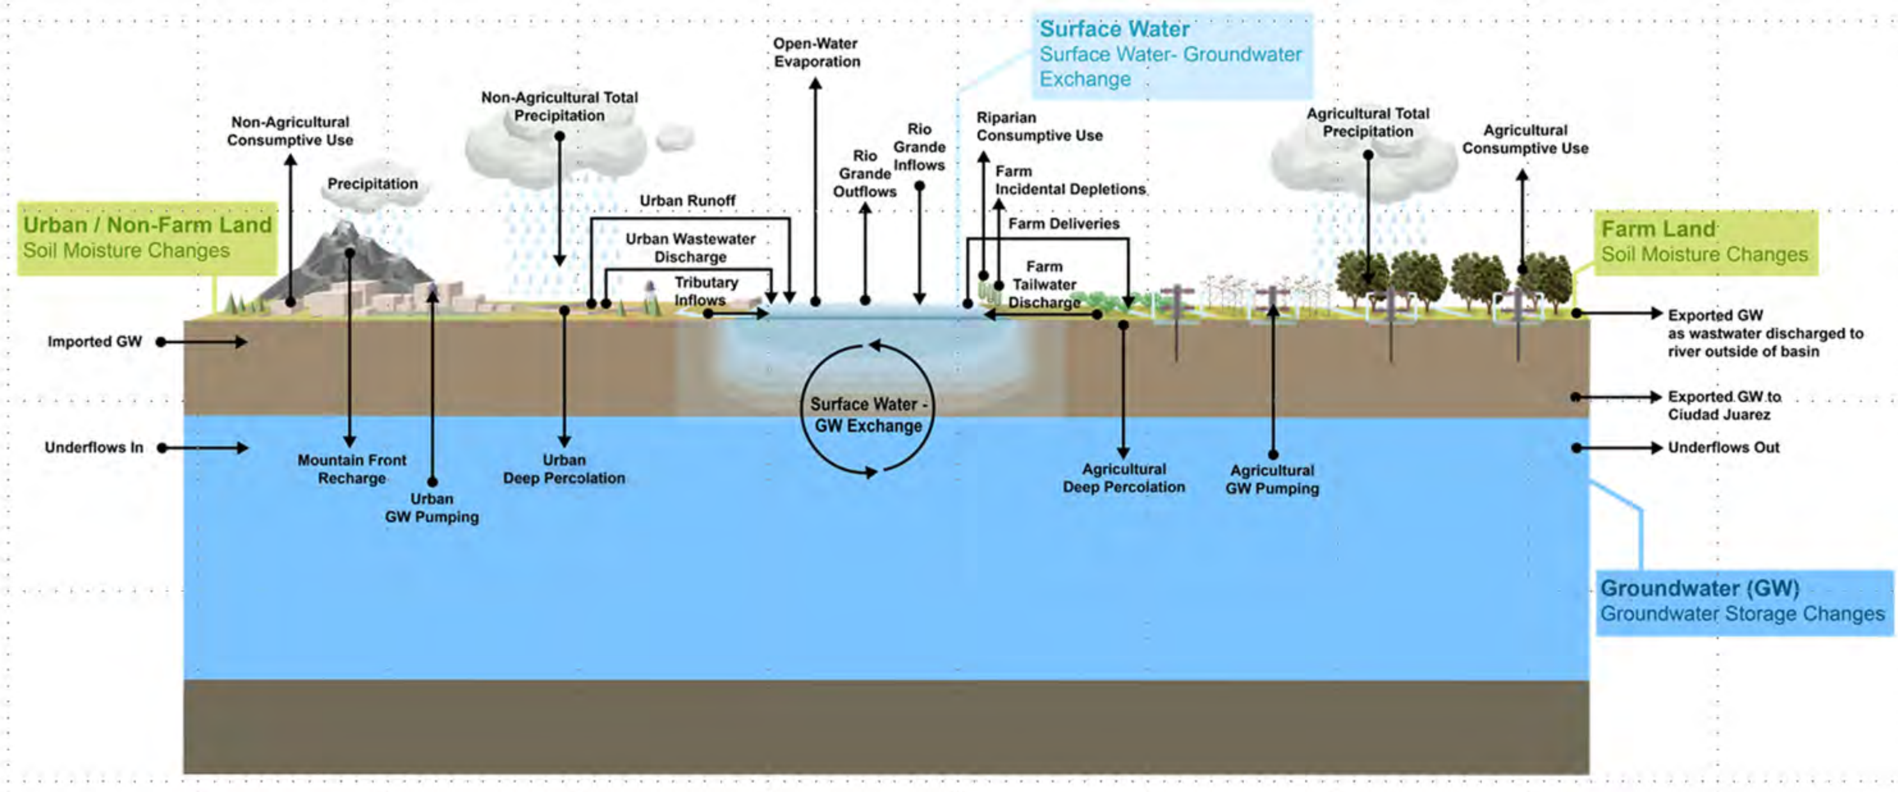

Figure 1.2. Water Budget Diagram for Rincon and Mesilla Basins

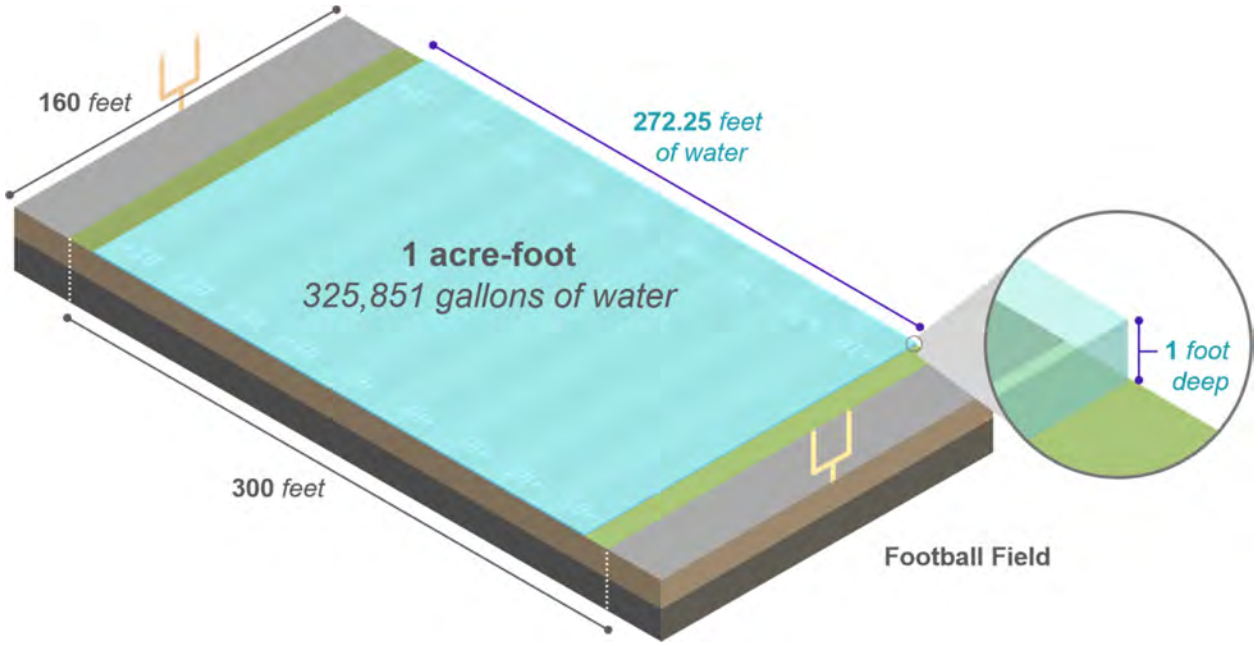

Figure 1.3. Graphical Depiction of 1 Acre-Foot of Water

2 LAND-SURFACE WATER BUDGET

When applied to the land-surface budget, Equation (1) becomes:

$$[Q_{LW\text{-}in}] - [Q_{LW\text{-}out}] = \Delta S_{SM} \quad (2)$$

Where,

$Q_{LW\text{-}in}$ is the sum of land-surface water inflows;
$Q_{LW\text{-}out}$ is sum of land-surface water outflows; and
ΔS_{SM} is change in soil moisture.

The land-surface water budget comprises a farm (agricultural) water budget and a non-farm water budget. The farm water budget represents farm lands, defined as areas where irrigated crops are grown. Considering all components of the land-surface water budget, Equation (2) becomes:

$$[P_f+P_{nf}+SW_f+GW_{app\text{-}f}+GW_{app\text{-}nf}] - [CU_f+CU_{nf}+QSW_f+QSW_{nf}+WW+DP_f+DP_{nf}+GW_e] = \Delta S_{SM} \quad (3)$$

Where,

P_f is precipitation on agricultural (farm) lands;
P_{nf} is precipitation on non-farm lands (urban and undeveloped);
SW_f is applied surface water to farms (farm deliveries);
$GW_{app\text{-}f}$ is applied groundwater to farm lands (agricultural pumping);
$GW_{app\text{-}nf}$ is applied groundwater to urban (non-farm) lands, includes imported;
CU_f is agricultural crop consumptive use;
CU_{nf} is urban consumptive use;
QSW_f is agricultural surface water return flow, including runoff both applied surface water and precipitation;
QSW_{nf} is surface water return flow from non-farm lands (runoff);
WW is urban wastewater discharges;
DP_f is deep percolation to groundwater from farm lands (agricultural);
DP_{nf} is deep percolation to groundwater from non-farm lands; and
GW_e is exported groundwater.

All components of the land-surface water budget can be derived from available data or the analysis of available data. **Figure 2.1** provides a graphical depiction of Equation (3).

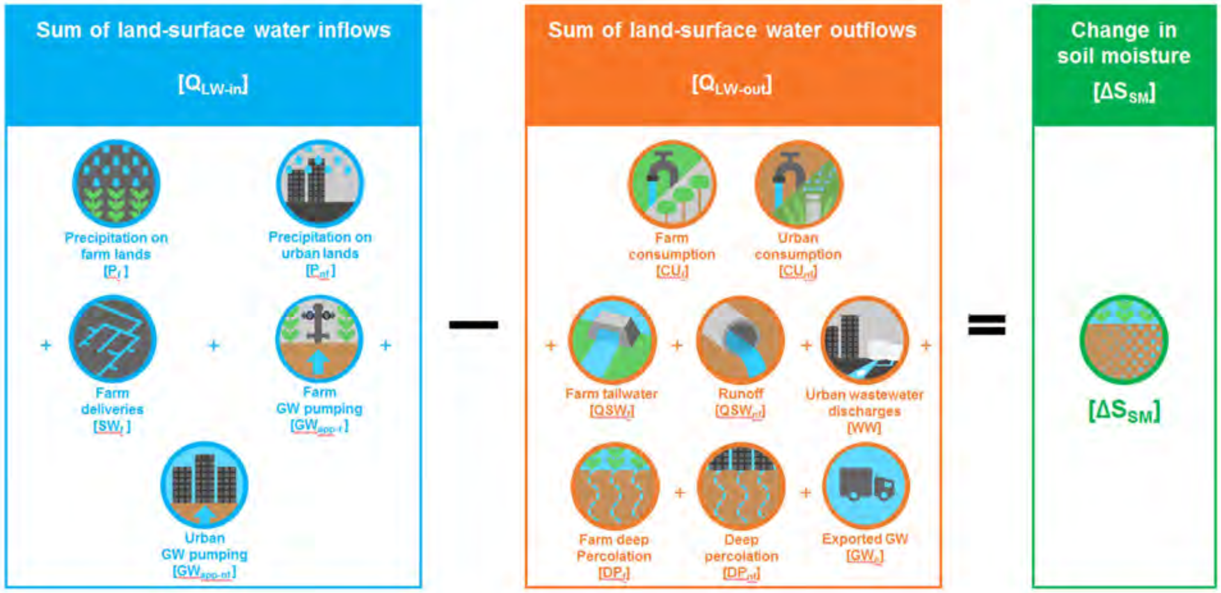

Figure 2.1. Graphical Depiction of the Land-Surface Water Budget Equation

A farm water budget analysis was conducted to estimate monthly farm deep percolation and agricultural applied groundwater pumping in each basin. In addition, estimates for change in agricultural soil moisture storage and agricultural surface water return flows were also determined by the farm water budget analysis. A non-farm water budget analysis was conducted to estimate consumptive use, runoff, and deep percolation for urban and non-urban (upland watershed) areas in the basins, based on measured or estimated water supply and wastewater discharges.

The land-surface water budget and relationships with the surface water and groundwater budgets are shown on **Figure 1.2**. Deep percolation and mountain-front recharge are inputs to the groundwater budget. Urban runoff, tributary inflows to the river, surface water runoff from farm and non-farm lands, and wastewater discharge are inputs to the surface water budget.

The monthly, basin-wide land-surface water budgets for Rincon and Mesilla basins are summarized in the accompanying dataset named IntegratedWaterBudgets.xlsx. Annual land-surface water budgets for Rincon Basin and Mesilla Basin are summarized in this chapter of the report and tabulated in **Appendices A1 and A2**.

2.1 Farm Water Budget

The farm water budget quantifies precipitation on agricultural (farm) lands (P_f), surface water deliveries to farms (SW_f), agricultural applied groundwater (GW_{app-f}), agricultural consumptive use (CU_f), agricultural surface return flows (QSW_f), agricultural deep percolation (DP_f), and monthly change in soil moisture (ΔS_{SM}) in the Rincon and Mesilla basins. The maximum extent of agricultural lands included in this analysis is shown on **Figure 2.2** and acreages are described in the subsequent Model Inputs section of this report.

For this analysis, farm lands in each basin are represented by two categories: lands inside an irrigation district (Elephant Butte Irrigation District and El Paso County Water Improvement District #1) and lands outside an irrigation district. For lands inside the irrigation districts, crop irrigation is supplied by both surface water (farm deliveries) and supplemental groundwater. For lands outside the districts, crop irrigation is supplied solely by groundwater.

We calculated precipitation on farm lands, surface water deliveries, and agricultural surface water return flows from available precipitation and surface water delivery data described in the Model Inputs section of this report. Equivalent data are not available quantifying farm groundwater pumping and deep percolation. Instead, we developed a soil water balance model for the purpose of estimating agricultural groundwater pumping and deep percolation.

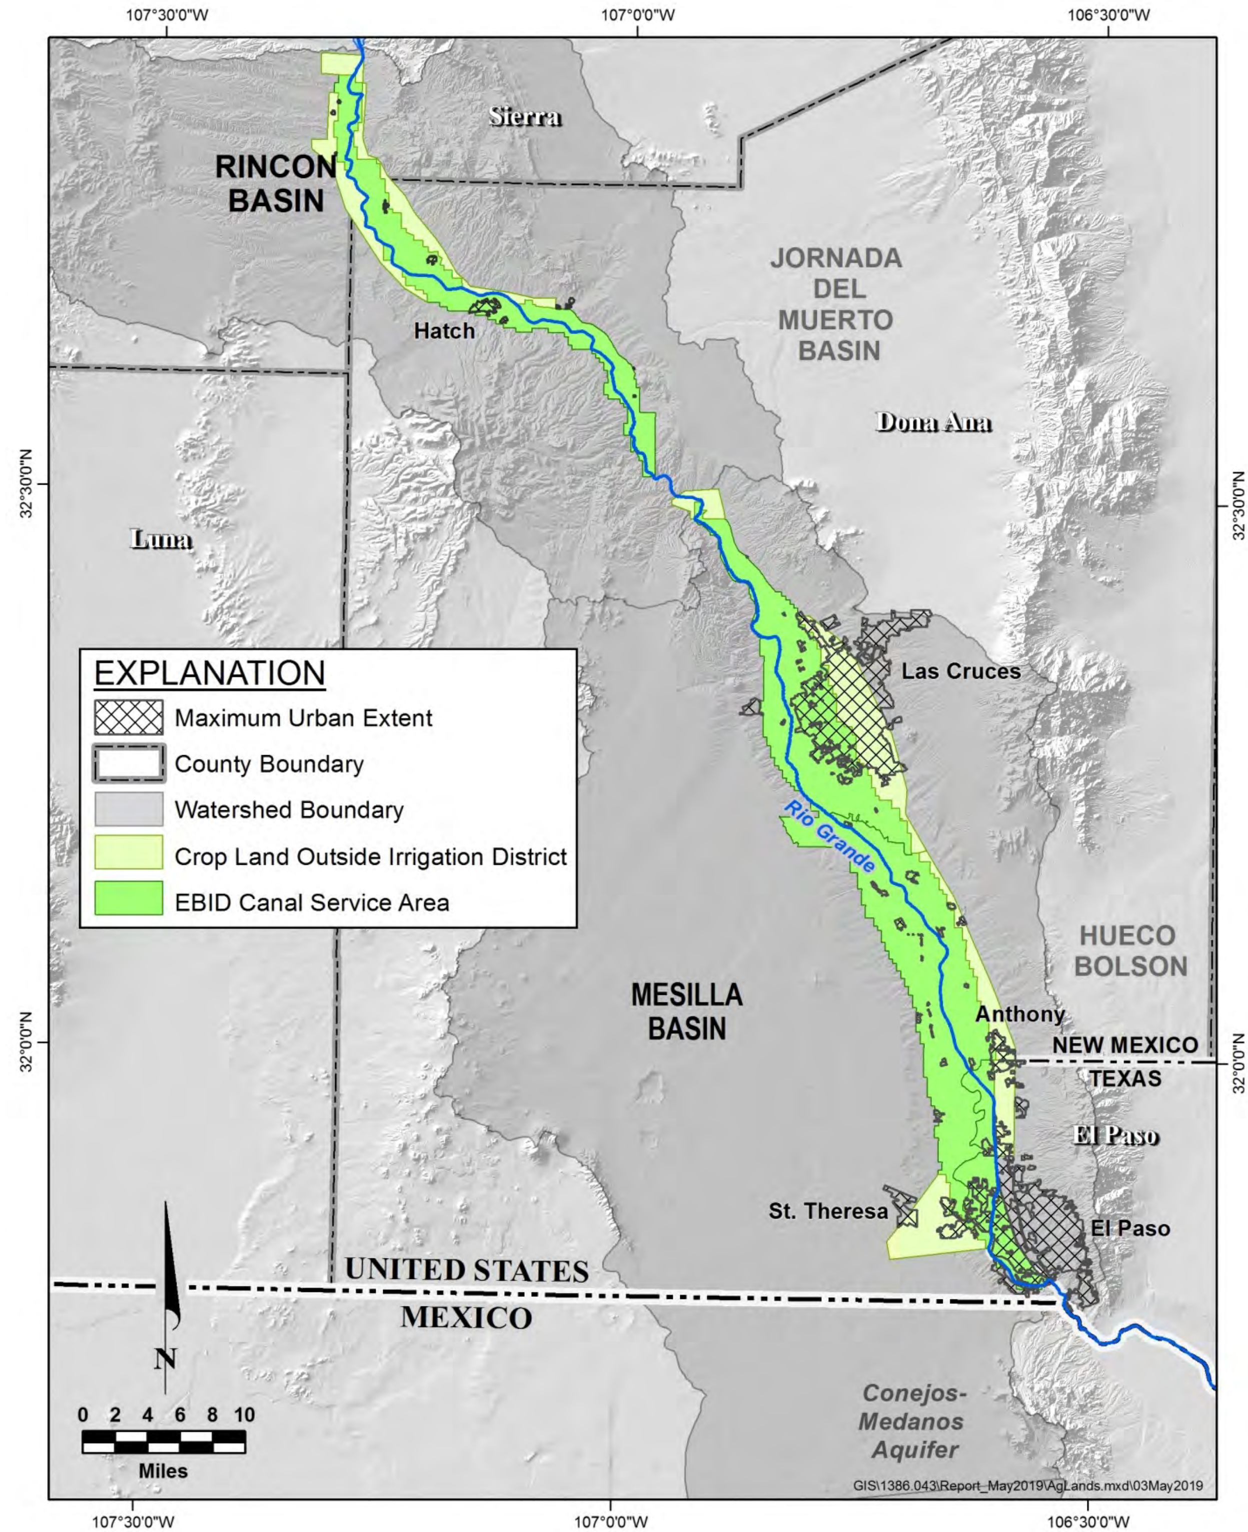

Figure 2.2. Maximum Extents of Agriculture and Urban Lands in Rincon and Mesilla Basins

2.1.1 Description of Soil Water Balance Model

A soil water balance model was developed to estimate agricultural groundwater pumping and deep percolation over the time period of interest, 1938 through 2016. The model tracks soil moisture within the maximum extent of irrigated agricultural lands of the Rincon and Mesilla basins on a monthly time step. The maximum extents of irrigated agricultural lands are described in the 'Model Input' section of this report. Four separate models were developed for this analysis: lands inside District boundaries in Rincon Basin, lands outside District boundaries in Rincon Basin, lands inside District boundaries in Mesilla Basin, and lands outside District boundaries in Mesilla Basin. The models follow identical governing equations and differ only in their respective data inputs.

The monthly soil water balance of the crop root zone is defined as follows:

$$S^t = S^{t-1} + \Delta S_a{}^t + INFPCP^t + INFSW^t + AGW^t - DP^t - AET^t \quad (4)$$

Where,

S is the total volume of water in the root zone;
ΔS_a is change in root zone water storage due to changing cropped acreage;
INFPCP is infiltration of precipitation;
INFSW is the portion of surface water delivery to farms that infiltrates into the root zone;
AGW is agricultural groundwater pumping;
DP is deep percolation, including field losses and on-farm conveyance losses;
AET is crop evapotranspiration; and
t is the time step counter, with t-1 representing previous time step (month).

For each month, the average soil moisture content in the root zone is computed as:

$$\theta^t_{avg} = S^t / V_{rz}{}^t \quad (5)$$

Where,

θ_{avg} is the average soil moisture content; and
V_{rz} is the volume of the crop root zone.

V_{rz} in Equation (5) is computed as the product of the total cropped acreage for a given month and the average root zone depth. Both the acreage and average root zone depth are described in greater detail in the Model Inputs section of this report.

The effect of changing cropped acreage is accounted for by ΔS_a in Equation (4), and is defined as follows:

$$\Delta S_a^{\,t} = 0, \qquad \text{if } A^t = A^{t-1}$$
$$\Delta S_a^{\,t} = Z_{r\text{-}avg} \times \theta_{nc}^{\,t-1} \times (A^t - A^{t-1}), \quad \text{if } A^t > A^{t-1} \qquad (6)$$
$$\Delta S_a^{\,t} = Z_{r\text{-}avg} \times \theta_{c}^{\,t-1} \times (A^t - A^{t-1}), \quad \text{if } A^t < A^{t-1}$$

Where,

A is cropped acreage;

θ_c is the average moisture content inside the cropped area; and

θ_{nc} is the average moisture content outside the cropped area (non-cropped area)

$Z_{r\text{-}avg}$ is the average root zone depth.

In the model, cropped acreage is defined to include cropped area during the growing season, and the month prior to the growing season for cotton and pecans. This definition accommodates the water management practice of pre-irrigation of the soil profile prior to cotton planting and the onset of the pecan growing season. With the exception of cotton and pecan pre-irrigation, land is defined as non-cropped outside of the growing season.

The monthly soil water balance for the non-cropped area is nearly identical to Equation (4), differing only in that infiltration of surface water, INFSW, and applied groundwater, AGW, are not included.

2.1.1.1 On-Farm Conveyance Losses

Some of the surface water delivered to the farm head gate is lost to percolation along on-farm laterals. The soil water balance model routes these conveyance losses directly to deep percolation. The model specifies zero conveyance losses of supplemental groundwater because wells could be installed in close proximity to, or piped to field inlets. The percentage of the farm delivery remaining after on-farm conveyance losses is defined as the farm conveyance efficiency (FCE). Therefore, on-farm conveyance losses are computed as follows:

$$CL^t = (1\text{-}FCE) \times FD^t \qquad (7)$$

FCE is estimated to be 90 percent, based on 10 percent on-farm lateral losses for medium loam soils reported by Blaney and Hanson (1965). It is likely that some improvements to on-farm conveyance structures have been undertaken on large farms since the 1960s; however, Skaggs and Samani (2004) note that the condition of on-farm conveyance structures on small farms remains generally inadequate and inefficient. For this reason, it is important to consider on-farm conveyance losses both historically and in current times.

Conveyance losses are added to field losses to calculate total farm deep percolation in Equation (4).

2.1.1.2 Surface Runoff of Applied Water

Some of the surface water delivered to the farm headgate is lost as surface runoff from the end of the field, and is called surface runoff of applied water or farm tailwater. Such tailwater loss does not infiltrate into the crop root zone, but instead returns to the surface water network. Blaney and Hanson (1965) estimated surface runoff loss for medium loam soils in New Mexico to be about 10% of surface water delivered at the farm headgate.

The soil water balance model computes surface runoff of applied water, SRO_{AW}, as a percentage of surface water delivered to the field, to account for on-farm conveyance losses:

$$SRO^{t}_{AW} = PCT_{TW} \times FCE \times FD^{t} \qquad (8)$$

In equation (8), PCT_{TW}, or tailwater percentage, is the percentage of surface water delivered to the field that is lost as surface water runoff. The tailwater percentage was adjusted as part of the soil water balance model calibration to match estimated actual crop evapotranspiration (ET) and metered groundwater pumping.

Surface runoff of applied water, SRO_{AW}, is added to surface runoff of precipitation – described in the section 'Precipitation Routing' – to calculate total surface water return flows from farm lands, QSW_{f}, in Equation (3).

Infiltration of surface water into the root zone, INF_{SW}, as defined in Equation (4), is the remaining portion of surface water delivered to the farm head gate after subtracting on-farm conveyance losses and farm tailwater as defined by Equations (7) and (8) respectively.

2.1.1.3 Non-uniform moisture distribution

The primary purpose of the soil water balance model is to estimate agricultural groundwater pumping and deep percolation. The disposition of irrigation water delivered to the fields, and specifically the relative proportions of the irrigation water that satisfy crop consumptive use or are lost to deep percolation below the root zone, depend on both the irrigation method and site-specific irrigation practices. Reliable calculations of agricultural groundwater pumping and deep percolation require that both factors be accounted for.

Nearly all irrigated acreage in the study area is surface-irrigated. This irrigation method can lead to spatially uneven, or non-uniform water application over the field if the cropped area is improperly leveled. In this situation, some portions of the field receive a disproportionately large amount of irrigation water; in these areas, crop consumptive use demands are fully satisfied and excess soil moisture sustains relatively high rates of deep percolation past the root zone. Conversely, other portions of the field receive a disproportionately small amount of irrigation water, and consequently are characterized by smaller rates of both crop consumptive use and deep percolation. Analysis of historical aerial imagery by Land IQ has demonstrated the effects on non-uniform water application on crop growth during the 1950s, prior to improvements in land-leveling technologies and their subsequent adoption in the Rincon and Mesilla basins.

The soil water balance model explicitly accounts for irrigation non-uniformity by distributing the monthly volume of irrigation water – derived from both surface and groundwater – over the field according to a common model for the distribution of infiltration over furrow- or basin-irrigated fields. This is called the power distribution model (Karmeli, 1978; Warrick, 1983):

$$(z_U - z) / (z_U - z_L) = x^{\beta} \quad (9)$$

Where,

z is the infiltration rate at a point;

z_U is the infiltration rate near the inlet to the field;

z_L is the infiltration rate at the end of the field;

x is the dimensionless distance from the inlet (fraction of total distance); and

β is the power law exponent controlling the curvature of the distribution.

The left-hand side of Equation (9) represents continuous reduction in infiltration rates moving from the field inlet to the end of the field, as illustrated in **Figure 2.3**.

It is assumed that the soil moisture distribution over the field corresponds to the infiltration distribution in Equation (9) because soil moisture depends on infiltration. One side of the field serves as the field inlet, so that x in Equation (9) is proportional to the percentage of the total field area.

The soil water balance model considers a collection of fields with different acreages. However, for a collection of fields with arbitrary and variable size, the infiltration distribution over the entire cropped area is identical to what would be obtained by separately adding up individual distributions over the collection of fields, provided that the average infiltration rate is the same.

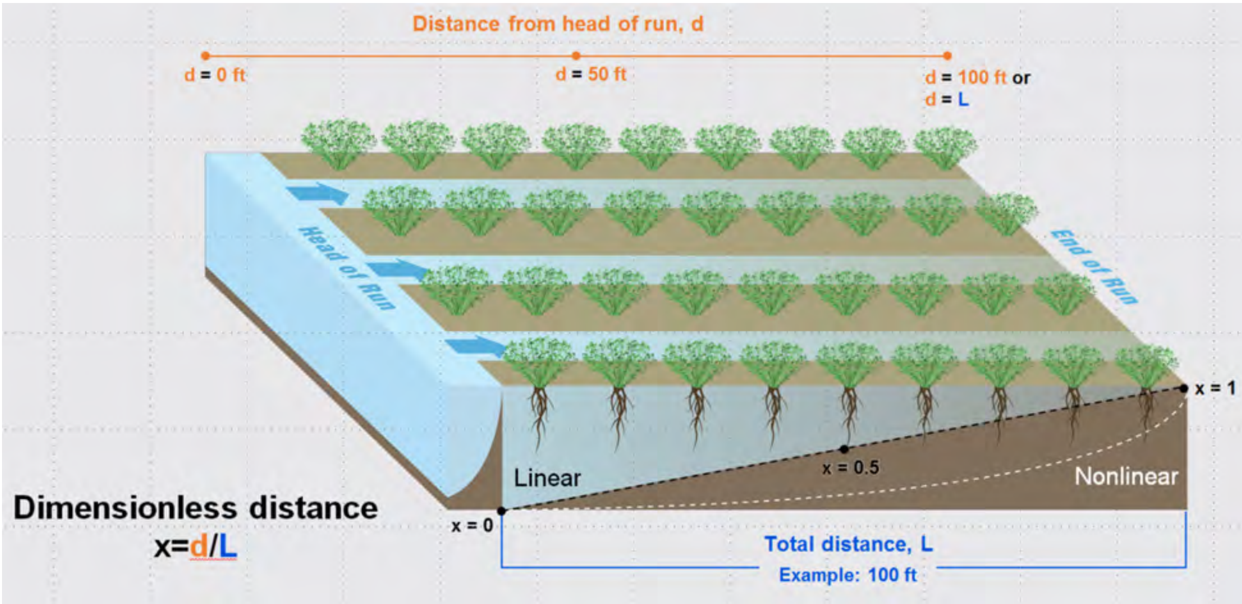

Figure 2.3. Diagram of Irrigation Non-Uniformity Showing Depth Infiltrated as a Function of Dimensionless Distance from Source

Based on Equation (9) and the assumptions outlined above, the following power distribution model is used to define moisture distribution over the cropped area:

$$(\theta_U - \theta) / r_\theta = a^\beta \qquad (10)$$

Where,

$r_\theta = \theta_U - \theta_L$ is the range of soil moisture content;

θ_L is the minimum soil moisture content over the cropped area;

θ_U is the maximum soil moisture content over the cropped area;

a is the fraction of the total cropped area; and

β is the power constant.

The range of soil moisture content over the field, r_θ, is specified as an input to the model. The left hand side of Equation (10) is the percent difference between θ_U and θ, and ranges from zero to one, since the fraction of the total cropped area also ranges from zero to one. The average percent soil moisture, PCT_{avg}, is therefore computed by integrating Equation (10) from zero to one, and subtracting from 1:

$$PCT_{avg} = 1 - 1/(\beta+1) \qquad (11)$$

When $\beta=1$, PCT_{avg} is one-half; this represents a linear distribution. When $\beta>1$, PCTavg is greater than one-half. This is representative of a typical infiltration distribution in which most of the area receives infiltration is exceeding the average infiltration rate (Burt and others, 1997). **Figure 2.3** illustrates linear and non-linear moisture distributions.

Given the average moisture content over the cropped area as defined in Equation (5), the power constant β, and the soil moisture range, r_θ, the upper and lower limits of the moisture distributions are computed as follows:

$$\theta_U = \theta_{avg} + r_\theta \times (1\text{-}PCT_{avg}) \quad (12)$$
$$\theta_L = \theta_U - r_\theta \quad (13)$$

Combining equation (10) with equation (12) yields an expression for the soil moisture at a point as a function of the percent area:

$$\theta_{point} = \theta_{avg} + r_\theta \times (1/(\beta+1) - a^\beta) \quad (14)$$

The parameters β and r_θ control the shape of the soil moisture distribution. Given these parameters, the lower bound on soil moisture, θ_L, controls the total volume of soil moisture in the root zone. All three parameters were adjusted as part of the soil water balance calibration, as discussed in the section 'Soil Water Balance Calibration'.

The distribution of irrigation water over the field controls the distribution of crop consumptive use and deep percolation, as discussed above. The soil water balance model also explicitly calculates variation in crop consumptive use and deep percolation over the field, as discussed in the following sections, 'Field Losses and Total Farm Deep Percolation' and 'Crop Evapotranspiration'.

2.1.1.4 Field Losses and Total Agricultural Deep Percolation

Field losses (FL) are defined as water flux from the base of the root zone (deep percolation at the field). If the moisture distribution in the root zone is relatively uniform, then the vertical water flux from the root zone is approximately equal to the unsaturated hydraulic conductivity, $K(\theta)$. This condition is also referred to as unit hydraulic gradient or gravity drainage, and is relatively common in a deeply wetted soil profile as would be found beneath an irrigated field.

The unsaturated hydraulic conductivity is calculated according to the widely-used model of van Genuchten (1980):

$$K(\theta) = K_{sat} \times \Theta^{1/2} \times [1\text{-}(1\text{-}\Theta^{1/m})^m]^2 \quad (15)$$

Where,

$\Theta = (\theta-\theta_r)/(\theta_{sat}-\theta_r)$ is the dimensionless moisture content;

θ_r is the residual moisture content of the soil;

θ_{sat} is the saturated moisture content, or total porosity of the soil;

K_{sat} is the saturated hydraulic conductivity of the soil;

$m = \lambda/(\lambda+1)$; and

λ is the pore-size distribution index of the soil.

Under the assumption of gravity drainage, Equation (14) defines water flux as a function of moisture content at a point. To calculate to total field losses over the cropped area, Equation (15) must be integrated over the cropped area:

$$FL^t = A^t \times \int K[\theta_{point}(a)]\, da \quad (16)$$

Equation (16) is computed in the soil water balance model using trapezoidal integration, with θ(a) defined based on Equation (15). Total deep percolation (DP) from farms is the sum of field losses (FL) and on-farm conveyance losses (CL).

Non-cropped areas are not irrigated, so deep percolation beneath non-cropped areas (DPnc) is simply calculated as:

$$DP_{nc} = A_{nc}^t \times K(\theta_{nc}^t) \quad (17)$$

Where,

A_{nc}^t is the non-cropped area;
θ_{nc}^t is the average moisture content of the non-cropped area.

2.1.1.5 Crop Evapotranspiration

Land IQ calculated crop evapotranspiration under standard conditions – referred to in this report as theoretical crop evapotranspiration – based on meteorological data and representative crop coefficients. Land IQ also estimated historical actual evapotranspiration (AET) based on reported crop yield, with lower AET earlier in the study period. Lower rates of AET were due primarily to poor irrigation water management and distribution uniformity, with better irrigation water management in current times. The historical AET therefore represents crop ET under soil water stress conditions.

The soil water balance model uses theoretical crop ET as input data, and computes AET based on simulated moisture conditions in the root zone. Under soil water stress conditions, root zone moisture is too low, and AET will be reduced below the theoretical crop ET. Allen (1998) provides a simple model of AET under water stress conditions, which is used in the soil water balance model:

$$AET_{point} = K_s \times K_c \times ET_o \quad (18)$$

Where,

AET_{point} is actual ET at a point;
K_s is the water stress coefficient;
K_c is the crop coefficient; and
ET_o is the reference ET.

The quantity $K_c \times ET_o$ is the theoretical crop ET provided as a data input to the model. The section 'Model Inputs' discusses the ET dataset in greater detail. When $K_s = 1$, then AET_{point} is equal to the theoretical crop ET.

The water stress coefficient is computed as follows:

$$K_s = 0, \text{ if } \theta \leq \theta_{wp}$$
$$K_s = (\theta - \theta_{wp}) / (\theta_{crit} - \theta_{wp}), \text{ if } \theta_{wp} < \theta < \theta_{crit} \quad (19)$$
$$K_s = 1, \text{ if } \theta \geq \theta_{crit}$$

Where,

θ_{wp} is the moisture content at wilting point; and
θ_{crit} is the critical soil moisture.

The critical soil moisture is defined:

$$\theta_{crit} = \theta_{fc} - DF \times (\theta_{fc} - \theta_{wp}) \quad (20)$$

Where,

θ_{fc} is the moisture content at field capacity; and
DF is a soil water depletion factor.

The section 'Model Inputs' describes data inputs used to calculate θ_{crit} according to Equation (20).

Equations (18) and (19) show how AET depends on soil moisture. These equations define AET at a point. To calculate total AET over the cropped area requires integrating Equation (18) over the total cropped area:

$$AET = A^t \times \int AET_{point} [\ \theta_{point}(a)\ ]\ da \quad (21)$$

Equation (21) is computed in the soil water balance model using trapezoidal integration, with $\theta_{point}(a)$ defined based on Equation (14).

AET in cropped areas is calculated using Equation (21). AET in the non-cropped area is defined as bare soil evaporation, and is described in Section 2.1.3.

2.1.1.6 Agricultural Groundwater Pumping

The availability of supplemental groundwater for irrigation provides farmers with the flexibility to increase crop AET and therefore yield by alleviating soil water stress conditions as described above. For this analysis, the year 1951 represents the time when farmers within the districts began pumping substantial amounts of groundwater for irrigation purposes, concurrent with curtailed RGP surface water deliveries to farms. New Mexico and Texas well records indicate that irrigation well installations began to increase in the 1950s, as described in the Groundwater Outflows section of this report. Lands outside the districts do not receive surface water deliveries and thus have relied solely on groundwater for the entire study period.

Prior to the adoption of supplemental groundwater pumping for irrigation within District lands in the 1950s, the lower bound on soil moisture, θ_L, is unconstrained in the soil water balance model. Beginning in 1951, θ_L is estimated in order to reproduce adjusted AET, which incorporates information on historic changes in crop yield (Land IQ). Section 2.1.5 describes the method for estimating θL to match adjusted AET. The estimated value of θ_L is called θ_L^*. Inserting θ_L^* into Equations (13) and (14) provides an expression for average moisture content of the root zone beginning in 1950:

$$\theta^*_{avg} = \theta_L^* + r_\theta \times (PCT_{avg}), \qquad \text{if } \theta_L < \theta_L^* \qquad (22)$$

As implemented in the soil water balance model, θ_{avg} is calculated according to Equations (4) and (5) without supplemental pumping – that is, AGW = 0 in Equation (7). Then, θ^*_{avg} is calculated according to Equation (22) if $\theta_L < \theta_L^*$. Otherwise, supplemental pumping is not required to satisfy $\theta_L \geq \theta_L^*$, and $\theta^*_{avg} = \theta_{avg}$ as calculated in Equation (5).

Agricultural groundwater pumping is calculated by substituting θ^*_{avg} into Equation (4) and rearranging:

$$AGW^t = \theta^{t}*_{avg} \times V^t_{rz} - S^{t-1} - \Delta S_a{}^t - INFPCP^t - INFSW^t + DP^t(\theta^t*_{avg}) + AET^t(\theta^t*_{avg}) \qquad (23)$$

The last two terms in Equation (23) implicitly require determining the upper and lower limits on moisture content over the cropped area based on θ^{t*}_{avg} with Equations (12) and (13), and numerical integration over the corresponding moisture interval according to Equations (16) and (21).

Given the required infiltration of applied water to achieve θ^*_{avg}, the corresponding agricultural groundwater pumping, AGW, can then be calculated from Equation (23).

2.1.2 Precipitation Routing

Precipitation is the natural source of soil moisture in the study area. Precipitation that falls on the ground infiltrates into the soil at a rate depending on ground cover, physical characteristics of the soil, and antecedent moisture. The portion of precipitation that is in excess of the infiltration rate becomes surface runoff.

Monthly precipitation time series were developed for the Rincon and Mesilla basins based on historical datasets from the Precipitation-Regression on Independent Slopes Model (PRISM) (Daly and others, 2008). The PRISM historical datasets (available for download from the PRISM Climate Group at Oregon State University) consist of continuous, spatially distributed precipitation surfaces with grid cell size of 4 square kilometers (km2) (or about 1.5 square miles). For each basin, monthly precipitation was calculated as the area-weighted average precipitation of the monthly PRISM surface for grid cells within the study area. **Figure 2.4** shows historic annual precipitation used in the Rincon and Mesilla basin water budgets. Annual precipitation amounts recorded at weather stations at Caballo Reservoir Dam and at the New Mexico State University were assessed to verify the accuracy of the interpolated, basin-wide PRISM estimates. The station data are generally consistent with PRISM estimates (**Figure 2.4**), indicating that PRISM estimates are reasonable to use for this analysis.

Total precipitation falling on agricultural lands, urban lands, and the upland watershed are summarized in **Table 2.1**.

Annual values are based on monthly PRISM precipitation data.

2.1.2.1 Surface Runoff of Precipitation from Agricultural Lands

Return flows of excess precipitation water falling on agricultural lands is called surface runoff of precipitation. We used the Soil Conservation Service (SCS) curve number method (USDA, 2004) to develop an empirical relationship between monthly total precipitation and monthly surface runoff.

Developing the empirical relationship consisted of two steps. First, we used the curve number equation to calculate daily surface runoff based on daily precipitation data recorded at Caballo Dam and New Mexico State University. These calculations used a curve number value of 85 for both the Rincon and Mesilla basins, based on curve number values for hydrologic soil group C (which is representative of loam soil) tabulated by Rawls (1993).

Second, we summed daily precipitation and runoff by month, and used a best-fit line to approximate the relationship between monthly precipitation and monthly runoff. A separate best-fit line was developed for the Rincon Basin based on precipitation data from Caballo Dam, and for the Mesilla Basin based on precipitation data from New Mexico State University. The monthly precipitation-runoff relations are based on characteristics of precipitation at the daily time scale such as intensity and frequency, and the assumed SCS curve number. The empirical relationships for Rincon and Mesilla are:

$$SRO_{PCP\text{-}RIN} = 0.0144\times(PCP_{RIN})^{2.649}\ ;\ (R^2=0.5312) \qquad (24)$$

$$SRO_{PCP\text{-}MES} = 0.0133\times(PCP_{MES})^{2.727}\ ;\ (R^2=0.5007) \qquad (25)$$

Where,

$SRO_{PCP\text{-}RIN}$ is monthly surface runoff of precipitation on agricultural lands in the Rincon Basin
PCP_{RIN} is monthly precipitation in the Rincon Basin
$SRO_{PCP\text{-}MES}$ is monthly surface runoff of precipitation on agricultural lands in the Mesilla Basin
PCP_{MES} is monthly precipitation in the Mesilla Basin

Figure 2.5 illustrates the approximated empirical relationship between monthly precipitation and monthly runoff.

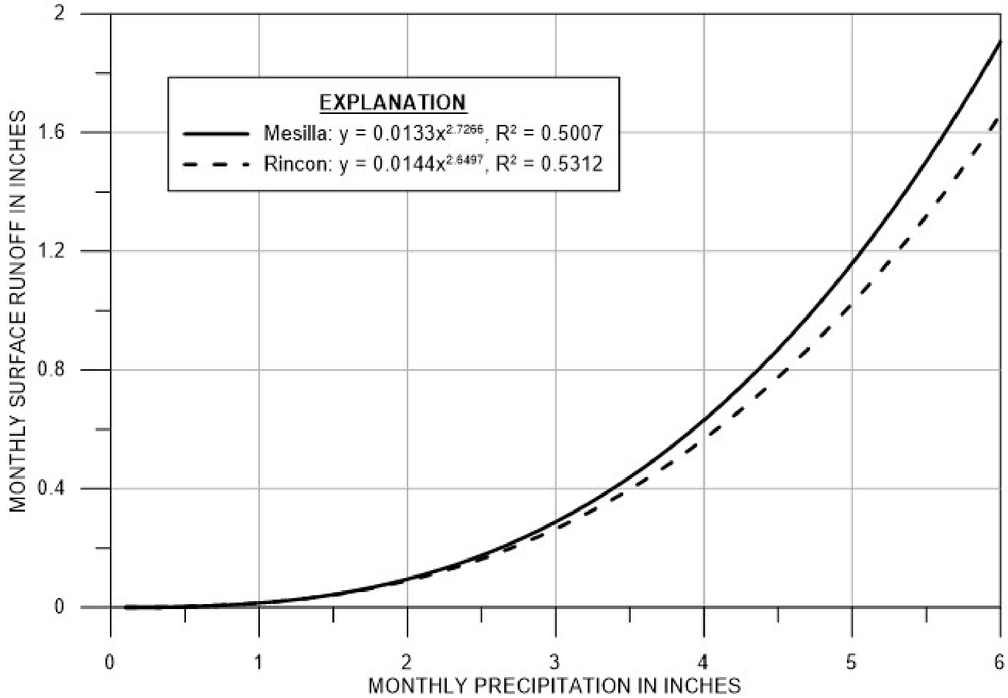

Figure 2.5. Empirical Monthly Rainfall-Runoff Relationship for Rincon and Mesilla Basins

2.1.2.2 Effective Precipitation on Agricultural Lands

A portion of the monthly crop ET and off-season bare soil evaporation is satisfied by precipitation – this is known as effective precipitation. Effective precipitation was estimated using empirical equations adopted by the U.S. Bureau of Reclamation (USBR) – referred to herein as the USBR method. The USBR method is recommended for arid and semi-arid regions. Percent of precipitation that is effective precipitation is provided in increments of monthly rainfall, as shown in **Table 2.2**.

Table 2.2. Empirical Equations Used to Estimate Effective Precipitation

Equation	Range
$P_{eff} = 0.95 \times P$	$P \leq 1$
$P_{eff} = 0.95 + 0.90 \times (P-1)$	$1 < P \leq 2$
$P_{eff} = 1.85 + 0.82 \times (P-2)$	$2 < P \leq 3$
$P_{eff} = 2.67 + 0.65 \times (P-3)$	$3 < P \leq 4$
$P_{eff} = 3.32 + 0.45 \times (P-4)$	$4 < P \leq 5$
$P_{eff} = 3.77 + 0.25 \times (P-5)$	$5 < P \leq 6$
$P_{eff} = 4.02 + 0.05 \times (P-6)$	$P > 6$

Where,

P is precipitation in inches; and

P_{eff} is effective precipitation, in inches.

We used basin-wide precipitation estimates from PRISM, as previously described, for effective precipitation calculations. Monthly effective precipitation was subtracted from total monthly crop ET rates, with the remaining monthly ET supplied to the soil water balance model as crop ET demand to be satisfied by applied irrigation water.

For months when the total precipitation exceeded the sum of effective precipitation and surface runoff, the remaining precipitation was assigned as infiltration to the root zone – INFPCP as described in Equation (4). This ensures that all precipitation is accounted for.

2.1.3 Model Inputs

2.1.3.1 Crop Acreage and Evapotranspiration

The farm soil water balance models encompass the maximum cropped acreages provided by Land IQ for this analysis. The Rincon farm budget encompasses an area of 20,726 acres (about 32 square miles): 18,828 acres within the Elephant Butte Irrigation District's (EBID) Arrey canal service area, and 1,898 acres outside the district boundaries. The Mesilla farm budget encompasses an area of 92,648 acres (about 145 square miles): 89,814 acres within EBID's Leasburg, Eastside, and Westside canal service areas and the portion of El Paso County Water Improvement District #1 (EPCWID #1) located in Mesilla Basin, and 2,834 acres outside the districts' boundaries. These outside areas represent agricultural lands that are supplied solely by groundwater pumping. Agricultural lands in the basins are shown on **Figure 2.1**.

Crop distribution and evapotranspiration (ET) (crop consumptive use) datasets for the Rincon and Mesilla valleys prepared by Land IQ (delivered January 26, 2018) were used in this farm water budget analysis. The Land IQ datasets contain annual acreages and monthly ET data for nineteen crop categories, along with annual ET adjustment factors computed based on analysis of historic crop yield. Disaggregated crop acreages for canal service areas and areas outside district boundaries were provided by Land IQ.

We used crop acreage data provided by Land IQ for 1938-2014, and we estimated disaggregated acreages for 2015 and 2016 by applying the 2014 crop proportions from the Land IQ dataset to the reported total acres for the respective year.

We processed the crop consumptive use dataset from Land IQ to prepare input files for the soil water balance model. The soil water balance model simulates total ET from all the crops, and so we computed total crop ET as a summation over all crop types over the study period; these totals represent historical actual crop ET accounting for changes in crop yield. We also calculated theoretical crop ET rates for each crop by dividing adjusted crop ET by the corresponding crop ET adjustment factor. The adjusted Land IQ AET rates are referred to herein as target AET rates, meaning that they reflect the best available estimates, and should be reproduced by the soil water balance model to the extent possible.

Annual total crop consumptive use volumes calculated by Land IQ for Rincon and Mesilla basins are shown on **Figure 2.6 and Figure 2.7**. Annual crop consumptive use in the Mesilla Basin varied between about 166,000 AF in 1938 to about 257,000 AF in 1997, with an average of about 220,000 AF. Annual crop consumptive use in the Rincon Basin varied between about 31,000 AF in 1938 to about 78,000 in 2011, with an average of about 52,000 AF. Effective precipitation satisfied between about 8% to 43% of crop consumptive use in both basins, although the highest effective precipitation as a percentage of consumptive use occurred in 1941 and was associated with anomalously high precipitation that year. From 1938 through 2016, precipitation satisfied, on average, about 20% and 19% of crop consumptive use in the Rincon and Mesilla Basins, respectively; remaining crop consumptive use was satisfied by applied water, either surface water or groundwater.

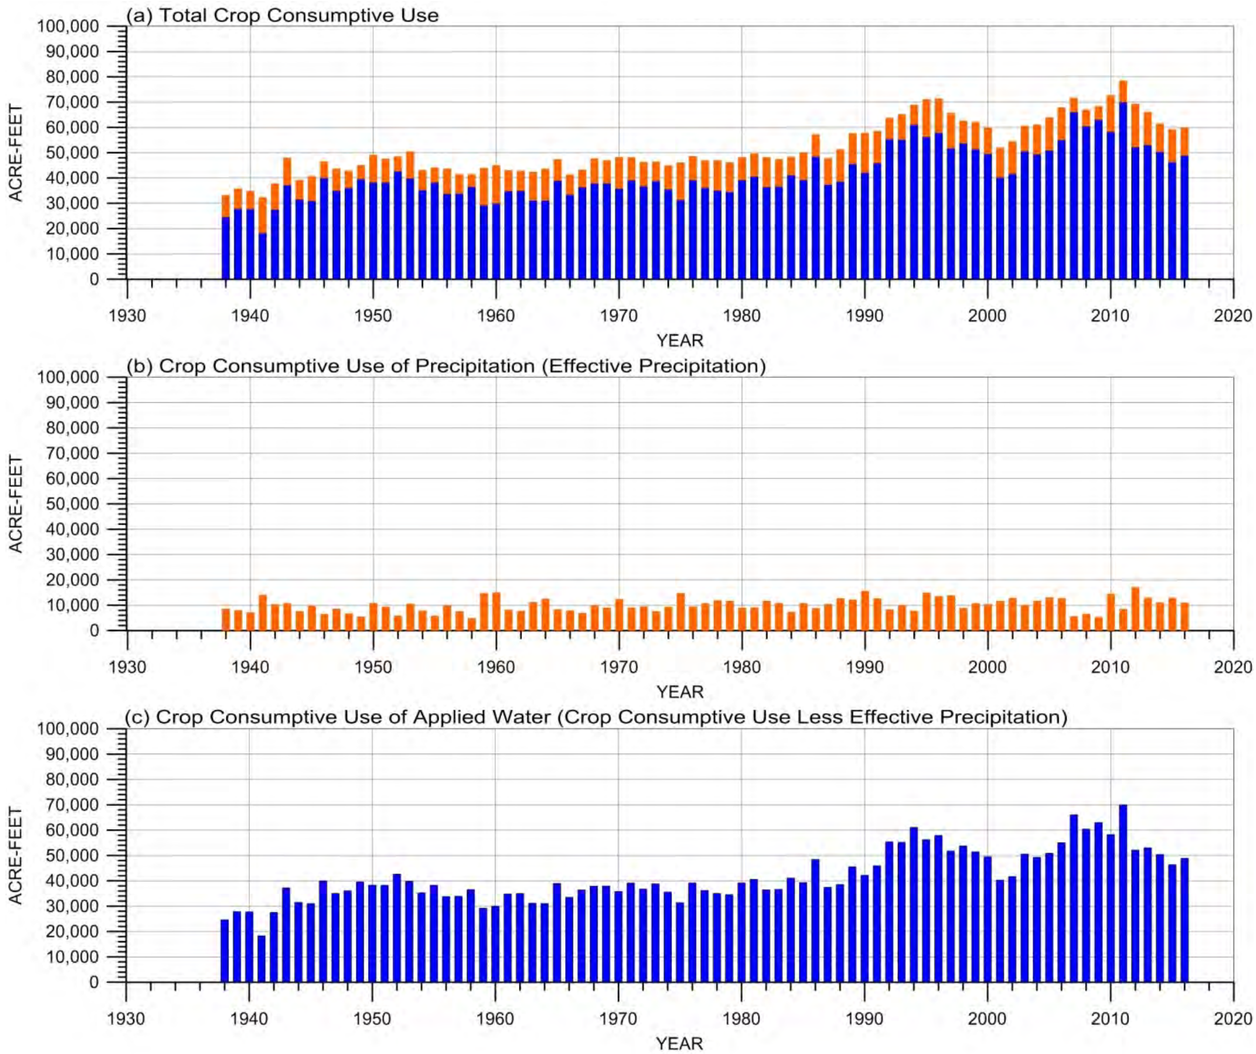

Figure 2.6. Annual Crop Consumptive Use Occurring on Agricultural Lands in Rincon Valley

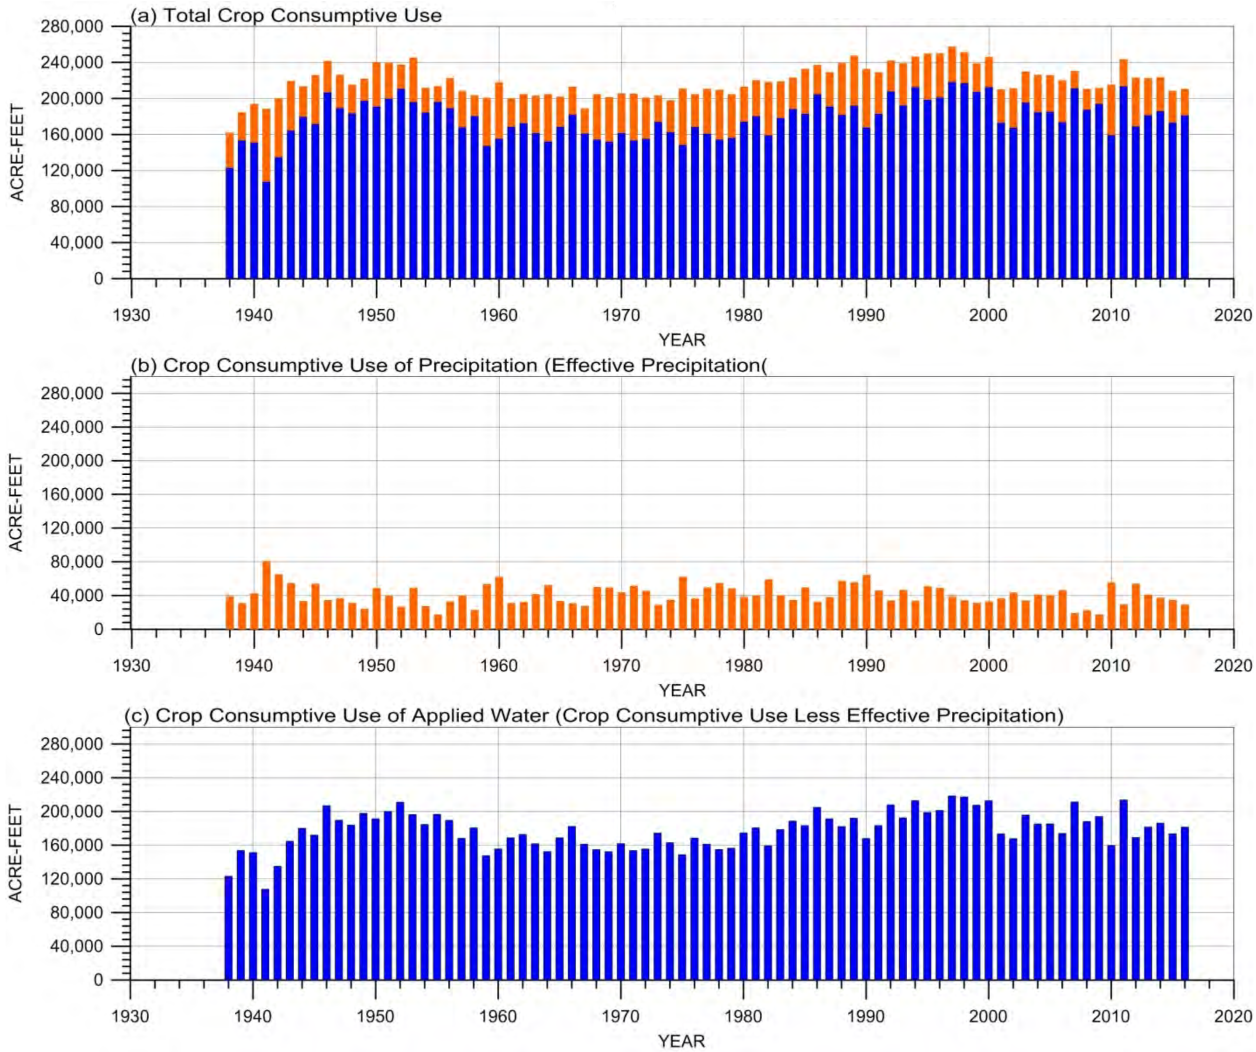

Figure 2.7. Annual Crop Consumptive Use Occurring on Agricultural Lands in Mesilla Valley

2.1.3.2 Double-Cropping

Most of the crops grown in the study area follow a single-cropping pattern, with land remaining fallow outside of the growing season. However, double-cropping is also practiced in a small portion (approximately 2% of total cropped acreage, on average) of the study area. The Land IQ datasets includes tabulation of total annual double cropped acreage within EBID, and determination of four main double-cropping systems. These four double-crop systems are Corn-Grain, Corn-Onion, Corn-Alfalfa, and Melons/Squash-Cole/Leafy Greens. The estimated proportions of total double cropped acreage dedicated to each of these four categories are 60%, 25%, 10% and 5%, respectively. Land IQ calculated the acreage associated with each of the four double-cropped systems based on total annual double cropped acreage and the representative proportions listed above.

We modified double-cropped acreage after checking to ensure that the double-cropped acreage did not exceed the reported harvest acreage of its components. If this constraining condition occurred in a given year, then the proportions were modified to be equal to the reported harvest acreage so that the double-cropped acreage would not exceed the harvest acreage of its components. Specifically, excess double-cropped acreage for a given system was re-assigned to the other double cropped systems in the order Corn-Grain, Corn-Onion, Corn-Alfalfa, and Melons/Squash-Cole/Leafy Greens.

Total monthly ET rates were calculated by aggregating all crop categories within each basin. ET rates for the double-cropped systems were determined based on the monthly ET rates of the component crops.

Evaluation of spatial crop datasets from Land IQ indicate that double-cropping is minor outside of the EBID and EPCWID district boundaries. Double-cropping is specified in the models to solely occur within the district boundaries.

2.1.3.3 Non-Crop Acreage and Evapotranspiration

The soil water balance model tracks all root zone soil moisture, including in cropped and non-cropped areas. For non-cropped areas, this requires the computation of bare soil evaporation. To represent bare soil evaporation, a monthly crop coefficient is calculated using a methodology described by the U.S. Department of Agriculture (1993). The method depends on the frequency between precipitation events and the reference crop ET during each month. When event frequency is less than four days:

$$K_a = (1.286-0.27\times f_p)\times \exp\{[0.254-1.07\times \ln(f_p)]\times ET_o\} \quad (26)$$

When event frequency is greater than or equal to four days:

$$K_a = 2\times f_p^{-0.49\times}\exp\{[-0.51-1.02\times \ln(f_p)]\times ET_o\} \quad (27)$$

Where,

K_a is average monthly crop coefficient for bare soil evaporation;
f_p is average monthly interval between precipitation events; and
ET_o is average reference crop ET (inches per day).

Daily precipitation data for the Caballo Dam weather station were analyzed to determine the appropriate interval between precipitation events for each month. The Caballo dataset was used because of its long record of daily data. These monthly estimates were used for both the Rincon and Mesilla basins, assuming that storm frequencies are comparable between basins.

The average monthly crop coefficients for bare soil evaporation in Mesilla Basin during non-growing season months range from 0.188 in May to 0.464 in September, with an average of about 0.356. Average monthly crop coefficients for Rincon Basin are virtually the same as for Mesilla Basin, with an average of about 0.359. Winter bare soil evaporation is calculated for areas where crops are grown exclusively during the primary growing season, whereas summer bare soil evaporation is calculated for areas where crops are grown exclusively during the secondary growing season.

2.1.3.4 Soil Properties

Soil properties required for the soil water balance model include the residual moisture content, permanent wilting point, critical soil moisture, field capacity, total porosity, pore size distribution index, and saturated hydraulic conductivity (K_{sat}). Distribution of soils classes within the Rincon and Mesilla Valleys were determined based on the Soil Survey Geographic Database (SSURGO) (NRCS, 2016). The dominant soil types in the Mesilla Valley are clay loam, loam, loamy sand, in order of dominance. In the Rincon Valley, dominant soil types are sandy loam, clay loam, and loamy sand, in order of dominance. Collectively, these soils make up at least 70% of their respective basin. A loam soil was chosen as the representative soil type for the soil water balance analysis based on the dominant soils present in these basins. Values of the total porosity (θs), wilting point (θ_{wp}), soil field capacity (θ_{fc}), pore-size distribution index (λ), and K_{sat} were obtained from published data by Rawls and others (1982) for loam soil. The critical soil moisture was calculated according to Equation (19), using area-weighted depletion fractions as reported by Allen (1998) for each crop type.

Table 2.3 shows the soil property values represented in the farm soil water balance models for Rincon and Mesilla basins. Values are reported using units of feet and months, for consistency with the model units and water budget analysis.

Table 2.3. Soil Hydraulic Property Values Used in Farm Soil Water Balance Calculations for Rincon and Mesilla Basins

Soil Property	Value
Residual moisture, θ_r (ft^3/ft^3)	0.027
Wilting point, θ_{wp} (ft^3/ft^3)	0.117
Critical soil moisture, θ_c (ft^3/ft^3)	0.184 (Rincon), 0.182 (Mesilla)
Field capacity, θ_{fc} (ft^3/ft^3)	0.27
Total porosity θ_s (ft^3/ft^3)	0.463
Pore-size distribution index, λ (-)	0.252
Saturated hydraulic conductivity, K_{sat} (ft/month)	31.17

Source: Rawls and others (1982), for loam soil, critical soil moisture calculated based on soil depletion factors for specific crops reported by Allen (1998)

2.1.3.5 Rooting Depth

The root zone volume defined in Equation (5) depends on crop acreage and average root zone depth. The average root zone depth used in Equation (5) is averaged twice: over crop types, and over time.

The soil water balance model simulates total ET from all the crops, and so we first calculated a monthly time series of average root zone depth as an area-weighted average over the different crop types over the study period. **Figure 2.8** provides a graphical depiction of area-weighted average root zone depth considering three crop types. The soil water balance model treats root zone thickness as constant in time to minimize perturbations to root zone volume associated with start and end of the growing season for different crops. We calculated the time-averaged root zone depth as the average value of the monthly time-series of crop area-weighted average rooting depth.

Rooting depths for each crop type were defined based on field and laboratory studies of crop root development in southern New Mexico, where available, and based on literature values when specific studies were not available. Double-cropped rooting depths assumed the larger depth between the crops included in each double-crop system. **Table 2.4** summarizes crop rooting depths used for the soil water balance model.

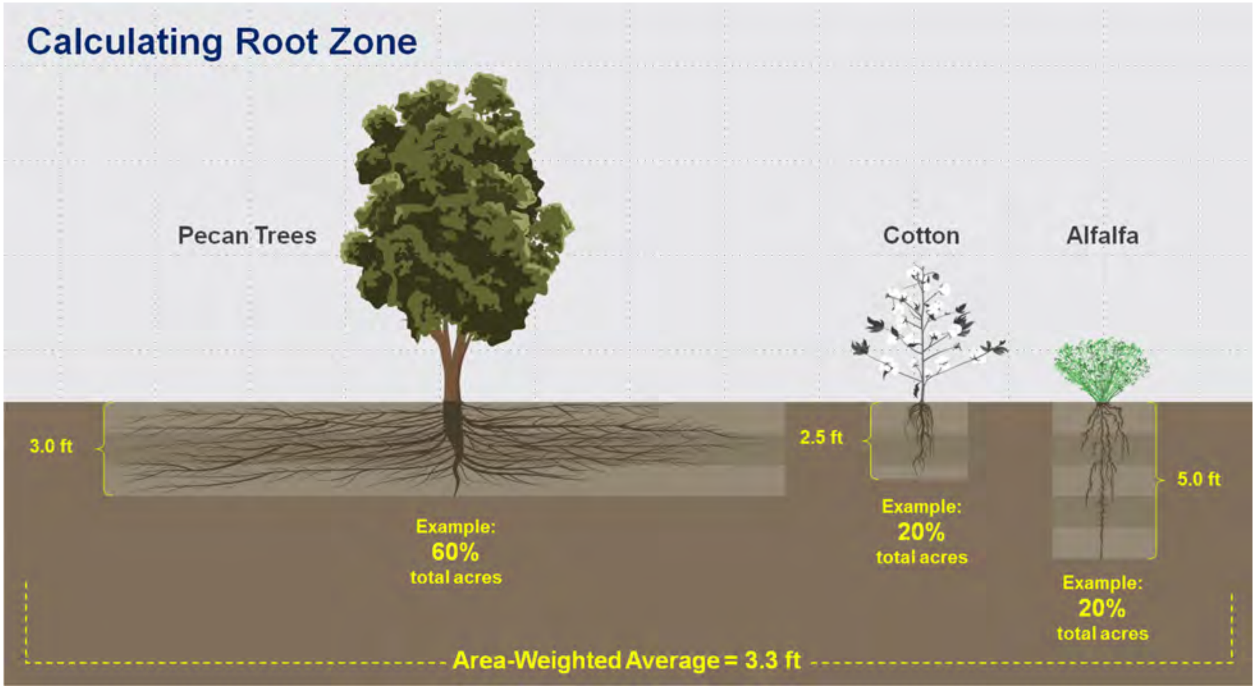

Figure 2.8. Example Calculation of Area-Weighted Average Rooting Depth Over Three Crop Types

Table 2.4. Crop Rooting Depths Used in Farm Soil Water Balance Models for Rincon and Mesilla Basins

Crop Type	Rooting Depth (feet)	Data Source
Alfalfa	4.92	Abdul-Jabbar and others (1982)
Asparagus	5.00	NRCS (1997)
Chili/Peppers	2.00	NRCS (1997)
Cole/Leafy Greens	2.00	NRCS (1997)
Corn/Silage	4.00	NRCS (1997)
Cotton	2.46	Al-Khafaf and others (1979)
Grain	4.00	NRCS (1997)
Grapes	5.00	NRCS (1997)
Hay	4.00	NRCS (1997)
Legumes	3.00	NRCS (1997)
Melons/Squash	3.00	NRCS (1997)
Misc/Other	2.95	Calculated as average rooting depth over annual crops
Onions	2.00	NRCS (1997)
Pasture	4.00	NRCS (1997)
Pecans/Other Trees	3.00	Herrera and Sammis (2001)
Root Crop	3.00	NRCS (1997)
Tomato	3.00	NRCS (1997)
Turf	0.49	Leinauer and Smeal (2012)
Irrigated Annuals	2.95	Calculated as average rooting depth over annual crops
Corn-Grain (Double Crop)	4.00	Maximum of individual components
Corn-Onions (Double Crop)	4.00	Maximum of individual components
Corn-Alfalfa (Double Crop)	4.92	Maximum of individual components
Melons/Squash – Cole/Leafy Greens (Double Crop)	3.00	Maximum of individual components

2.1.4 Implementation of Model Equations

The farm water budget was implemented using GoldSim simulation software developed by GoldSim Technology Group. GoldSim provides a general-purpose platform for simulation of dynamic systems. The software was originally developed for water balance analyses.

Four GoldSim models were developed for Rincon and Mesilla basins, each with models for crop lands inside and outside district boundaries. Farm water budget variables and equations were implemented as defined in the previous sections. Equations in which the state variables are dependent on the outputs (Equations (14) and (17)) are solved using standard explicit iteration methods. Data inputs are loaded into the GoldSim models using an Excel spreadsheet named Inputs.xlsx. Model results for cropped (c) and non-cropped (nc) areas in lands inside (in) and outside (out) district boundaries within each basin are exported from the GoldSim model as Excel spreadsheets named *Results_c_Rincon_in.xlsx, Results_c_Rincon_out.xlsx, Results_c_Mesilla_in.xlsx, Results_c_Mesilla_out.xlsx, Results_nc_Rincon_in.xlsx, Results_nc_Rincon_out.xlsx, Results_nc_Mesilla_in.xlsx, and Results_nc_Mesilla_out.xlsx*.

2.1.5 Soil Water Balance Model Calibration

The soil water balance model was calibrated to match available historic data as closely as possible. The calibration consisted of adjusting surface runoff of applied water, or farm tailwater, and the soil moisture uniformity parameters within reasonable ranges to simultaneously match historic data and conceptual trends.

Historic data used in the model calibration are described below. The main conceptual trends considered in the model calibration were:

- Improvements in irrigation uniformity
- Reductions in farm tailwater losses from surface water deliveries

2.1.5.1 Data Used for Model Calibration

Historic data used in the model calibration include:

- Adjusted crop AET rates (Land IQ) accounting for observed historical trends in crop yield
- Recent metered groundwater pumping at registered irrigation wells
- Estimates of on-farm irrigation efficiency

Metered pumping data are described in the Section 4.2.3 of this report. Reported crop efficiency estimates range from 0.64 to 0.76 for chiles (Al-Jamal and others, 1997), 0.88 to 0.97 for cotton (Deras, 1999), 0.72 to 0.95 for pecans (NM Pecan Grower Settlement Agreement, 2008; Samani and Al-Katheeri, 2001), and 0.97 for alfalfa (Al-Jamal and others, 1997). Ahadi and others (2013) estimated basin-wide average farm efficiency to be about 64%.

2.1.5.2 Adjustment of Soil Moisture Uniformity Parameters

The shape of the soil moisture distribution is described by the parameters β and r_θ defined in the section 'Non-uniform moisture distribution'. These parameters control the curvature and the range of soil moisture in the cropped area, respectively.

The power constant, β, determines the relative portion of the cropped area receiving above-average infiltration. It is therefore expected that the value of β should increase over the study period, reflecting improvements in irrigation management. The value of β was estimated to fall between 1 and 2 over the historical period.

The soil moisture range, r_θ, determines the bounds on soil moisture. Given the average soil moisture over the cropped area, increasing r_θ means that the moisture conditions will be wetter near the source end, and drier at the tail end of the field. It is therefore expected that the value of r_θ should decrease over the study period, reflecting improved irrigation uniformity due to changes in irrigation management practices such as land leveling. Given the uniformity parameters β and r_θ, the average soil moisture, and correspondingly, the required application of supplemental groundwater, is controlled by the lower bound on the moisture distribution, θ_L. We estimated a time-series of θ_L that, when used as input to the soil water balance model, would best reproduce the adjusted crop AET rates developed by Land IQ. The estimated value of θ_L is called θ_L^* and is used with Equations (22-23) to calculate supplemental groundwater pumping for the period of time beginning in 1951 through present.

No crop AET occurs in portions of the cropped area where $\theta \leq \theta_{wp}$. Crop AET computed by the soil water balance model can be therefore be partitioned into two parts, consistent with Equation (19): AET from land where $\theta \geq \theta_{crit}$, and AET from land where $\theta_{crit} > \theta > \theta_{wp}$:

$$AET = A \times K_c \times ET_o \times [a_{crit} + \overline{K_s} \times (a_{wp} - a_{crit})] \quad (28)$$

$\overline{K_s}$ in Equation (28) is the average water stress coefficient in land where $\theta_{crit} > \theta > \theta_{wp}$. a_{crit} refers to the fraction of the cropped area for which $\theta \leq \theta_{crit}$. a_{wp} refers to the fraction of the cropped area for which $\theta \geq \theta_{wp}$. Dividing the computed AET in Equation (28) by the theoretical ET provides an expression for the simulated bulk ET adjustment factor, α:

$$\alpha = a_{crit} + \overline{K_s} \times (a_{wp} - a_{crit}) \quad (29)$$

To reproduce the total adjusted crop AET (Land IQ) requires that α match the ratio of total adjusted AET to total theoretical ET over all crop types. This can be accomplished by adjusting a_{crit} and $\overline{K_s}$, both of which are functions of the irrigation uniformity parameters.

Substituting θ_{crit} into Equation (10) and solving for the fraction of the total cropped area, a, provides an expression for a_{crit}. Similarly, substituting θ_{wp} into Equation (10) and solving for the fraction of the total cropped area, a, provides an expression for a_{wp}.

$a_{crit} = [1 – (\theta_{crit} - \theta_L)/r_\theta]$^$(1/\beta)$ (30)

$a_{wp} = [1 – (\theta_{wp} - \theta_L)/r_\theta]$^$(1/\beta)$ (31)

An expression for $\overline{K_s}$ is obtained by integrating $K_s[\theta(a)]$ with respect to the fraction of the cropped area, a, over the range from a_{crit} to a_{wp}:

$\overline{K_s}$ = [1 / (1 – a_{crit})] × [C_1 × (a_{wp} – a_{crit}) + (C_2 / (β + 1)) × (a_{crit}^(β+1) + β × (a_{wp} – a_{crit}) + a_{wp} – a_{crit} – a_{wp}^(β+1)] (32)

Where,

$C_1 = (\theta_L – \theta_{wp}) / (\theta_{crit} – \theta_{wp})$ (33)

$C_2 = r_\theta / (\theta_{crit} – \theta_{wp})$ (34)

After fixing the estimated time series of β and r_θ, we used Equations (29-34) to compute α as a function of θ_L, and in this way, to compute the lower bound on soil moisture, θ_L^*,that would be required to match the adjusted crop AET rates developed by Land IQ.

2.1.5.3 Estimation of Farm Tailwater

Prior to the widespread use of supplemental groundwater for irrigation, the average soil moisture inside the irrigation district boundaries depended on precipitation and the availability of surface water deliveries. During the early years of the study period (1938-1950) with full project allocation, simulated soil moisture is relatively high, and simulated AET is also higher than the adjusted AET rates provided by Land IQ, even with a relatively low value of β, and a relatively high value of r_θ. It is therefore assumed that farm tailwater was higher early during the study period (1938-1950), which is consistent with the general observation that irrigation management during this period of time was poor relative to current irrigation management practices.

Farm tailwater as a percentage of surface water delivered to the field was adjusted to reproduce the crop AET rates developed by Land IQ, with the expectation that the percentage of tailwater would decrease with time due to improvements in irrigation management.

2.1.6 Results of Soil Water Balance Model

This section of the report summarizes the results of the farm soil water balance models. Results of the soil water models and overall farm water budgets are compiled for numerical model development into Excel files named *FarmBudget_Zoned_in.xlsx* (inside districts) and *FarmBudget_Zoned_out.xlsx* (outside districts).

2.1.6.1 Agricultural Groundwater Pumping

Agricultural groundwater pumping is calculated based on Equations (22) and (23); these pumping rates are referred to as simulated groundwater pumping, meaning that they are computed within an individual simulation using the soil water balance model. Prior to 1951, the applied water demand within districts is satisfied exclusively by surface water deliveries to farms. In 1951 and later, the applied water demand within districts is satisfied by surface water deliveries and supplemental groundwater pumping. The applied water demand outside districts is satisfied exclusively by groundwater pumping.

Annual surface water deliveries to farms (farm deliveries) and agricultural groundwater pumping in Rincon and Mesilla basins are shown on **Figures 2.9 and 2.10**, respectively. Farm deliveries were compiled as part of the Surface Water Budget preparation, and are discussed in greater detail in the section 'Surface Water Deliveries to Farms'.

For reference, **Figures 2.9 and 2.10** also show metered annual irrigation groundwater pumping volumes reported by the New Mexico Office of the State Engineer (NMOSE) at metered points of groundwater diversion associated with irrigation water rights, grouped by basin. Simulated agricultural groundwater pumping shown in **Figure 2.10** includes on lands in both New Mexico and Texas, whereas metered irrigation groundwater pumping data is available only for irrigation wells located in New Mexico. It is expected that simulated agricultural groundwater pumping for New Mexico and Texas should be greater than metered irrigation groundwater pumping for New Mexico only, and this is demonstrated in **Figure 2.10**.

Total simulated pumping for Rincon irrigation wells in the study area is on average 4 percent smaller than metered groundwater pumping. A similar comparison cannot be done for the Mesilla Basin, because metered pumping data for irrigation wells in the Texas portion of the Mesilla Basin are not available.

Agricultural groundwater pumping in Rincon and Mesilla basins varied through time depending principally on surface water availability. Groundwater pumping generally increased during years when surface water deliveries were low, and vice versa. The largest groundwater withdrawals occurred during the early to mid-1950s, and from 2003 through 2016, when surface water deliveries to farms were small for a multiple consecutive years. The smallest amount of groundwater pumping occurred during the period of full Project allotment from 1979 through 2002.

From 1938 through 2016, average annual groundwater pumping was about 100,000 AF in the Rincon Basin and 100,000 AF in the Mesilla Basin. However, widespread installation of irrigation wells to provide supplemental groundwater for irrigation did not begin in earnest until the 1950s drought, and it is therefore more meaningful to provide statistical summaries on groundwater pumping for crop irrigation beginning in the 1950s. From 1951 through 2016, average annual groundwater pumping was about approximately 29,000 AF in Rincon Basin and 265,000 AF in Mesilla Basin. From 1951 through 2016, groundwater contributed about 46% of total applied irrigation water supply in the Rincon Basin, and 43% of the total applied irrigation water supply in the Mesilla Basin.

During periods of limited surface water deliveries in the 1950s and from 2010 to 2016, the relative contribution of groundwater to the total applied water demand is substantially greater than during periods of full allocation, as occurred during the 1990s. During 2011, for example, groundwater contribution to total irrigation water supply exceeded 90% for both the Rincon and Mesilla Basins.

Monthly agricultural groundwater pumping to satisfy crop water demand is used directly as input to the groundwater budget for the entire study period from 1938 through 2016.

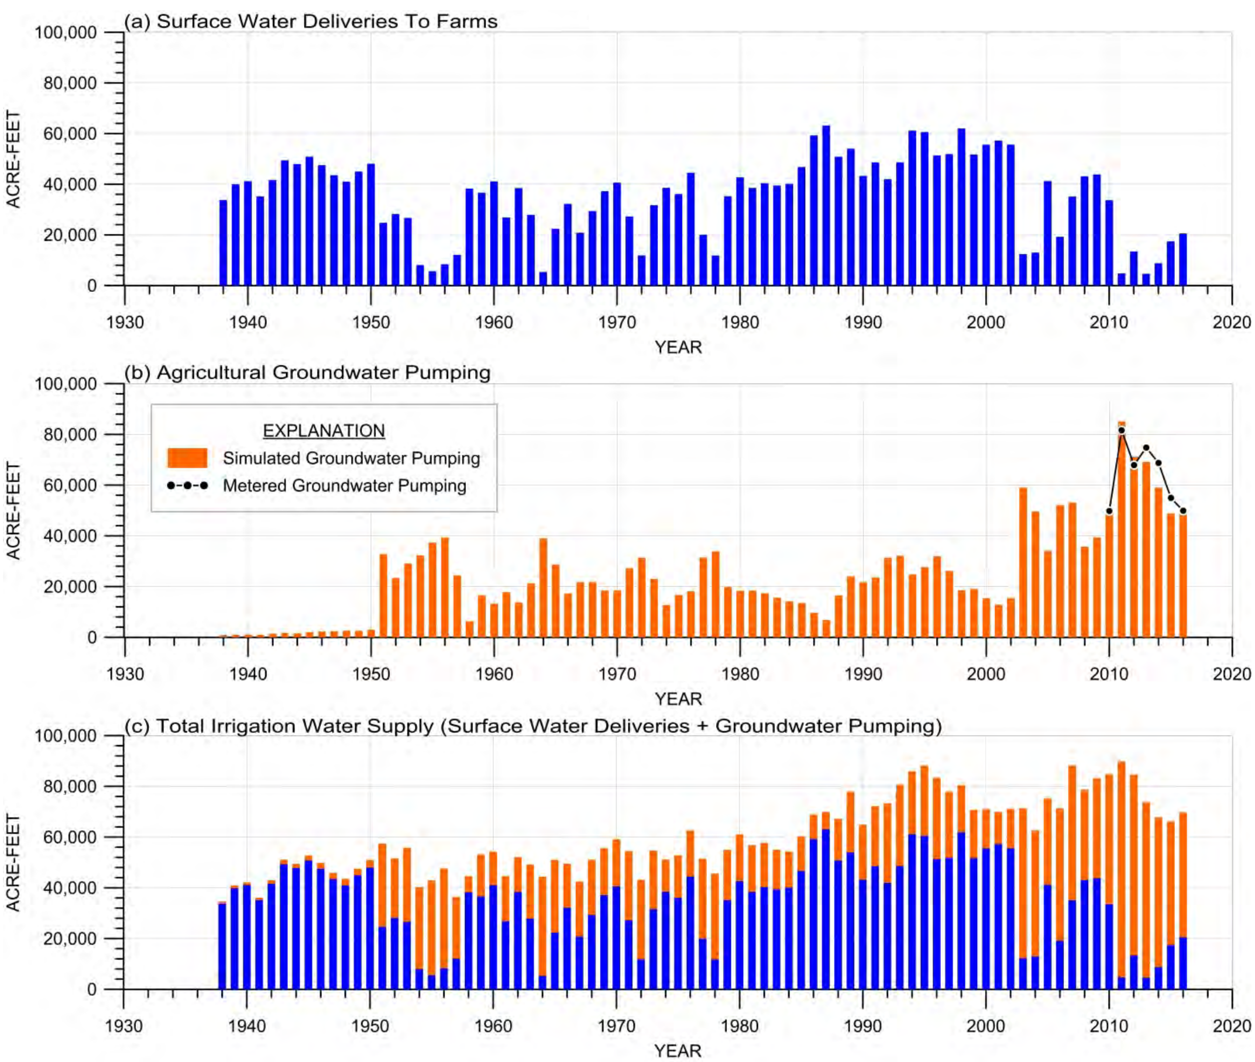

Figure 2.9. Annual Irrigation Water Supply, Rincon Basin: 1938 through 2016

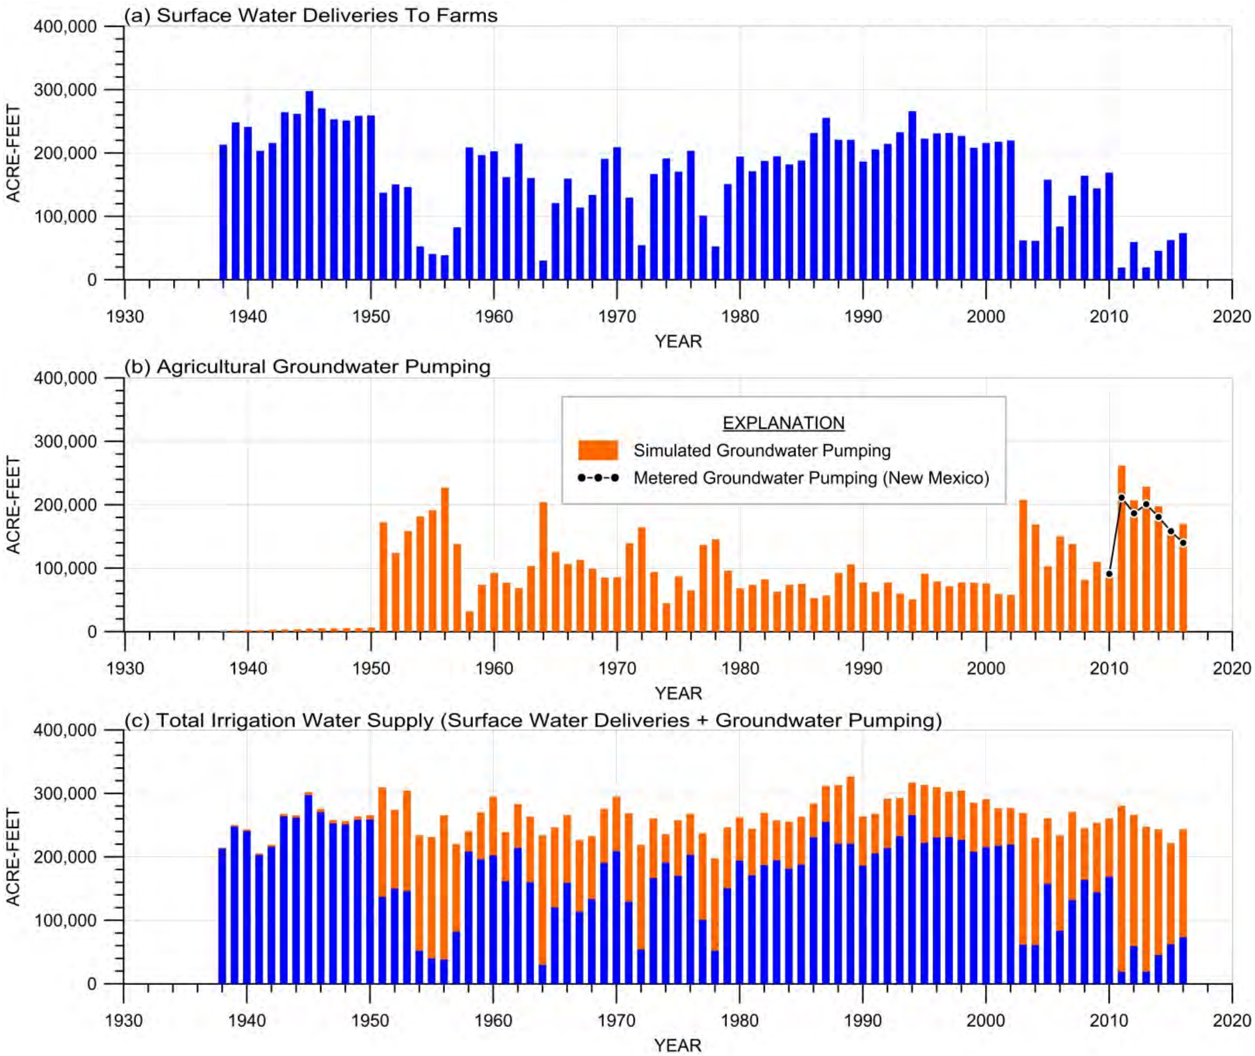

Figure 2.10. Annual Irrigation Water Supply, Mesilla Basin: 1938 through 2016

2.1.6.2 Agricultural Deep Percolation

Within the soil water balance model, monthly deep percolation is calculated as the sum of on-farm conveyance losses and field losses. From 1938 through 2016, field losses made up between 31% to 97% of total deep percolation annually in the Rincon Basin, and 47% to 95% in the Mesilla Basin. The average contribution of field losses to total deep percolation during this time was about 69% in the Rincon Basin and 70% in the Mesilla Basin. Average annual field losses were about 9,000 AF in the Rincon Basin and 39,000 AF in the Mesilla Basin.

Average annual total deep percolation – including both on-farm conveyance losses and field losses – was about 12,000 AF in the Rincon Basin and 55,500 AF in the Mesilla Basin.

Annual agricultural deep percolation in Rincon and Mesilla basins is shown on **Figures 2.11a and 2.12a**. Field losses include soil moisture derived from both applied irrigation water and precipitation; however, the contribution from applied irrigation water is substantially greater than contributions from precipitation. Monthly values of agricultural deep percolation calculated by the soil water balance model are used directly as input to the groundwater budget for the entire study period from 1938 through 2016.

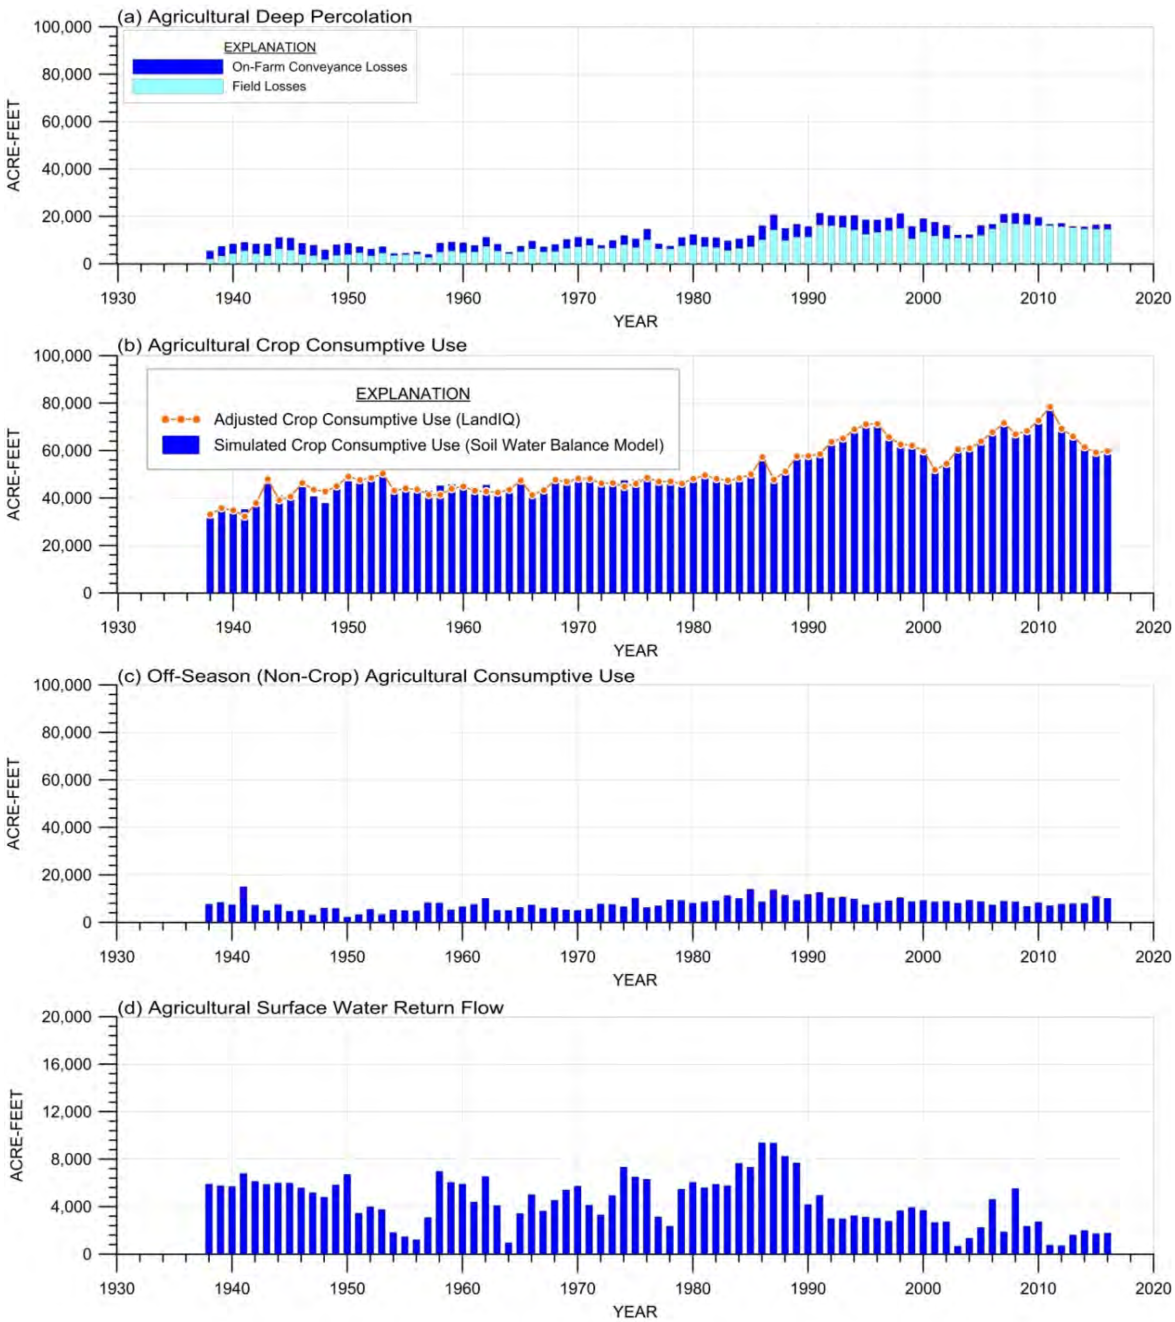

Figure 2.11. Annual Farm Water Budget Outflows in Rincon Basin

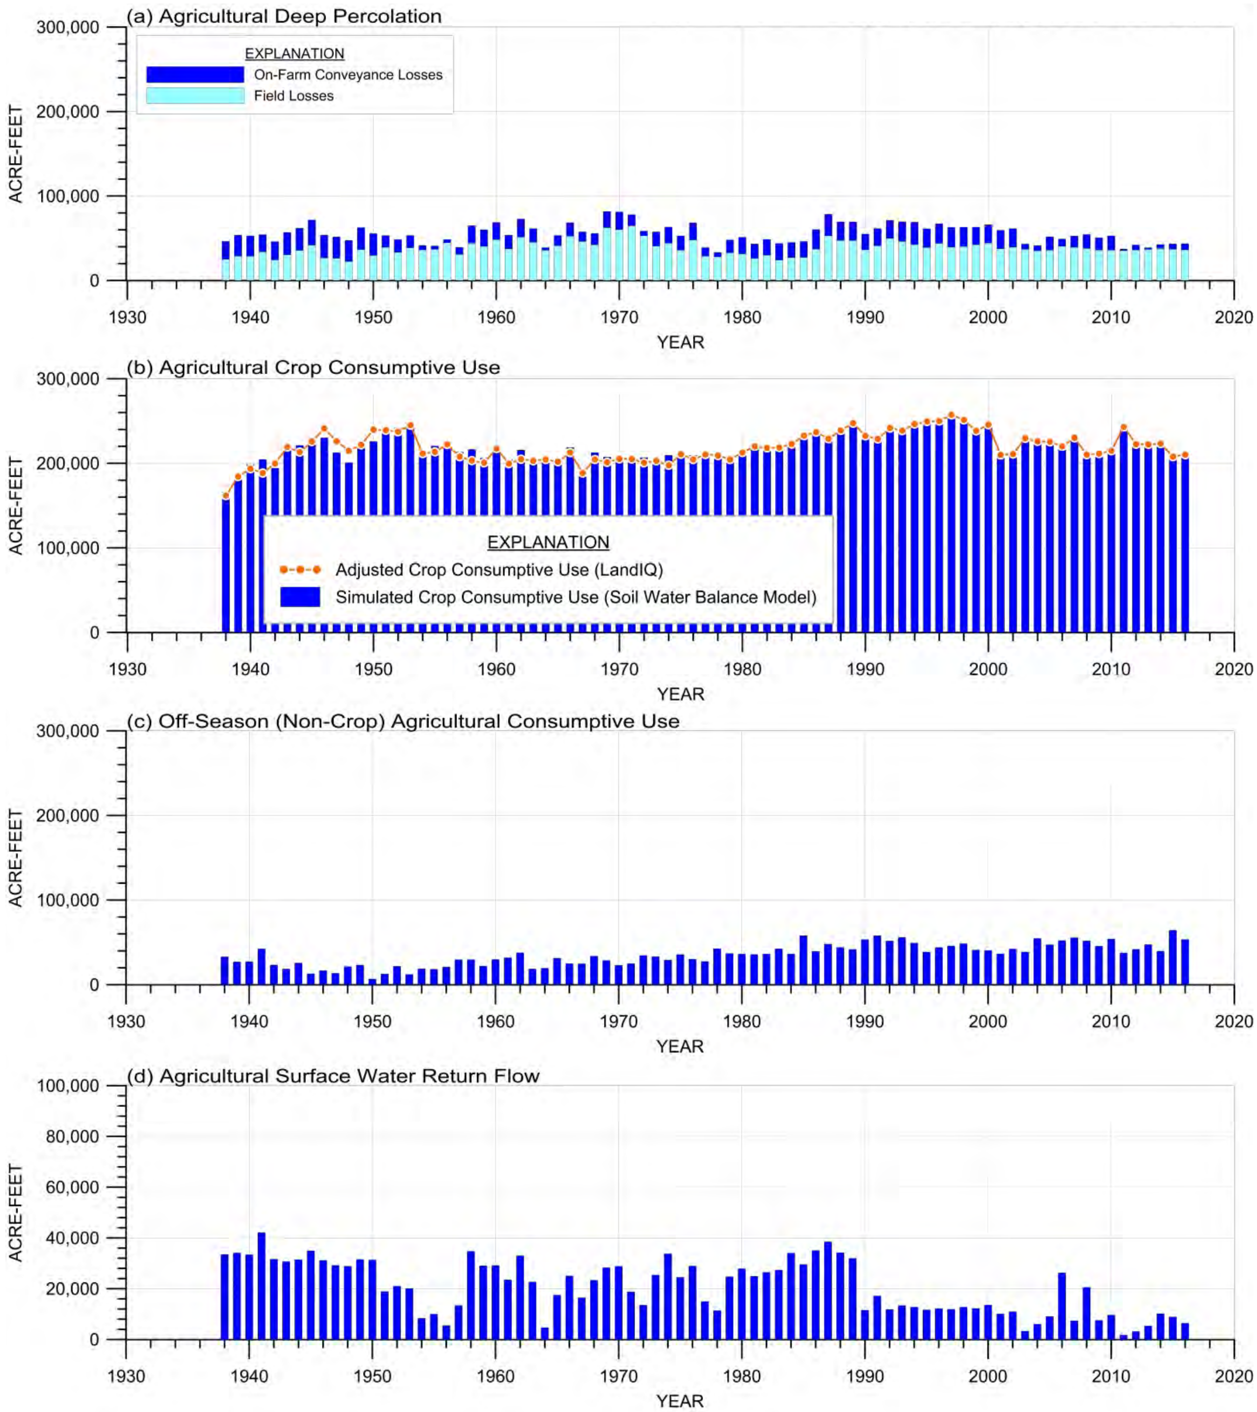

Figure 2.12. Annual Farm Water Budget Outflows in Mesilla Basin

2.1.6.3 Crop Consumptive Use

The soil water balance model computes crop consumptive use based on theoretical crop evapotranspiration rates and simulated soil moisture conditions. For this analysis, the monthly theoretical evapotranspiration rates are from crop consumptive use datasets prepared by Land IQ.

Crop AET is equal to the theoretical evapotranspiration when soil moisture is greater than or equal to critical soil moisture, as defined in Section 2.1.1. For non-cropped areas, bare soil ET is calculated as the product of the bare soil coefficients defined in Equations (26-27) and the reference ET rate, ET_o.

Annual crop consumptive use for Rincon and Mesilla basins are shown on **Figures 2.11b and 2.12b**. For reference, **Figures 2.11b and 2.12b** also show adjusted crop consumptive use, or AET, developed by Land IQ for the Rincon and Mesilla Basins, respectively. From 1938 through 2016, average simulated annual crop AET is about 52,000 AF for the Rincon Basin and about 220,000 AF for the Mesilla Basin.

Estimated annual volumes of off-season consumptive use, or soil evaporation from fallow farm lands in the Rincon and Mesilla basins are shown on **Figures 2.11c and 2.12c**. Average annual off-season consumptive use is estimated to be about 8,000 AF in Rincon Basin and about 35,000 AF in Mesilla Basin.

2.1.6.4 Agricultural Surface Water Return Flow

Surface runoff from agricultural land is assumed to occur both during irrigation events and in response to large storm events, during which rainfall rates would exceed the storage and infiltration capacity of on-farm infrastructure to capture and retain water flowing off of irrigated fields. Surface runoff of applied water was initially set based on typical values for New Mexico (Blaney and Hanson, 1965), and later adjusted as part of the soil water balance model calibration. Surface runoff of precipitation is estimated with empirical relationships for precipitation and runoff using the SCS curve number method (USDA, 2004), as previously described.

Agricultural surface water return flow to the surface water system is shown on **Figures 2.11d and 2.12d**. Runoff discharges from precipitation are highly variable due to varying precipitation. Average annual agricultural surface water return flow is estimated to be about 4,400 AF in the Rincon Basin and 20,600 AF in the Mesilla Basin.

2.1.6.5 Irrigation Efficiency

Water-resources studies in agricultural areas sometimes use the concept of farm irrigation efficiency both to forecast irrigation water demands and also to estimate historical rates of unmetered groundwater pumping. The term farm irrigation efficiency as used here is defined as the percentage of irrigation water applied that is available for crop consumptive use, based on irrigation water delivered to the farm headgates. Farm irrigation efficiency is not known with great precision for farm lands in the Rincon and Mesilla Basins.

The soil water balance model described in this report does not specify a value for the farm irrigation efficiency, but instead calculates the average farm irrigation efficiency over all farm lands in each basin. Farm efficiency is calculated on an annual time-scale to remove effects of soil moisture carryover between months.

Farm irrigation efficiencies are computed from soil water balance model results by dividing simulated crop AET by the total volume of applied water, including farm deliveries and farm groundwater pumping. The theoretical evapotranspiration provided as input to the soil water balance model was adjusted to remove effective precipitation, so that simulated crop AET reflects demands satisfied by applied irrigation water. These farm irrigation efficiencies are referred to as simulated irrigation efficiency because they are not specified as inputs to the model, but are instead calculated based on monthly rates of crop ET and groundwater pumping simulated using the soil water balance model. Differences between simulated crop AET and applied irrigation water are due to on-farm conveyance losses, farm tailwater losses, and field losses consisting of deep percolation past the base of the root zone.

Figure 2.13 shows simulated irrigation efficiency for the Rincon and Mesilla Basins. Simulated farm irrigation efficiency for the Rincon Basin varies between 55 percent and 85 percent, with an average value of about 70 percent. Simulated farm irrigation efficiency for the Mesilla Basin varies between 59 percent to 80 percent, with an average value of about 69 percent. These computed efficiencies are consistent with previously published values of irrigation efficiency at the basin scale, as discussed in the section 'Data Used for Model Calibration'.

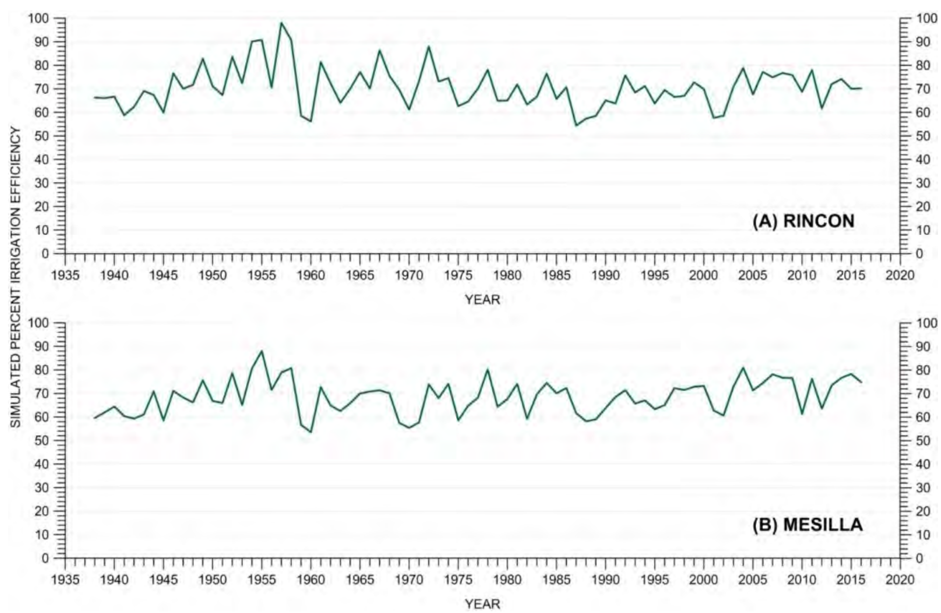

Figure 2.13. Simulated Irrigation Efficiency for Rincon and Mesilla Basins

US_MSJ_00001961

2.2 Non-Farm Water Budget

The terms P_{nf}, $GW_{app\text{-}nf}$, CU_{nf}, QSW_{nf}, WW, DP_{nf}, and GW_e in Equation 3 were quantified by developing non-farm water budgets. Non-farm lands in the study area include urban areas and undeveloped areas consisting primarily of native vegetation. The non-farm water budget is subdivided into urban lands and upland areas that are not classified as farm (agricultural) or urban (i.e., watershed area minus farm and urban areas) (**Figure 2.1**). The urban water budget is evaluated by water source: applied water and precipitation water. The applied water budget analysis is based on measured or estimated groundwater withdrawals (pumping), measured or estimated wastewater discharges, and estimates for consumptive use and deep percolation. The precipitation water budget analysis uses monthly precipitation and estimates for consumptive use (i.e., effective urban precipitation) and runoff to estimate urban deep percolation of precipitation. Use of surface water deliveries for non-farm purposes is minor compared to groundwater use and considered negligible for this analysis.

2.2.1 Urban Applied Water Budget

The urban (non-farm (nf)) applied water budget is defined by the following equation:

$$GW_{app\text{-}nf} = CU_{app\text{-}nf} + WW + DP_{nf} + GW_e \quad (35)$$

Each term contains several components, as follows:

$$GW_{app\text{-}nf} = GW_{MI} + GW_{DOM} + GW_{IMP} \quad (36)$$

$$CU_{app\text{-}nf} = CU_{POU} + CU_{WW} + CU_{DOM} \quad (37)$$

$$WW = WW_{SW} + WW_{EXP} \quad (38)$$

$$DP_{nf} = DP_{AW} + DP_{CL} + DP_{Septic} \quad (39)$$

Where,

GW_{MI} is municipal and industrial groundwater pumping;

GW_{DOM} is domestic groundwater pumping;

GW_{IMP} is imported groundwater from adjacent basins;

GW_e is exported groundwater to adjacent basins;

CU_{POU} is urban consumptive use of applied water at point of use;

CU_{WW} is consumptive use of wastewater;

CU_{DOM} is consumptive use of domestic pumping;

WW_{SW} is wastewater discharge to surface water;

WW_{EXP} is exported wastewater;

DP_{AW} is deep percolation of applied water.

DP_{CL} is deep percolation of conveyance losses; and

DP_{Septic} is deep percolation of domestic pumping via septic discharge.

The urban applied water budget was developed for specific municipal entities and rural users using reported or estimated groundwater pumping and wastewater datasets and estimates for consumptive use and deep percolation based on relevant information in available reports for the study area.

2.2.1.1 Urban Applied Water Inflows

Inflow terms for the urban applied water budget include urban groundwater pumping from wells within the basins and imported groundwater from wells outside the basins. The amount of surface water used to satisfy urban consumptive use is negligible compared to groundwater use in study area.

2.2.1.1.1 Urban Groundwater Pumping

Urban applied groundwater is the total volume of pumped groundwater that is used internally in the Rincon and Mesilla basins for non-irrigation purposes. Urban pumping in Rincon and Mesilla basins is described in Section 4.2.2 of this report. Urban groundwater inflows from the land-surface water budgets are outflows from the groundwater budgets.

2.2.1.1.2 Imported Groundwater

Imported groundwater is pumped groundwater that is conveyed into the Rincon or Mesilla basins from wells located outside the alluvium basin designated for this water budget analysis. In Rincon Basin, imported groundwater is served to the communities of Hatch and Rincon. Hatch receives groundwater from wells in the adjacent Nutt-Hockett basin to the west and Rincon receives groundwater from wells in the Jornada Basin to the east. In Mesilla Basin, a portion of water treated at the Las Cruces wastewater treatment facility is groundwater pumped from Moongate Water Company wells located in the adjacent Jornada Basin to the east. Montgomery & Associates tabulated imported groundwater volumes from metered pumping data reported in the NMOSE W.A.T.E.R.S. database for specific wells owned by the communities. According to metered pumping records, pumping from the wells identified as the sources of imported water began in 2000 in Rincon Basin and in 2003 in Mesilla Basin. The volumes of imported groundwater to Rincon Basin increased from about 55 AF in 2000 to about 475 AF in 2014. The volumes of imported groundwater to Mesilla Basin increased from about 20 AF in 2003 to about 650 AF in 2014. Imported groundwater is a minor source of water to the study area.

2.2.1.2 Urban Applied Water Outflows

Outflow terms for the urban applied water budget include wastewater discharge, consumptive use, deep percolation, and exported groundwater.

2.2.1.2.1 Urban Wastewater Discharge

The wastewater discharge term (WW) of the urban applied water budget equation consists of wastewater discharge to the surface water network (Rio Grande) and exported wastewater.
A portion of urban groundwater pumping is discharged to the surface water system as treated wastewater. Treated wastewater is discharged into the surface water system from multiple discharge facilities in the Rincon and Mesilla basins. Information on monthly wastewater discharges was obtained from the United States Environmental Protection Agency (EPA) (2016) for 2000 through 2016. For years without EPA discharge data, we estimated wastewater discharges for the selected facilities using relationships between pumping and wastewater discharges during years when both datasets were available. Wastewater discharges were assumed to begin during the year when each facility was constructed.

According to the U.S. EPA's online Discharge Monitoring Report (DMR) Pollutant Loading Tool, the largest wastewater discharge facilities in the Rincon and Mesilla basins include:
City of Las Cruces - Utilities (Jacob Hands WTF), Sunland Park WWTP, Anthony Water and Sanitation District, El Paso Electric – Rio Grande Generating Station, Dona Ana County Utilities Department, El Paso's Northwest WWTP (John T. Hickerson Reclamation Facility), Salem WWTP, and Village of Hatch. The Hatch and Salem facilities are located within Rincon Basin; the remaining facilities are located within Mesilla Basin. We obtained wastewater discharge data and reclaimed water use data from El Paso Water Utilities for this analysis. Discharge data for 1989 through 2016 were used for the El Paso WWTF.

Annual estimated and reported wastewater discharges into the surface water network in each basin is shown on **Figures 2.14a and 2.15a**. Wastewater discharges in Mesilla Basin steadily increased through time from the 1950s through 2016. Wastewater treatment plants in Rincon Basin were built in in the late 1990s and discharge a relatively small amount of treated wastewater into the surface water system.

The El Paso WWTF discharges treated wastewater to the Rio Grande downgradient from the Mesilla basin outlet specified for this study, which is located at the USGS Rio Grande at El Paso stream gaging station. Because they occur downgradient from the study area, the El Paso wastewater discharges are categorized as exported groundwater for this water budget analysis, as described in subsequent sections of this report.

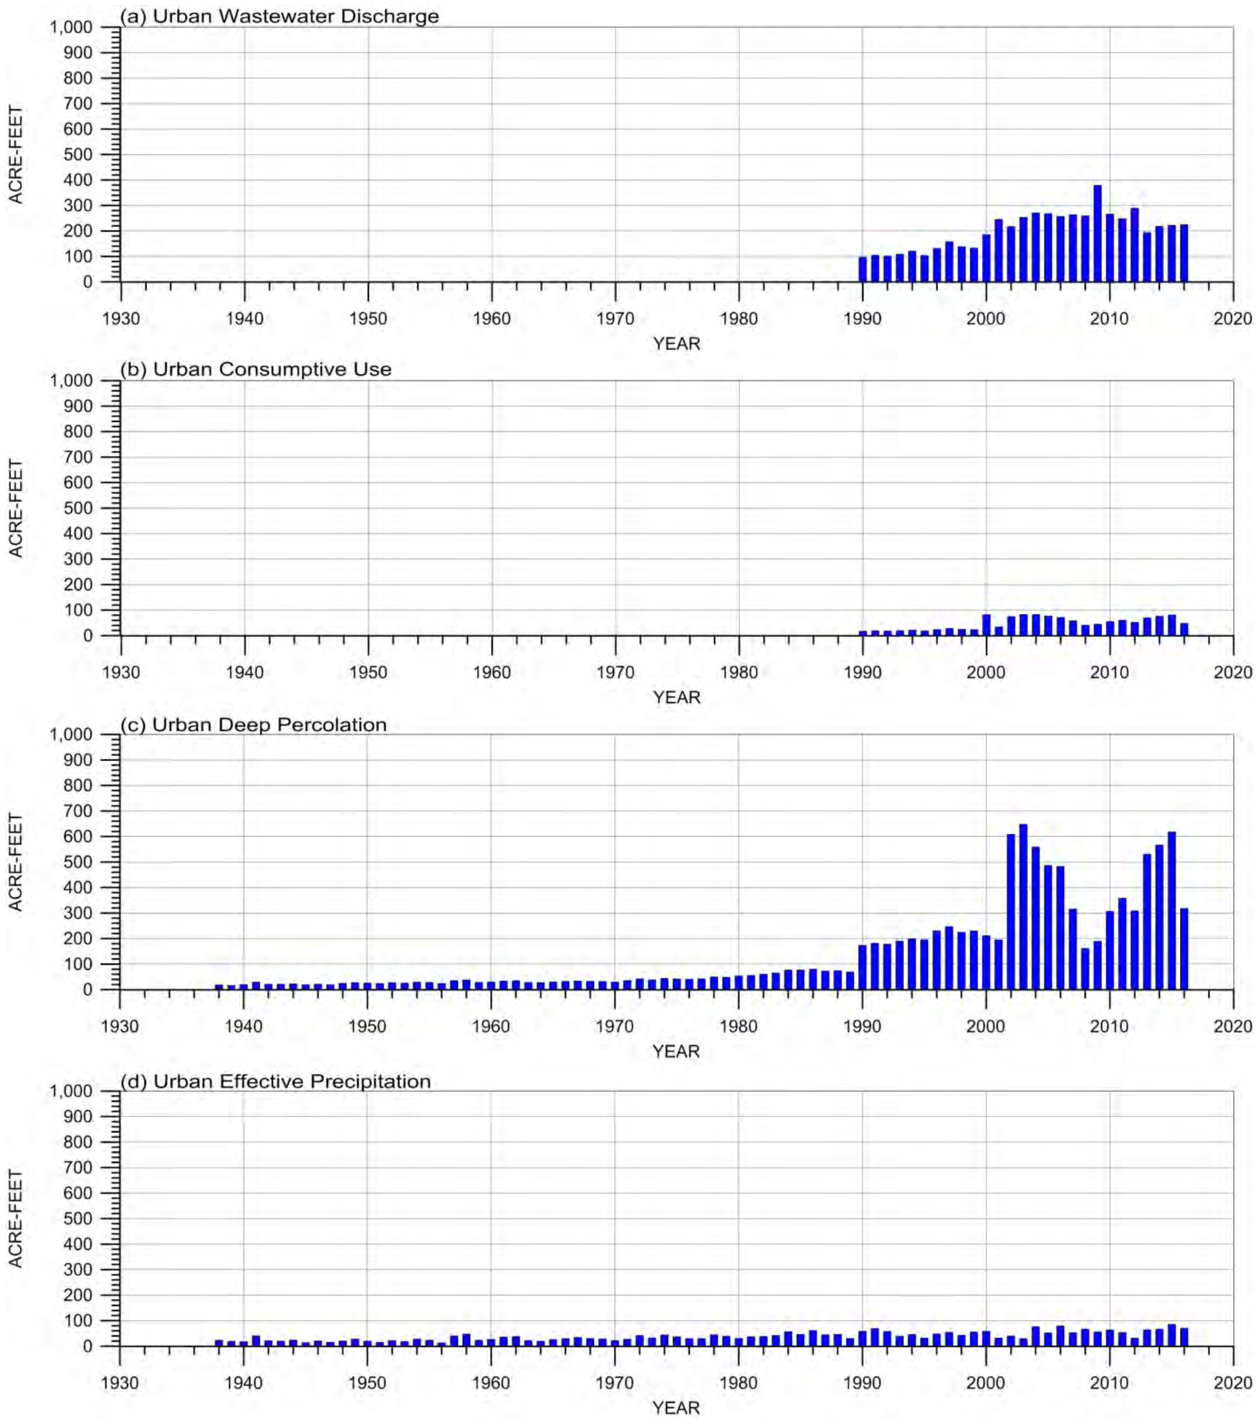

Figure 2.14. Selected Estimated Annual Urban Water Budget Components for Rincon Basin

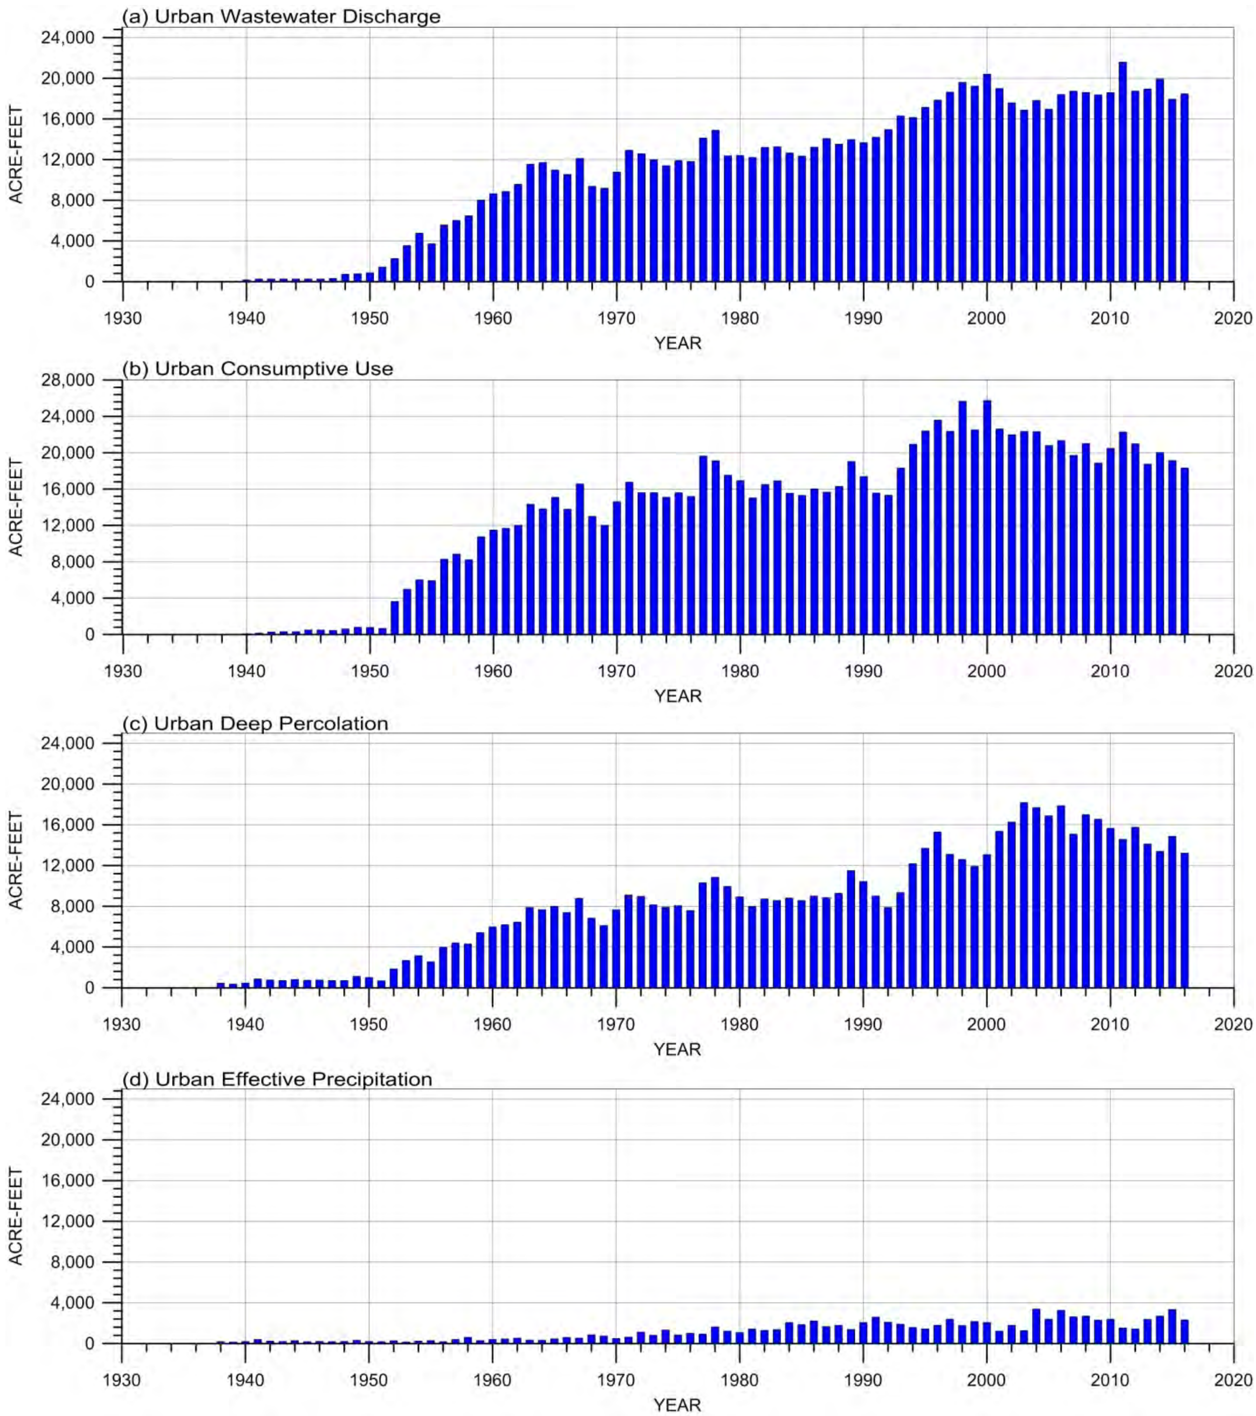

Figure 2.15. Selected Estimated Annual Urban Water Budget Components for Mesilla Basin

2.2.1.2.2 Urban Consumptive Use

The urban consumptive use of applied water term ($CU_{app\text{-}nf}$) of the urban applied water budget equation consists of consumptive use at point-of-use, consumptive use of treated wastewater, and consumptive use of domestic pumping. Consumptive use at point-of-use of applied water is calculated as a percentage of urban applied groundwater (municipal and industrial (M&I) pumping) for each municipal entity. For Las Cruces, a consumptive use estimate of about 36 percent of applied groundwater is used for this analysis for 1938 through 1951, and 47 percent of applied groundwater for 1952 through 2016 based on the Las Cruces 40-Year Plan prepared by JSAI (2008; 2017) and third party review by Greg Young. The increase in percent of applied water represents an increase in irrigation for outdoor landscaping. These percentage estimates were initially applied as constant values during the analysis period. However, they were reduced for months when data show that applied groundwater supplies were smaller than estimated urban consumptive use. For a given month when the percent estimate was larger than groundwater supply, urban consumptive use was estimated as the residual of the urban applied water budget (with zero going to deep percolation of applied water). Based on this approach, on average, annual urban consumptive use of applied water is approximately 27 percent of applied groundwater for 1938 through 1951 and approximately 38 percent for 1952 through 2016. For El Paso, consumptive use estimates of 40 percent (pre-2000) and 33 percent (post-2000) of applied groundwater are specified based on results of a study by Mermitte and Mace (2012). For urban entities without reported consumptive use data, consumptive use of applied water is assumed to be on the order of 10 to 50 percent of the total applied water supply for those entities, based on the Las Cruces 40-Year Plan and adjusted to account for other water budget components for the communities. Groundwater used by the El Paso Electric plant is assumed to be 100 percent consumed; for this analysis, wastewater discharges from this facility are assumed to be from reclaimed water supplied by El Paso Water Utilities. Outdoor urban applied water is assumed to be 100 percent consumed.

Consumptive use of wastewater occurs when the water is discharged into lined ponds where it is fully consumed by evaporation processes, or when the water is reused by reclaimed water programs. Groundwater that is pumped from a few Las Cruces supply wells is conveyed to the West Mesa wastewater treatment facility where it is treated and discharged by sprinklers over a patch of land and fully consumed by evapotranspiration processes (JSAI, 2008). A portion of El Paso wastewater is consumed by reuse as reclaimed water. Wastewater from the town of Anthony, Texas and all other entities are fully consumed unless otherwise previously described for Urban Wastewater Discharges. Prior to the construction of the El Paso Northwest WWTF, wastewater is assumed to have been discharged to lined ponds where the water was fully consumed by evaporation processes.

Consumptive use of septic discharge from domestic pumping is calculated as 55 percent of pumped groundwater if the pumped well is within 1 mile from the Rio Grande. Groundwater withdrawals from domestic wells located outside the 1-mile corridor are 100 percent consumed by evaporation processes. This approach is based on methods described in a domestic well study for New Mexico by NMOSE (2000).

Estimated annual urban consumptive use of applied water (groundwater) for Rincon and Mesilla basins is shown on **Figures 2.14b and 2.15b**. Urban consumptive use of groundwater is relatively small in Rincon Basin. Urban consumptive use of groundwater in Mesilla Basin has gradually increased through time from the 1950s until about 2000. After about 2000, urban consumptive use stabilized or slightly declined through 2016.

2.2.1.2.3 Urban Deep Percolation

Deep percolation term consists of deep percolation of applied water, domestic pumping septic discharge, and conveyance losses.

Deep percolation of applied water is calculated as a residual from the difference between total applied groundwater and all the losses from total consumptive use, total wastewater discharge, conveyance losses, and deep percolation of septic discharge from domestic wells. In some instances, the residual calculation resulted in negative deep percolation, which is physically impossible. For these times, urban consumptive use and deep percolation of urban conveyance losses were adjusted in a manner that prevented the deep percolation estimate from being negative.

Estimated annual deep percolation of urban applied groundwater for Rincon and Mesilla basins is shown on **Figures 2.14c and 2.15c**. Urban deep percolation of applied water in Mesilla Basin gradually increased from smaller than 1,000 AF in the 1950s to larger than 15,000 AF by 2005.

Deep percolation from domestic well septic discharge is calculated as 45 percent of pumped groundwater if the domestic well is within 1 mile of the Rio Grande. Deep percolation of domestic well septic discharge does not occur outside the 1-mile corridor because all the water is fully consumed by evaporation process. This approach is based on methods described in a domestic well study for New Mexico by NMOSE (2000).

Deep percolation from conveyance losses are calculated as a percentage of applied groundwater. Conveyance losses occur from leaks along the distribution pipelines and booster stations.
No evidence exists for substantial flows of groundwater into the water or wastewater conveyance systems, presumably because depths to groundwater are relatively large in the urban areas with substantial conveyance infrastructure. Las Cruces conveyance losses are approximately 13 percent of applied groundwater according to the Las Cruces 40-Year Plan by JSAI (2008). El Paso has conveyance losses of approximately 7 percent, based on average of reported percentages from the EPWU 2014 Conservation Plan. All other entities have an assumed conveyance loss of 5 or 10 percent of applied groundwater, which is generally within the range

of Las Cruces and El Paso values. Conveyance loss percentages for the other entities were adjusted in their respective applied water budgets to prevent deep percolation of applied water from being negative, as previously described.

2.2.1.2.4 Exported Groundwater

Groundwater exports occur as wastewater discharges downstream from the basin outlet and as groundwater from the Mexico portions of Mesilla Basin conveyed to Ciudad Juarez outside the basin.

Wastewater discharges occur from the John T. Hickerson Water Reclamation Facility in northwest El Paso at the southern end of Mesilla Basin. This facility is supplied by pumped groundwater from wells in Mesilla Basin. The majority of wastewater treated at this facility is discharged directly to the Rio Grande downstream from the Mesilla Basin outlet designated for this analysis. The portion of treated effluent that is not discharged to the river is used in El Paso's Northwest Wastewater Reclamation Facilities Project in northwest El Paso. We obtained monthly effluent discharge data from the City of El Paso for the Hickerson facility. According to the wastewater data, effluent discharges to the river began in 1989 and continue through present day. This effluent discharge is treated as groundwater export because the water is Mesilla groundwater that is discharged to the river outside the Mesilla Basin water budget study area. These exported groundwater rates ranged from about 5,000 AF in 1990 to about 9,700 AF in 2000, and then declined slightly after 2000 when the reclaimed water project began operations.

In 2010, Ciudad Juarez began pumping groundwater from its constructed wellfield in the Conejos-Medanos aquifer for supplemental municipal water supply. Water is conveyed from the wellfield to Ciudad Juarez, located approximately 15 miles to the east in the adjacent Hueco Bolson (or El Paso Valley), via the Conejos-Medanos Aqueduct. Pumping from the Conejos-Medanos wellfield is summarized in Chapter 4.2.3 of this report.

2.2.2 Urban Precipitation Water Budget

The urban precipitation water budget was developed over a control area defined by the maximum extent of urban land in the basins. For this analysis, urban lands are spatially defined as the extent of high-density urban areas as developed by Land IQ. The increasing acreage of urban lands through time is incorporated into this analysis. The maximum urban extent for each basin was defined as the maximum spatial extent of areas delineated for high density urban mapping years by Land IQ: 1,021 acres for Rincon Basin and 38,209 acres for Mesilla Basin. The maximum extents of urban lands are shown on **Figure 2.2**. The cities of Las Cruces and El Paso are the most prominent urban areas in Mesilla Basin; the village of Hatch is the main urban area in Rincon Basin.

For each high density urban mapping year, the disposition of lands within the fixed maximum urban extent was defined. Specifically, the acreage of agricultural, non-agricultural/non-urban, and high-density urban lands were defined for this analysis. Changes in land use composition within the Rincon and Mesilla basins has resulted in declining acreage of agricultural and non-agricultural/non-urban lands and increasing acreage of high-density urban lands. For this analysis, the maximum extent of urban lands is referred to as the urban control area, where the total area remains constant but relative proportions of land uses change through time. Representative changes in land use within the urban control area are shown on **Figure 2.16**.

Changes in land use within the maximum urban extent for Rincon and Mesilla basins are pertinent to the non-farm water budget because the land use type directly determines the acreages to be considered in certain components of the urban precipitation water budgets. The urban precipitation water budget is defined by the following equation:

$$P_{urb} = P_{eff\text{-}urb} + CU_{P\text{-}urb} + QSW + DP_P \qquad (40)$$

Where,

P_{urb} is total precipitation falling on urban lands;

$P_{eff\text{-}urb}$ is effective precipitation for urban landscaped areas (consumptive use);

$CU_{P\text{-}urb}$ is consumptive use of precipitation on undeveloped areas within the urban lands control area;

QSW is surface water return flows from urban lands (urban runoff); and

DP_P is deep percolation of precipitation falling on urban lands.

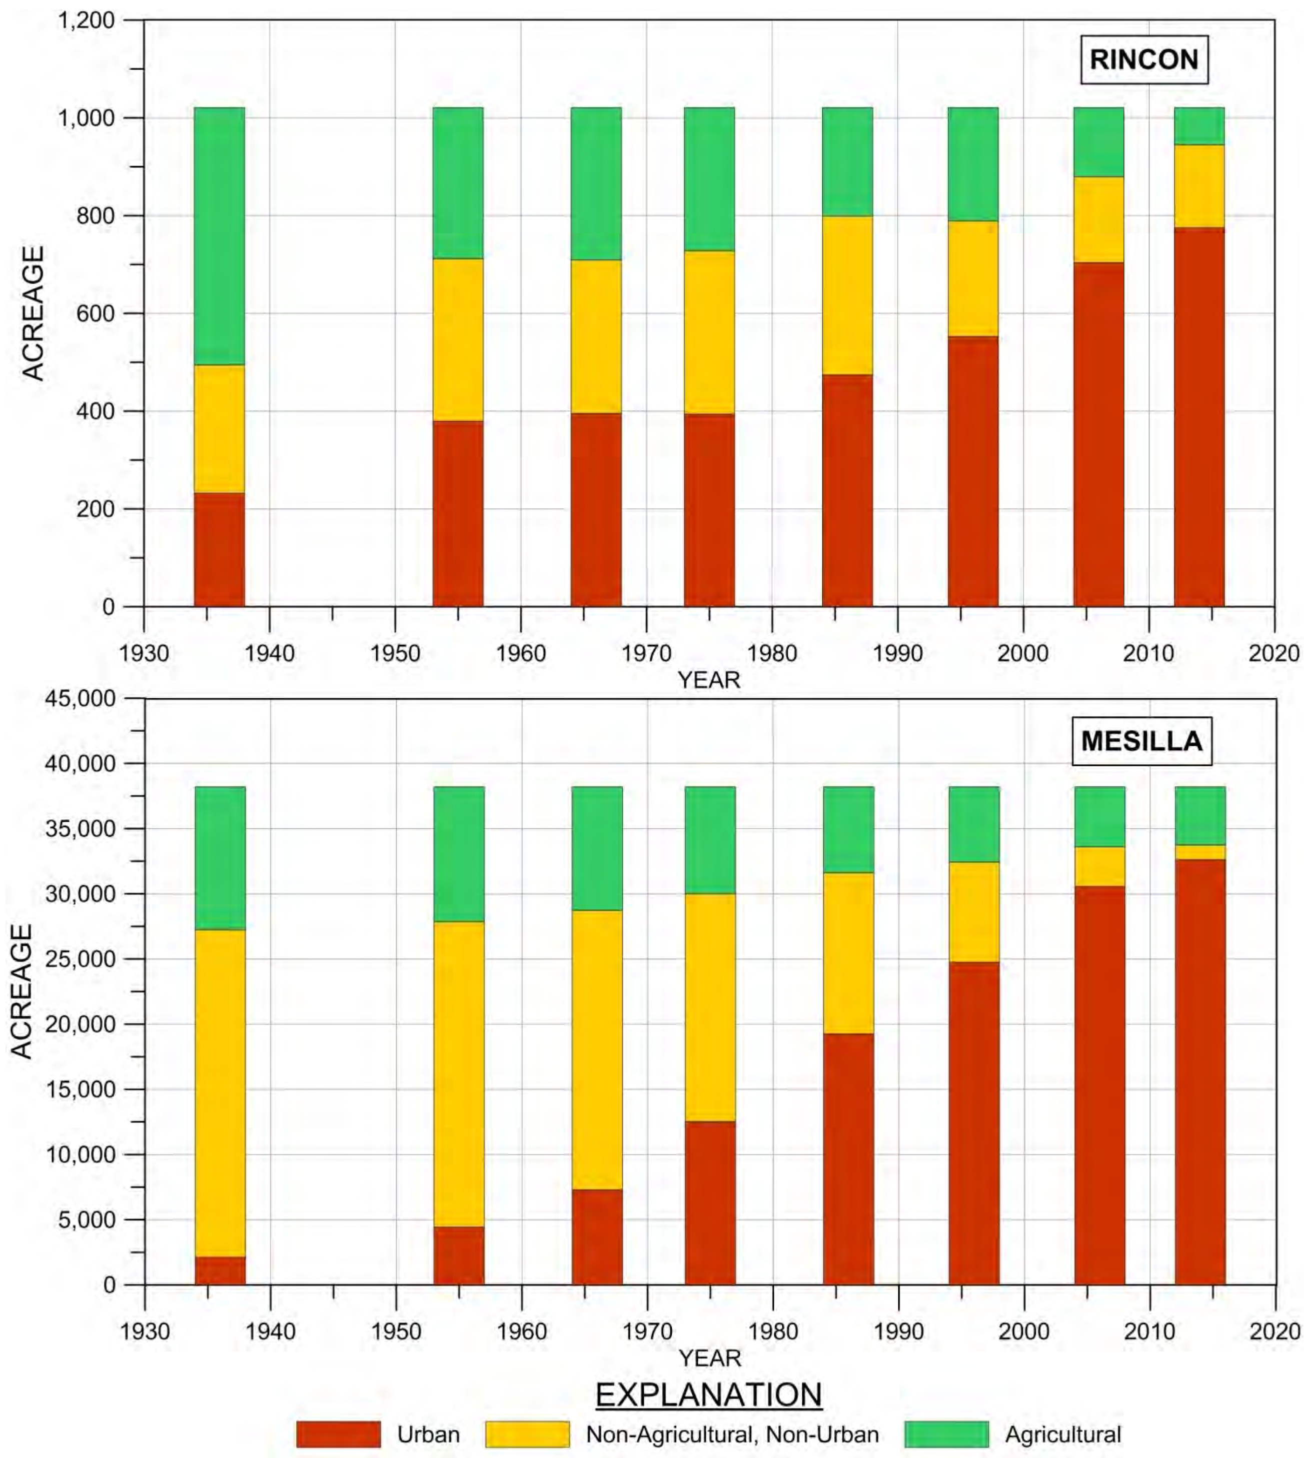

Figure 2.16. Changes in General Land Use Acreages within Maximum Extents of Agriciltural and High-Density Urban Lands in Rincon and Mesilla Basins

2.2.2.1 Total Precipitation

Some of the precipitation falling on urban lands contributes toward satisfying urban consumptive use in the form of irrigated landscaping such as turfgrass in parks and playing fields, gardens, trees, and shrubs – this is defined as urban effective precipitation, and occurs by definition within urbanized areas. The remaining precipitation falling on urban lands either produces return flows to the surface water network, urban deep percolation, or is lost to the atmosphere as evapotranspiration from undeveloped, non-agricultural lands. Total monthly volumetric urban precipitation is calculated as the area-weighted average monthly precipitation rate from PRISM for lands within the maximum extent of urban area, multiplied by the urban control area. The PRISM dataset is previously described in Section 2.1.1 of this report and annual urban precipitation is included in **Table 2.1**. Acreages were estimated by linear interpolation between high density urban mapping years.

2.2.2.2 Effective Precipitation on Developed Urban Lands

Effective precipitation is the amount of rainfall that is used to meet evapotranspiration of growing vegetation. Urban effective precipitation is conceptualized for this analysis as the portion of precipitation falling on urban areas that satisfies a portion of urban consumptive use. For this analysis, irrigated landscaping is the only category of urban consumptive use that can be satisfied by effective precipitation. Other urban consumptive uses are satisfied by applied water and are incorporated into the urban applied water budgets described in previous sections of this report. Monthly rates of urban effective precipitation were calculated separately for the Rincon and Mesilla Valleys based on the USBR method (Stamm, 1967) previously described in Section 2.1.2 of this report. These relations require as data inputs the total monthly precipitation, the depth of usable soil water storage, and the total monthly evapotranspiration that may be satisfied by precipitation.

Monthly precipitation rates were used as developed from the PRISM dataset, and described previously in section 2.1.2. Warm-season turfgrass is judged to be representative of urban consumptive use for landscaping. The soil water storage depth (1.5 inches) and monthly ET (range from 0 to 0.265 inches per month, total of 3.1 feet per year) are defined based on rooting depth and seasonal ET reported by Leinauer and Smeal (2012).

Volumetric monthly effective precipitation is calculated by multiplying the effective precipitation rate and the total area over which precipitation can contribute to urban consumptive use. That area is defined in turn by the total area of high-density urban land for the Rincon and Mesilla basins, as determined by Land IQ, multiplied by a coefficient representing the fraction of high-density urban land that consists of landscaped area. The fraction of high-density urban lands that consists of landscaped vegetation was estimated using point sampling and remote sensing methods. This assessment used a LANDSAT 8 multispectral satellite image with Normalized Difference Vegetation Index (NDVI) data from July 2013 to identify the type of urban vegetation within each 90-foot by 90-foot pixel of the image. This analysis does not attempt to characterize detailed changes in land use through time. Instead, the July 2013 image is used to represent a regional approximation of percentage of lands in each basin with dense vegetation. The image was clipped to the mapped high-density urban lands shown on **Figure 2.2**. Each image pixel contains an NDVI value representing the average vegetation type within the pixel area. The NDVI value for each pixel was extracted to a point location located at the center of the pixel. A total of 292,969 uniformly-spaced pixel points are located within the mapped urban areas within the study area. Points with NDVI values equal to or greater than 0.3 are considered to be dense landscape vegetation for this analysis. A NDVI value of 0.6 was initially applied for dense vegetation, based on estimates by the USGS Remote Sensing Phenology program (USGS, 2017). However, the value was decreased to 0.3 based on comparisons with vegetation visible in aerial imagery. Higher NDVI values result in substantial turf and other heavily vegetated areas not being assigned as dense vegetation.

The percent landscaped area was determined by dividing the number of points classified as "dense vegetation" by the total number of points located within the mapped high-density urban lands. The results of this point sampling assessment indicates that approximately 11 percent of all high-density urban acreage in Rincon and Mesilla basins is landscaped and contributes to urban consumptive use of precipitation. **Figure 2.17** shows the point sampling results for an example area in the City of Las Cruces in Mesilla Basin. **Figures 2.14d and 2.15d** show the time-series of volumetric urban effective precipitation as calculated by the procedure previously described.

Figure 2.17. Example Results of Point Sampling for Estimating Landscaped Urban Vegetation Acreage

2.2.2.3 Urban Runoff (Return Flows)

Average annual pre-development return flows to the surface water network, including direct runoff and lateral flow in soils, were estimated by Tetra Tech (2015) for the Las Cruces area to be 0.18 inches per year (in/yr), or 1.9 percent of average annual precipitation, with 0.52 percent direct runoff and 1.35 percent lateral flow. These percentages were applied to all mapped urban lands in the basins. Adjusting the analysis to account for different watershed characteristics in the El Paso area would result in only slight changes in total basinwide estimates, and thus was not incorporated into this analysis. Expansion of impervious surfaces such as pavement and roofing, associated with urbanization, increases surface runoff. The effect of urbanization on surface runoff in southern New Mexico has not been previously quantified. The effect of urbanization on surface runoff due to residential expansion in southern Arizona, for which climate, vegetation, and soils are similar, showed that surface runoff is 26 times greater in a residential area than in undeveloped land (Kennedy and others, 2013). Using this estimate, it is assumed that surface runoff increases from 0.52 percent to 14 percent of average annual precipitation. It is further assumed that lateral flow in soils is eliminated due to urbanization. The net effect is that return flows to the surface water network increase from 1.9 percent to 14 percent of precipitation.

2.2.2.4 Urban Deep Percolation of Precipitation

Precipitation water at the land surface that is not consumptively used or returned to the surface water network is assumed to percolate below the root zone, ultimately becoming groundwater recharge. Average annual pre-development deep percolation rate in Las Cruces was estimated by Tetra Tech (2015) to be 0.13 in/yr, or about 1.35 percent of average annual precipitation. These percentages were applied to all mapped urban lands in the basins. Adjusting the analysis to account for different watershed characteristics in the El Paso area would result in only slight changes in total basinwide estimates, and thus was not incorporated into this analysis. For this analysis, the percentage was increased (doubled) to 2.7 percent of annual precipitation to account for potential increase in deep percolation from stormwater retention and detention structures.

2.2.2.5 Evapotranspiration from Undeveloped Urban Lands

ET from bare soil and from native vegetation is the residual term in the urban precipitation water budgets and is calculated as the difference between total inflows and the sum of all remaining outflows. Results indicate that ET from undeveloped urban lands decreases through time as a result of the decrease in undeveloped acres through time. Estimated annual ET from undeveloped urban lands is about 84 and 92 percent of annual precipitation in Rincon and Mesilla basins, respectively, during the 1940s and 1950s and then gradually decreases to about 77 and 74 percent, respectively, by 2016.

The portion of local precipitation that ultimately becomes ET has been estimated by surface water modeling studies of pre-development conditions in urbanized areas in the state of New Mexico by Tetra Tech (2015). The results of these studies indicate that the average annual ET in Las Cruces under pre-development conditions was 9.31 in/yr, or 97 percent of average annual precipitation. For this analysis, total urban ET is equal to effective precipitation on developed urban lands (previously described) plus ET on undeveloped urban lands (described in this section). Estimated total urban ET is about 90 and 94 percent of annual precipitation in Rincon and Mesilla basins, respectively, in the 1940s and 1950s and then gradually declines to about 85 percent in both basins by 2016 due principally due to expansion of developed areas.

2.2.3 Upland Watershed Water Budget

The upland watershed water budget is defined by the following equation:

$$P_{WS} = CU_{SW} + QSW_{Trib} + DP_{MFR} \tag{41}$$

Where,
P_{WS} is total precipitation falling on upland watershed areas (non-farm, non-urban lands);
CU_{SW} is consumptive use of P_{WS} by native plant transpiration (excluding riparian) and soil evaporation (ET);
QSW_{Trib} is surface water return flows to the Rio Grande from contributing tributaries; and
DP_{MFR} is deep percolation to groundwater from P_{WS} (mountain-front recharge).

Precipitation falling on the upland watershed surrounding the urban and farm areas (**Figure 2.2**) in the study area ultimately is lost to ET, runoff, and mountain front recharge. Precipitation falling on the non-farm, non-urban areas of the upland watershed is summarized in **Table 2.1**. The runoff outflow component of this water budget is the tributary inflow component in the Surface Water Budget. Methods used for estimating tributary inflows are described in Section 3.1.2 of this report. Mountain-front recharge is an inflow component to the Groundwater Budget, as described in Section 4.1.4.

Consumptive use of precipitation falling on the upland watershed areas in the basins is computed as the residual term in the upland watershed water budget. This term is computed as precipitation minus the sum of tributary return flows and mountain-front recharge. The vast majority of this precipitation is consumed by evapotranspiration processes. Areal recharge in the basins is assumed to be negligible; instead, recharge is represented as mountain-front recharge.

3 SURFACE WATER BUDGET

When applied to the surface water budget, Equation (1) becomes:

$$[Q_{SW\text{-}in}] - [Q_{SW\text{-}out}] = \Delta S_{SW} \qquad (42)$$

Where, $Q_{SW\text{-}in}$ is surface water inflows; $Q_{SW\text{-}out}$ is surface water outflows; and ΔS_{SW} is the change in storage within the surface water network.

Considering all components of the surface water budget, Equation (42) becomes:

$$[RG_{in}+TF+QSW_f+QSW_{nf}+WW+Q_{GW\text{-}in}] - [RG_{out}+SW_f+ID_f+EOC_{RG}+Q_{GW\text{-}out}] = \Delta S_{SW} \qquad (43)$$

Where,

RG_{in} is Rio Grande inflows;
TF is tributary inflows from upland arroyos;
QSW_f is surface water return flows from farm lands (farm tailwater);
QSW_{nf} is surface water return flows from non-farm lands (runoff);
WW is urban wastewater discharges to Rio Grande;
$Q_{GW\text{-}in}$ is groundwater inflows to the surface water network;
RG_{out} is Rio Grande outflows;
SW_f is applied surface water to farms (farm deliveries);
ID_f is farm incidental depletions;
EOC_{RG} is open channel evaporation along Rio Grande; and
$Q_{GW\text{-}out}$ is surface water outflows to groundwater.

Assuming that the storage changes within the surface water network are negligible each month, Equation (43) can be used to solve the net groundwater-surface water exchange as the following:

$$Q_{GW\text{-}SW} = Q_{GW\text{-}out} - Q_{GW\text{-}in} = (\text{sum of outflows}) - (\text{sum of inflows}) = RG_{out}+SW_f+ID_f+ EOC_{RG} -RG_{in}-TF-QSW_f-QSW_{nf}-WW \qquad (44)$$

Where, $Q_{GW\text{-}SW}$ is net groundwater-surface water exchange, which includes interactions along the river, canals, and drains. No direct measurements of the groundwater-surface water exchanges are available; however, all other components of the surface water budget can be derived from available data or the analysis of available data. The net groundwater-surface water exchange is estimated as the quantity required to close the surface water budget.

Figure 3.1 provides a graphical depiction of Equation (44).

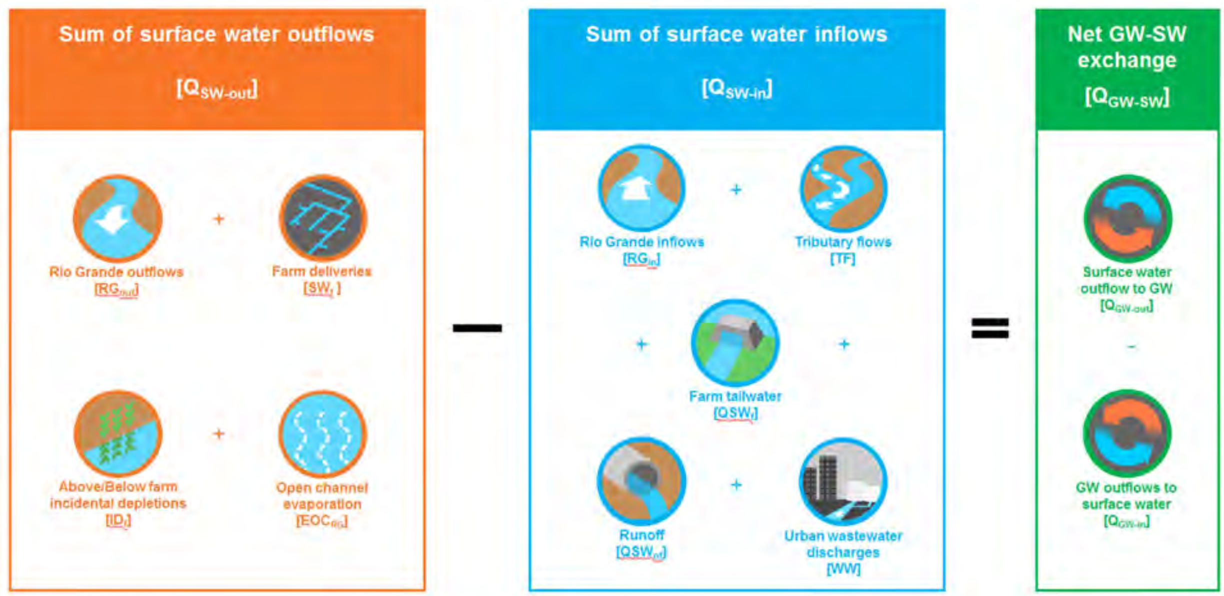

Figure 3.1. Graphical Depiction of Surface Water Budget Equation

The surface water budget and relationships with the land-water and groundwater budgets are shown on **Figure 1.2**. Farm deliveries are an input to the land-surface water budget. Net groundwater-surface water exchange is an input to the groundwater budget.

The monthly, basin-wide surface water budgets for Rincon and Mesilla basins are summarized in the accompanying dataset named *IntegratedWaterBudgets.xlsx*. Annual surface water budgets for Rincon Basin and Mesilla Basin are summarized in this chapter of the report and tabulated in **Appendices B1 and B2**.

3.1 Surface Water Inflows

3.1.1 Rio Grande Inflow

The Rio Grande enters Rincon Basin at a bedrock constriction at Caballo Dam and then flows generally southeastward to the bedrock constriction in Selden Canyon, which effectively separates Rincon Basin from Mesilla Basin. The Rio Grande enters Mesilla Basin at Selden Canyon, upstream from Leasburg Dam, and then flows southward through Mesilla Basin before exiting the southern end of the basin through the bedrock constriction at the Narrows in El Paso.

Main channel inflow to Rincon Basin is defined by streamflow in the Rio Grande below Caballo Dam. Daily mean streamflows below Caballo Dam were obtained from the International Boundary Water Commission (IBWC) for 1938 through 2006, the U.S. Geological Survey (USGS) from 2007 through 2013, and the Elephant Butte Irrigation District (EBID) for 2014.

US_MSJ_00001978

Monthly flow data for 2015 and 2016 were obtained from streamflow tables included in the respective Rio Grande Compact Commission Reports.

Main channel inflows to Mesilla Basin are defined by streamflow in the Rio Grande above Leasburg Dam. Daily mean streamflows above Leasburg Dam are reported by the United States Bureau of Reclamation (USBR) from 1938 through 1983. From 1984 through 2016, streamflow data are not reported for the Rio Grande above Leasburg Dam gage. For this period, streamflow above Leasburg Dam was computed as the sum of measured streamflow below Leasburg Dam and measured flow diverted into the Leasburg Canal, which has its head gate at the dam. Flow data for Leasburg Canal were obtained from the USBR and Elephant Butte Irrigation District (EBID). Flow data for below Leasburg Dam are not available for 2014 through 2016. Furthermore, flow data for 2011 and 2012 obtained from IBWC for below Leasburg Dam were determined to be anomalous when compared to historical measurements. A simple regression analysis was conducted to estimate flows in Rio Grande above Leasburg Dam to fill missing data for 2011, 2012, and 2014 through 2016. The regression equation (Flow above Leasburg = 0.9063*(Flow below Caballo) + 2044.8; r^2=0.98) is used to estimate monthly flows above Leasburg Dam using measured flows below Caballo Dam for the years with missing data.

Locations of streamflow gages used for defining the inflows and outflows of the surface water budgets are shown on **Figure 3.2**. Annual streamflows at the river inflow locations of the Rincon and Mesilla basins are shown on **Figure 3.3**.

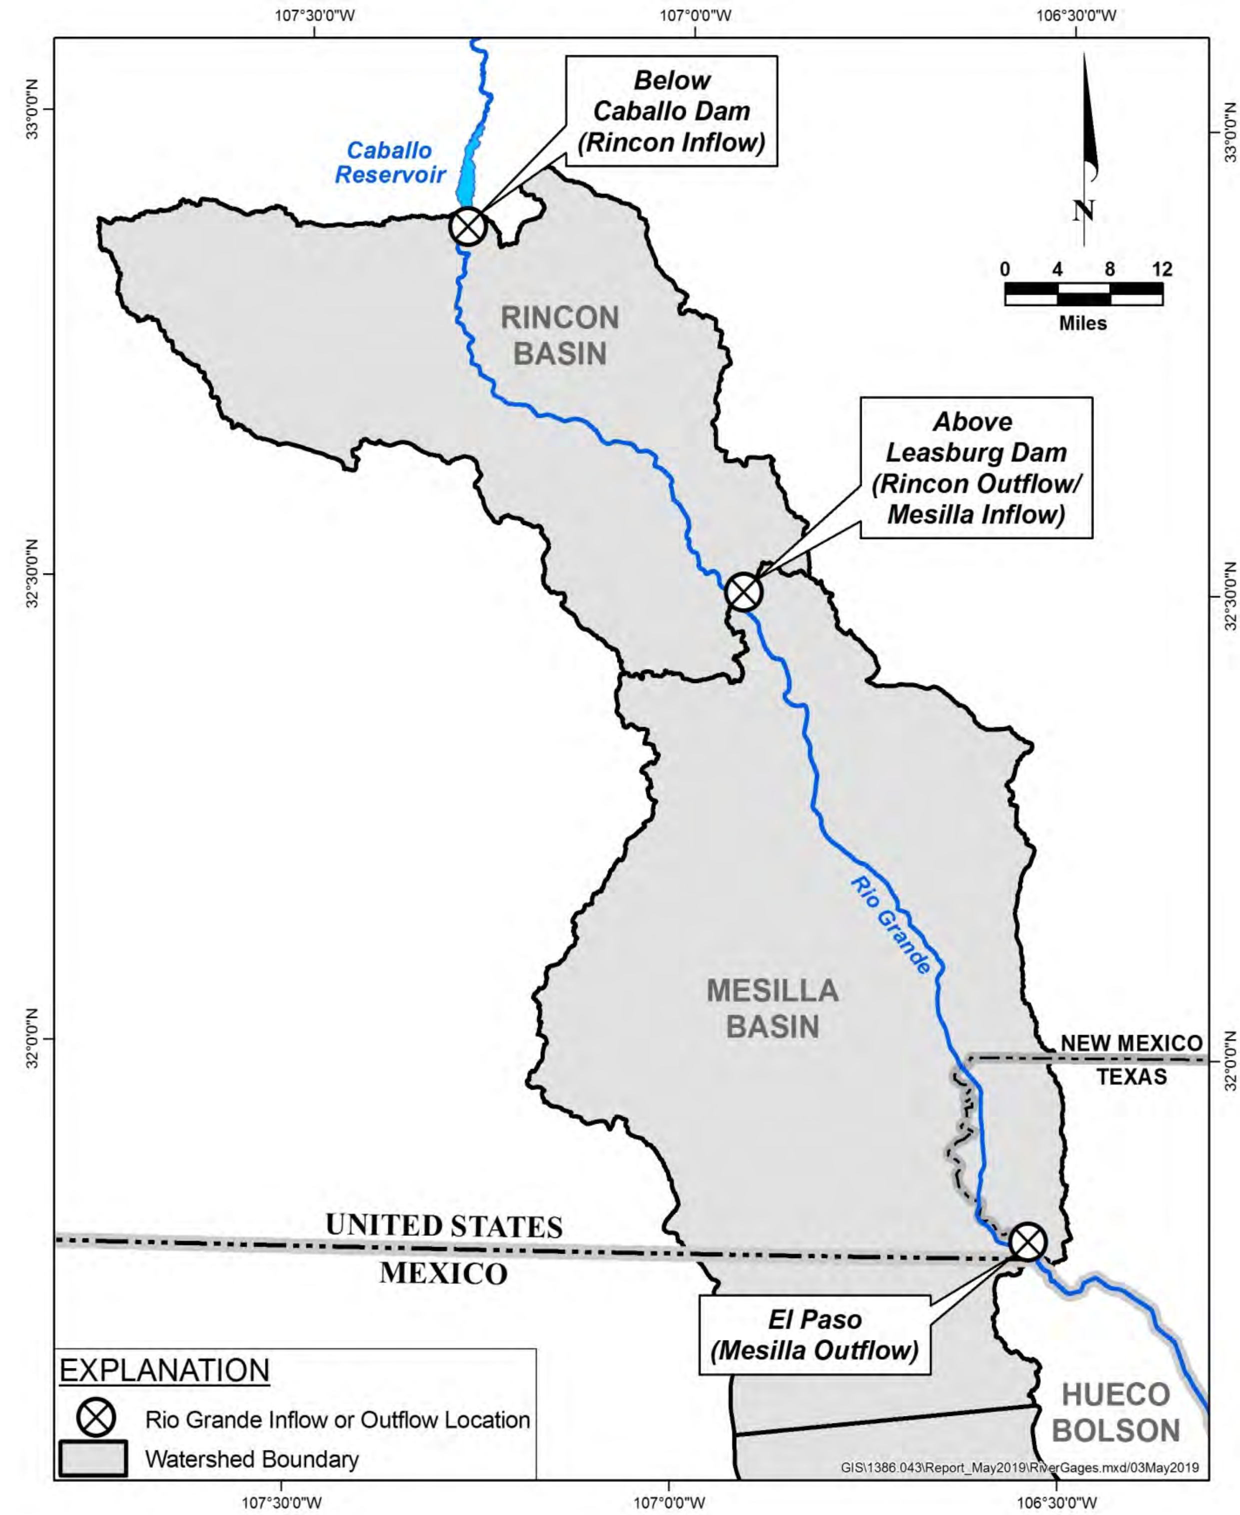

Figure 3.2. Locations of Rio Grande Inflows and Outflows in Rincon and Mesilla Basins

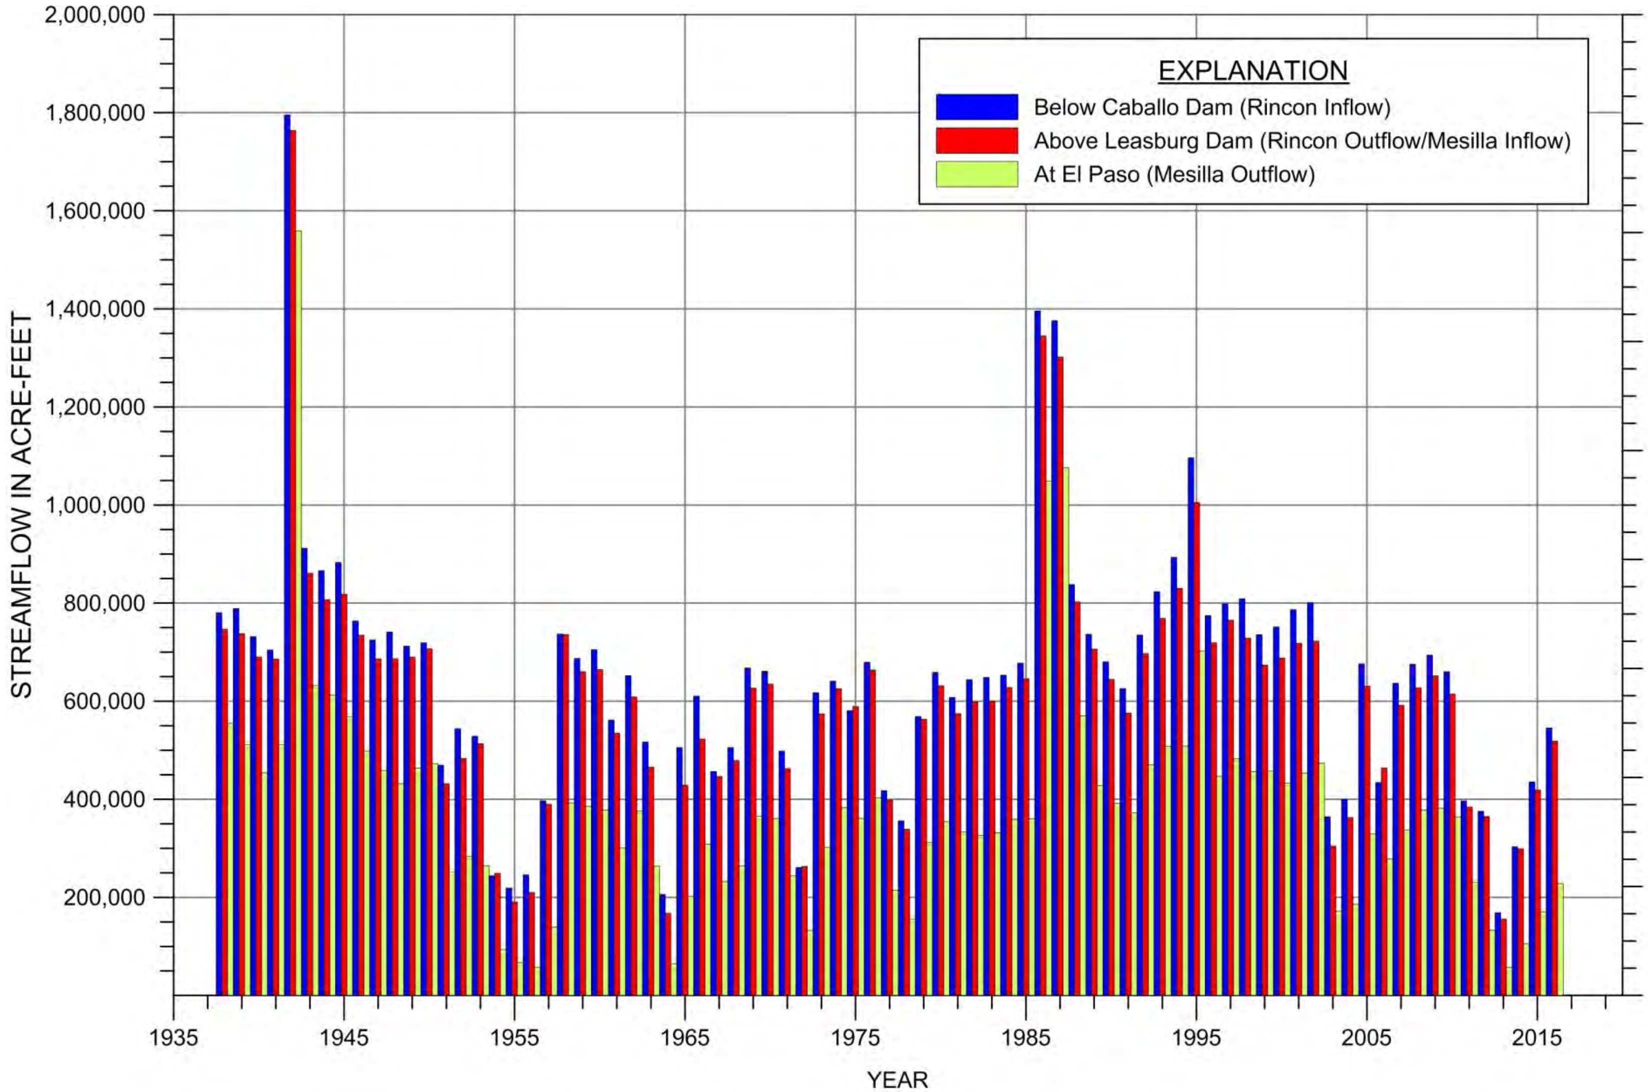

Figure 3.3. Annual Rio Grande Streamflows at Inflow and Outflow Locations in Rincon and Mesilla Basins

3.1.2 Tributary Inflow

Tributary inflows represent the volume of water that flows into the Rio Grande from ephemeral streams as a result of stormwater runoff in the upland areas of the study area. For this water budget analysis, runoff return flow volumes from urban and agricultural lands are estimated separately from runoff return flows from upland areas. Urban and farm lands were removed from the contributing watersheds considered for this tributary inflow analysis.

The U.S. Army Corps of Engineers (USACE) conducted hydrologic and hydraulic analyses for the Rincon and Mesilla basins for the Rio Grande Canalization Project (USACE and others, 1996). The USACE study delineated contributing and non-contributing sub-basins in the study area, and evaluated 100-year flood discharges at selected locations along the Rio Grande between Caballo Dam and American Diversion Dam. The contributing watersheds were digitized from the USACE report and used for this tributary inflow analysis. According to the USACE study, the Rincon Basin watershed (between Caballo Dam and Leasburg Diversion Dam) constitutes a major flood-producing area because of its steep-sloped arroyos that discharge directly to the Rio Grande. The Mesilla Basin (Between Leasburg Diversion Dam and American Diversion Dam) has less flood-producing potential because most arroyos discharge into the valley floor where flood waters pond in low-lying areas (USACE and others, 1996). Non-contributing sub-basins are associated with arroyos that do not have direct access through levees or railroad track embankments. The majority of tributary arroyos in Mesilla Basin do not contribute runoff discharges to the Rio Grande. Contributing watersheds in each basin are shown on **Figure 3.4**.

The watershed extent contributing to arroyo inflow was compared against watershed extent contributing to mountain-front recharge, and adjusted such that areas of overlap only contribute to mountain-front recharge. This ensures inflows to the surface water and groundwater system are consistent with estimated precipitation. Thus, for this analysis, tributary inflows to the river are generated only from precipitation falling within the alluvium basin.

Watershed runoff models require detailed streamflow data and information on physical characteristics for drainages and sub-watersheds. The lack of streamflow gages on the majority of drainages to the Rio Grande within the study area prevents the use of surface water modeling for determining tributary runoff for this water budget. Because of this limitation, we estimated runoff as a percentage of precipitation falling on the contributing watersheds.

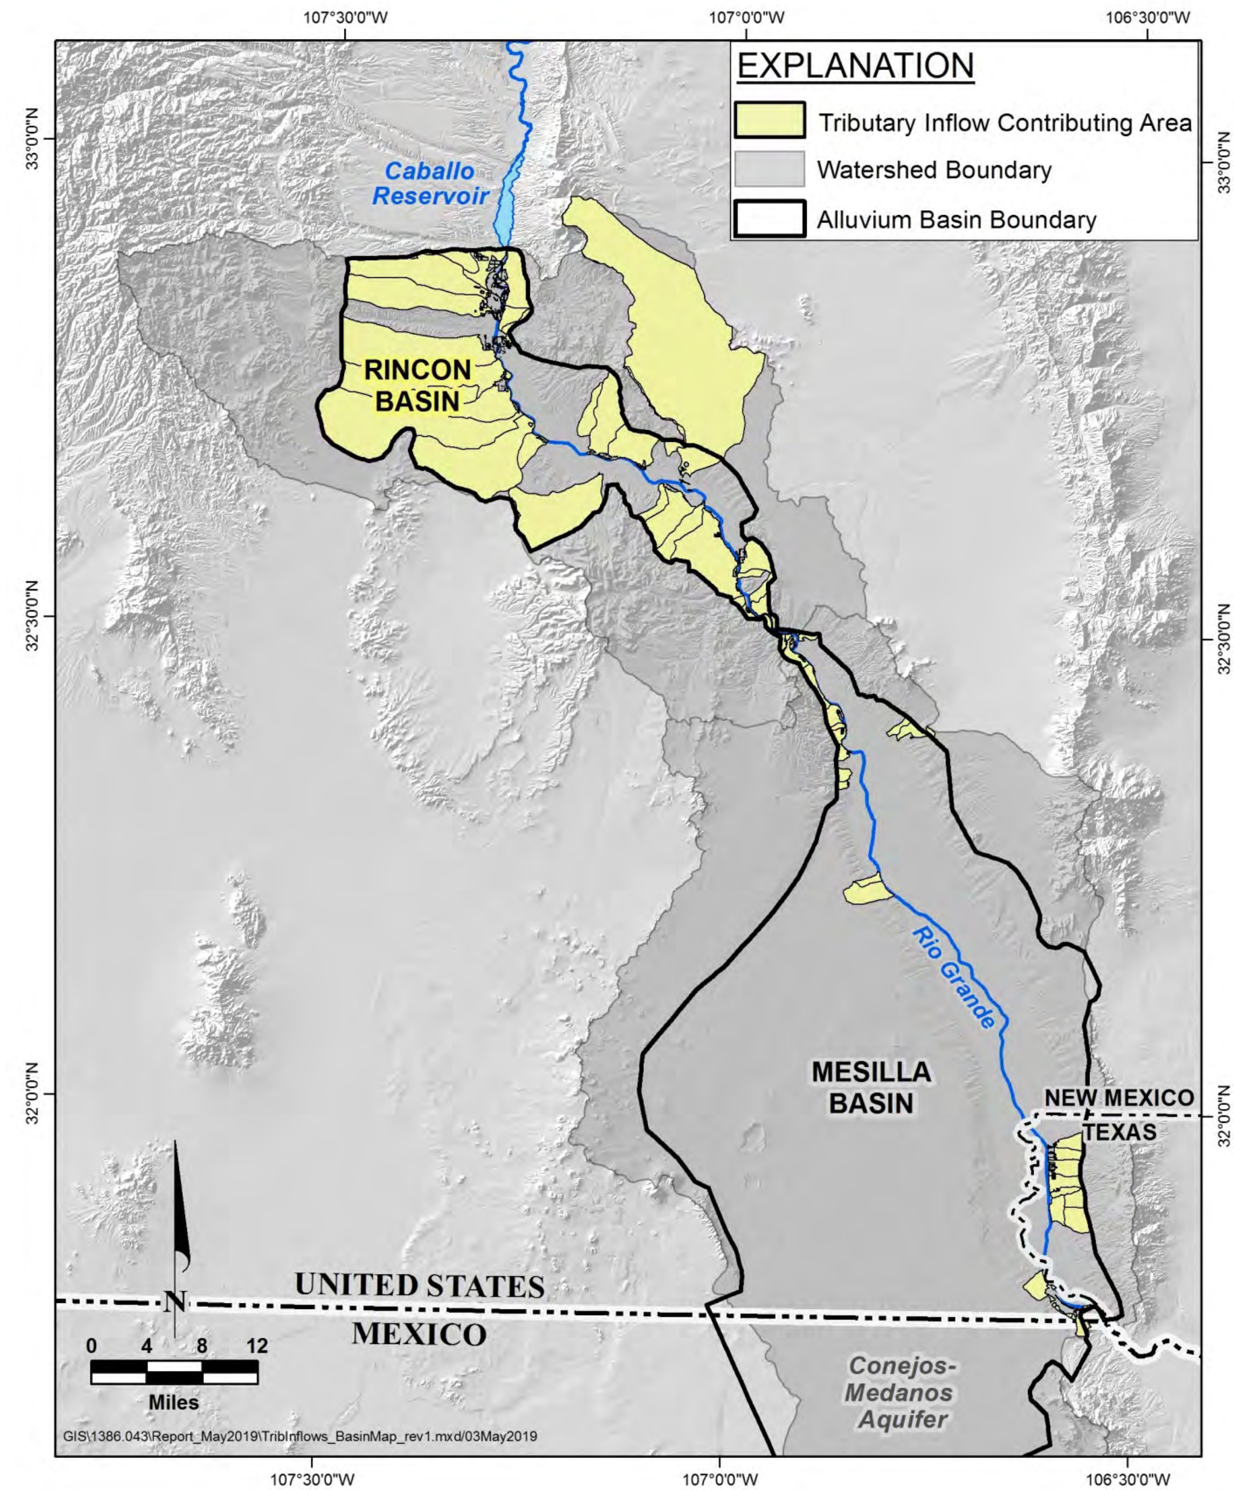

Figure 3.4. Sub-Watersheds Contributing to Tributary Inflows in Rincon and Mesilla Basins

Precipitation contributing to tributary inflows is based on monthly PRISM precipitation data. The PRISM dataset was previously described in Section 2.1.1 of this report. Basin precipitation is summarized in **Table 2.1**. Not all monthly precipitation becomes runoff and inflow to the Rio Grande. For this analysis, tributary inflows occur only during months when precipitation is greater than the average monthly precipitation based on PRISM data for 1938 through 2016. Average monthly precipitation is summarized on **Table 3.1**.

Table 3.1. Average Monthly Precipitation on Contributing Watersheds

Month	Rincon	Mesilla
January	0.47	0.52
February	0.41	0.44
March	0.25	0.30
April	0.29	0.26
May	0.30	0.39
June	0.59	0.63
July	1.68	2.07
August	1.85	2.23
September	1.43	1.66
October	0.83	0.99
November	0.48	0.53
December	0.62	0.75

Units in inches, based on monthly PRISM precipitation for 1938 through 2016.

Tributary inflow was assumed to be three percent of precipitation, based on results of a rainfall-runoff study conducted by Stone and Brown (1975) in a small semiarid watershed in the Jornada Basin in New Mexico. Annual tributary inflows in Rincon and Mesilla basins are shown on **Figure 3.5**. The estimated average annual tributary flows are about 5,500 AF in Rincon Basin and about 100 AF in Mesilla Basin.

As a comparison to the estimated tributary inflows described previously, stormflow volumes were quantified by a sequence of calculations using daily streamflow hydrographs compiled for stream gaging stations at the upstream and downstream ends of the Rincon Basin: Rio Grande below Caballo Dam, and Rio Grande above Leasburg Dam.

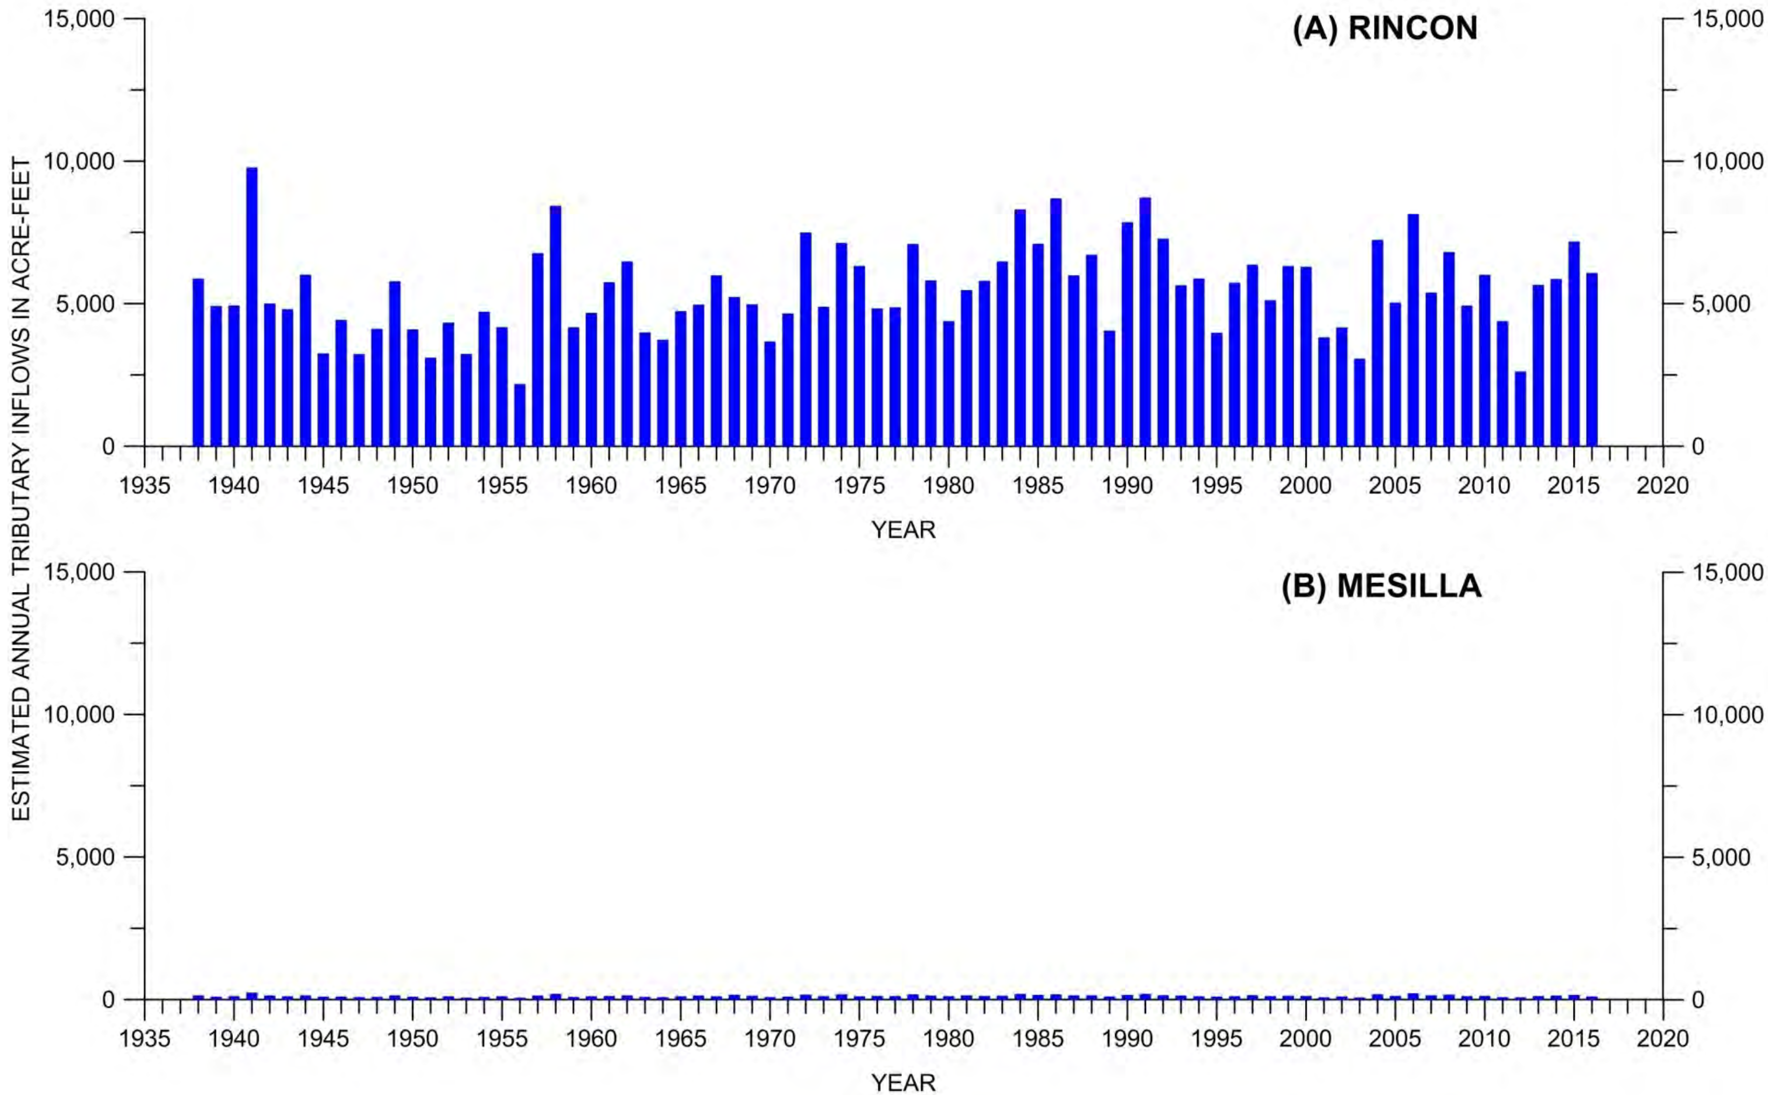

Figure 3.5. Estimated Annual Tributary Inflows for Rincon and Mesilla Basins

Periods of stormflow were identified over the period of record by days for which the mean daily streamflow recorded at Rio Grande above Leasburg Dam exceeds the previous day's mean daily discharge by a threshold streamflow change. An assumed threshold change of 250 cubic feet per second (cfs) was used for this analysis.

Each stormflow period is assumed to consist of four days. If the mean daily streamflow for a given day is at least 250 cfs greater than the mean daily streamflow from the previous day, then that day and the three subsequent days constitute the stormflow period.

For the stormflow period identified by the previous steps, the daily stormflow volume is calculated as the difference in mean daily discharge recorded at Rio Grande below Caballo Dam and Rio Grande above Leasburg Dam. The daily stormflow volumes are then summed for each month. Using this method, average annual tributary inflows in Rincon Basin are estimated to be about 3,530 AF.

Applying historic precipitation to the runoff curve for Rincon Basin specified in the Joint Investigation Report (JIR) resulted in runoff estimates that are appear to be vastly too large. Average annual runoff in Rincon Basin is estimated to be about 20,500 AF, using the JIR method. This magnitude of return flow to the river cannot be accounted for within the current water budgets. The JIR curve for Mesilla Basin resulted in average annual runoff of about 1,200 AF, which is generally consistent with estimates determined for this analysis.

3.1.3 Farm Surface Water Return Flow

Farm surface water return flow determined for the land-surface water budget described in Chapter 2 of this report are directly used as inflows to the surface water budgets for Rincon and Mesilla basins.

3.1.4 Urban Runoff Inflow

Urban runoff (returns to surface water system) determined for the land-surface water budget described in Chapter 2 of this report are directly used as inflows to the surface water budgets for Rincon and Mesilla basins.

3.1.5 Urban Wastewater discharges

Urban wastewater discharge is described in Section 2.2.1 of this report. Land-surface urban wastewater discharges are directly used as inflows to the surface water budgets for Rincon and Mesilla basins.

3.2 Surface Water Outflow

3.2.1 Rio Grande Outflow

Main channel outflows from the Rincon Basin are defined by streamflow in the Rio Grande above Leasburg, and are identical to Mesilla Basin main channel inflows as previously described. Main channel outflows from the Mesilla Basin are defined by streamflow in the Rio Grande at El Paso as reported by the International Boundary and Water Commission (IBWC) from 1938 through 2011. Additional data were obtained from streamflow table from the Rio Grande Compact Commission Report for 2012, from USBR for 2013, and from IBWC for 2014-2016. EBID also provided historic flow data for Rio Grande at El Paso; however, the values were redundant to the IBWC dataset. Annual streamflows at the outflow locations of the Rincon and Mesilla basins are shown on **Figure 3.3**. Annual streamflows at the outflow locations fluctuate from year to year and generally follow decadal-scale trends of relatively high and low flows.

3.2.2 Surface Water Deliveries to Farms

Water is diverted from the Rio Grande and delivered to farms for irrigation use in Rincon, Mesilla, and El Paso valleys via a conveyance network of canals and laterals. Based on an interview with Bert Cortez at USBR on April 26, 2019, canal system operators ("ditchriders") move diverted water through the distribution system by using a series of gates and turn outs. Ditchriders open the gates at turn outs to each farm and measures the amount delivered. The amount delivered is based on the farmers order for Project water.

Monthly deliveries to farms (farm deliveries) in the valleys are reported in U.S. Bureau of Reclamation crop reports and water distribution tables. The water distribution tables also summarize net project surface water supply, transportation losses, operational spills, and project surface water deliveries to non-farm users (municipal and industrial). However, a complete record of historical surface water deliveries to farms in the project area is not available from a single source, the period of record for reported farm deliveries is incomplete, and the reporting format changes through time. **Table 3.2** shows a summary of available farm delivery data by year.

Data Source:

Yellow	RGP annual history reports, scanned water distribution tables
Green	USBR: received as scanned water distribution tables for various years
Blue	EBID: received as annual totals in Excel file

Given these limitations, multiple sources of data and estimation methods are used to develop monthly datasets of surface water deliveries to farms in Rincon Valley, Mesilla Valley, and El Paso Valley for the entire study period from 1938 through 2016. Basinwide datasets are required for the farm soil water balance models developed for each valley, as previously described in Chapter 2 for Rincon and Mesilla basins. Annual deliveries to each valley, along with disaggregated deliveries to service areas and to districts, are summarized in **Table 3.3**.

Figure 3.6 shows irrigation district lands within each valley. EBID has lands in both Rincon and Mesilla valleys; EPCWID#1 has lands in both Mesilla and El Paso Valley; and Hudspeth County Conservation and Reclamation District 1 (HCCRD1) is located in the lower portions of El Paso Valley. Data sources and methods used to develop historic datasets for each valley are described in the following sections. Basinwide datasets were then disaggregated to summarize by district and by state.

3.2.2.1 Data Sources

Monthly values for deliveries were tabulated from scanned water distribution tables and imported into a database, which is described in a separate report. For each year, water distribution information is reported as aggregates for different project areas. The different reported project areas are shown in **Table 3.2**.

For 1938-1988, delivery data are reported in water distribution tables from Rio Grande Project History Annual Reports. Delivery data are not reported by district or subarea for 1956, 1971, 1972, 1973, and 1975; only Rio Grande Project total deliveries are reported for these years.

For 1989-2011, deliveries are reported in water distribution tables provided by the U.S. Bureau of Reclamation (USBR). Delivery data are not reported by district or subarea for 1992; only Rio Grande Project total deliveries are reported for this year. Water distribution tables from crop reports were also provided by EPCWID#1; however, the tables either were redundant of tables previously obtained by USBR or were blank.

Water distribution tables are not available for 2012 through 2016; however, total annual deliveries to EBID farms were provided by EBID for these years.

Water distribution tables for Hudspeth County Conservation and Reclamation District 1 (HCCRD1) are reported in the same RGP History Reports and USBR data as described above. Delivery data for the district are available for 1979 through 2006, except for 1990 and 1992.

Units in acre-feet
Deliveries are based data reported in U.S. Bureau of Reclamation crop report water distribution tables.
Bolded headers indicate inputs to farm water budgets.
EPCWID#1 = El Paso County Water Improvement District #1
HCRRD1 = Hudspeth County Conservation and Reclamation District 1

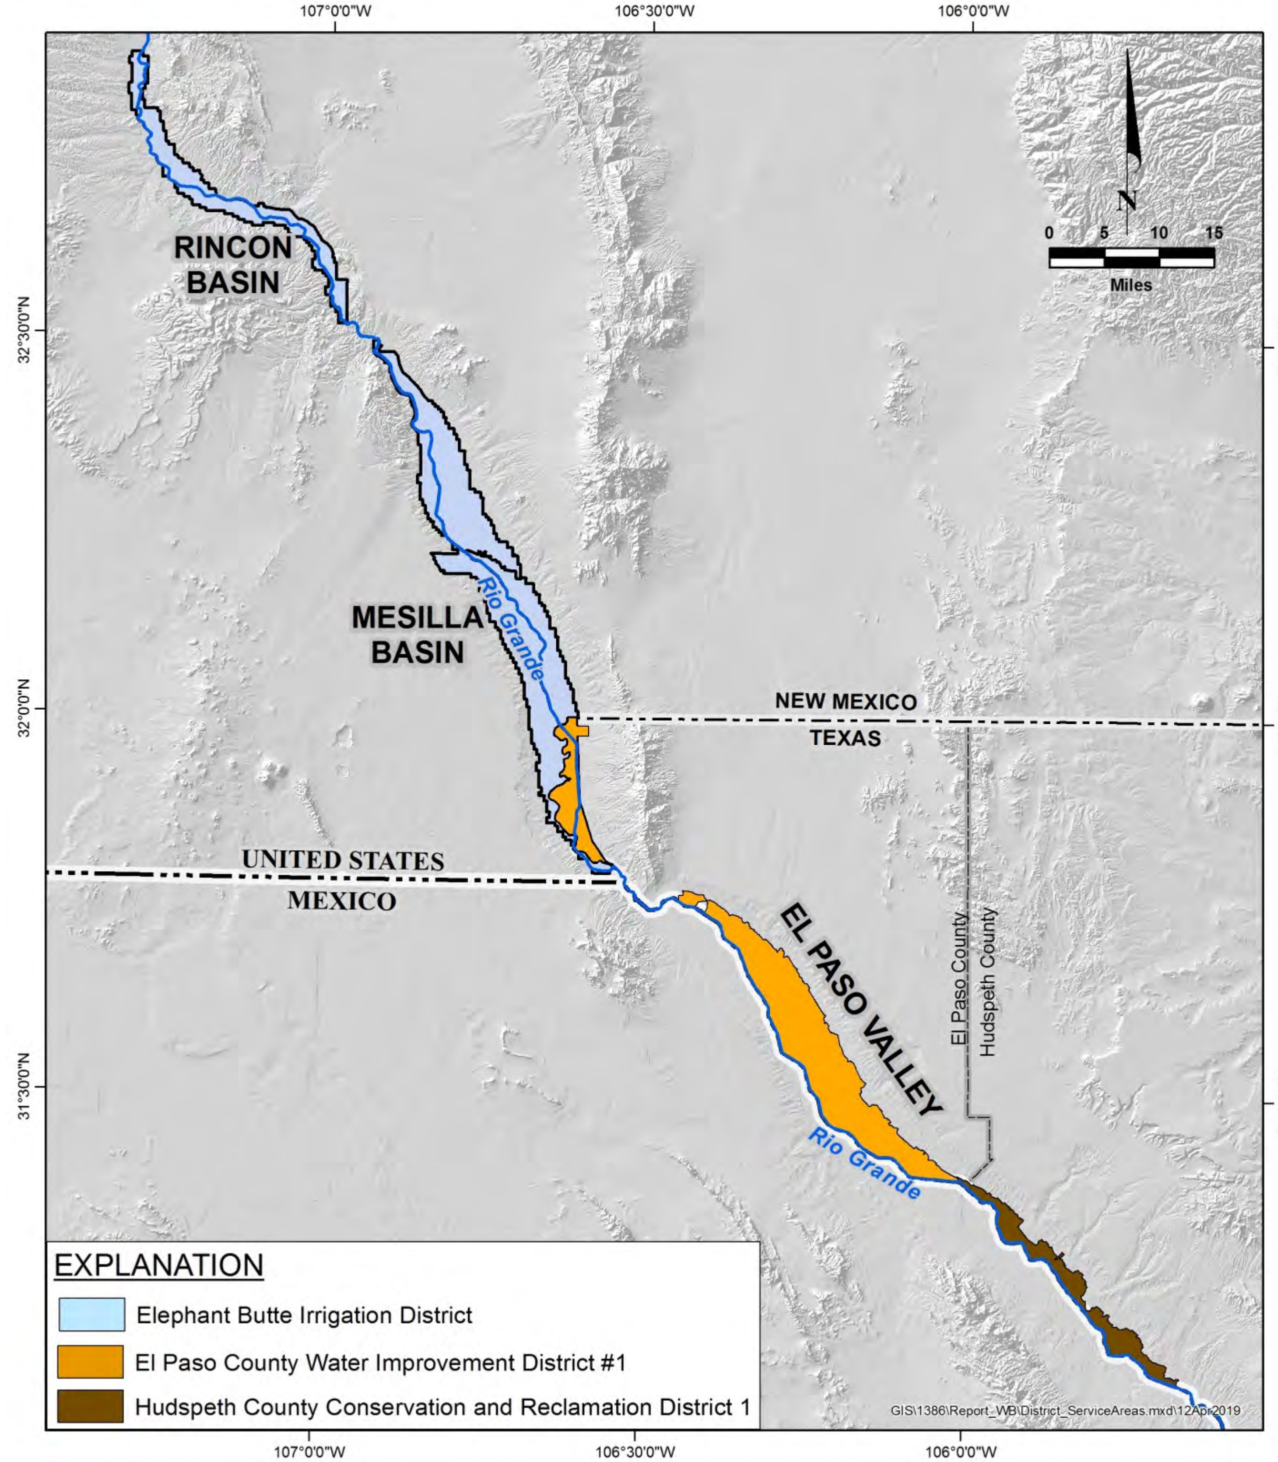

Figure 3.6. Irrigation District Lands in Project Area

3.2.2.2 Methods for Rincon and Mesilla Basins

From 1938 through 1978, water distribution tables summarize farm deliveries by Rio Grande Project subareas or basins (Rincon Unit, Mesilla Unit, El Paso/Ysleta Unit). After 1978, farm deliveries are reported by District (EBID, EPCWID#1, HCCRD) or EBID service area (Arrey, Leasburg, or Mesilla). For 1956, 1971, 1972, 1973, 1978 through 1990, 1992, 1993, 1994, and 2012 through 2016, farm delivery data are either missing or are reported in a manner that is inconsistent with other reporting periods (for example, deliveries reported for districts not by basin area). Basinwide deliveries are required for the water budget analyses described herein. For 1995 through 2011, total farm deliveries to Mesilla Basin is computed as the reported deliveries to EBID Mesilla service area plus estimated farm deliveries to Texas lands (EPCWID#1) in Mesilla Basin. Texas deliveries in Mesilla Basin are estimated as a portion of the total reported deliveries to EPCWID#1. Total reported deliveries to EPCWID#1 are disaggregated to Mesilla Basin and El Paso Valley based on district land acreages in each basin (83.5 percent in El Paso Valley and 16.5 percent in Mesilla Basin) (**Figure 3.6**). Monthly basinwide farm deliveries during the periods of missing or inconsistent data were estimated using regression models for Rincon and Mesilla basins that predict farm deliveries (Q_{fd}) as a function of several explanatory variables.

The regression model for the Rincon Basin takes the following form:

$$Q_{fd} = \beta_0 + \beta_1 \times Q_{rhg} + \beta_2 \times Q_{rhg}^2 + \beta_3 \times allot + \beta_4 \times Apr + \beta_5 \times Aug + \beta_6 \times Sep \qquad (45)$$

Explanatory variables used to estimate farm deliveries in Rincon Basin include monthly streamflow in the Arrey Canal (Q_{rhg}), the square of monthly streamflow in the Arrey Canal (Q_{rhg}), the annual surface water allotment (allot), and indicator variables for the months of April (Apr), August (Aug), and September (Sep). Indicator variables were added based on exploratory data analysis indicating that farm deliveries during those months tended to be under predicted in regression models considering only Arrey Canal flows and surface water allotment.

The regression coefficients in Equation (45) were estimated using monthly data during months for which farm deliveries were reported. Measured farm delivery data prior to 1950 were excluded from the regression to avoid potential influence of supplemental groundwater pumping on surface water delivery data. However, the regression equation is essentially the same with or without the pre-1950 data. **Table 3.4** summarizes the regression model used for Rincon farm deliveries, including the explanatory variables with associated coefficients and measures of statistical significance.

The final time series of farm deliveries in the Rincon Basin is based on reported farm deliveries, when available, and estimates from Equation (45) for months when farm deliveries were not reported.

Table 3.4. Summary of Explanatory Variables Used Iin Regression Model to Estimate Rincon Basin Farm Deliveries

Explanatory Variable	Coefficient (β)
Intercept (β_0)	-5.43×10^{2}
Monthly flow in Arrey Canal (β_1)	3.63×10^{-1}
Square of monthly flow in Arrey Canal (β_2)	5.81×10^{-6}
Annual RGP surface water allotment (β_3)	2.38×10^{2}
Indicator variable for April (β_4)	6.51×10^{2}
Indicator variable for August (β_5)	2.84×10^{2}
Indicator variable for September (β_6)	8.64×10^{2}

NOTE: Regression model estimated based on 492 reported monthly farm delivery values, with model R^2 = 0.89. Standard error of the regression is equal to 1,024.

The regression model for the Mesilla Basin takes the following form:

$$Q_{fd} = \beta_0 + \beta_1\times Q_{rhg} + \beta_2\times Q_{rhg}^{2} + \beta_3\times allot + \beta_4\times Apr + \beta_5\times Sep \quad (46)$$

The explanatory variables used to estimate farm deliveries in the Mesilla Basin are similar to those used for the Rincon Basin, with two exceptions. First, the term Qrhg in Equation (46) represents the sum of diversions in the Leasburg, Eastside, and Westside canals less El Paso Carriage. Second, the indicator variable for month of August was not included in the model. **Table 3.5** summarizes the regression model used for Mesilla farm deliveries, including the explanatory variables with associated coefficients and measures of statistical significance.

The final time series of farm deliveries for Mesilla Basin is based on reported farm deliveries, when available, and estimates from Equation (46) for months when farm deliveries were not reported.

Table 3.5. Summary of Explanatory Variables Used in Regression Model to Estimate Mesilla Basin Farm Deliveries

Explanatory Variable	Coefficient (β)
Intercept (β_0)	-1.44×10^{3}
Monthly flow in Leasburg, Eastside, and Westside Canals (β_1)	3.54×10^{-1}
Square of monthly flow in Leasburg, Eastside, and Westside Canals (β_2)	2.50×10^{-6}
Annual RGP surface water allotment (β_3)	5.39×10^{2}
Indicator variable for April (β_4)	3.74×10^{3}
Indicator variable for September (β_5)	3.51×10^{3}

NOTE: Regression model estimated based on 512 reported monthly farm delivery values, with model R^2 = 0.95. Standard error of the regression is equal to 3,167.

The regression equations were not used for 2015 and 2016 because data are unavailable for diversions for one of the major canals (Westside). For 2015 and 2016, reported total annual deliveries to EBID were disaggregated to EBID lands in Rincon and Mesilla basins based on proportional land acreages in each basin. According to geospatial datasets provided by the district, EBID lands extend across an area of 34,839 acres in Rincon Basin (25 percent of EBID lands) and 106,149 acres in Mesilla Basin (75 percent of EBID lands). Deliveries to EBID farms in Mesilla Basin are computed as 75 percent of reported total EBID deliveries, and deliveries to EBID farms in Rincon Basin are computed as 25 percent of reported total EBID deliveries. Deliveries to the Texas portion of Mesilla Basin (13,800 acres) were estimated as 13 percent of deliveries to EBID Mesilla, based on relative land acreages (acreage of Texas Mesilla is 13 percent of acreage of EBID Mesilla). Basinwide farm deliveries in Mesilla Basin are the sum of EBID Mesilla deliveries and Texas Mesilla deliveries. Annual deliveries were distributed to monthly deliveries based on the average monthly distribution from reported data.

Figures 3.7 and 3.8 shows the complete time series of annual farm deliveries including both original farm delivery data from RGP history reports and estimated farm deliveries based on the estimation methods previously described.

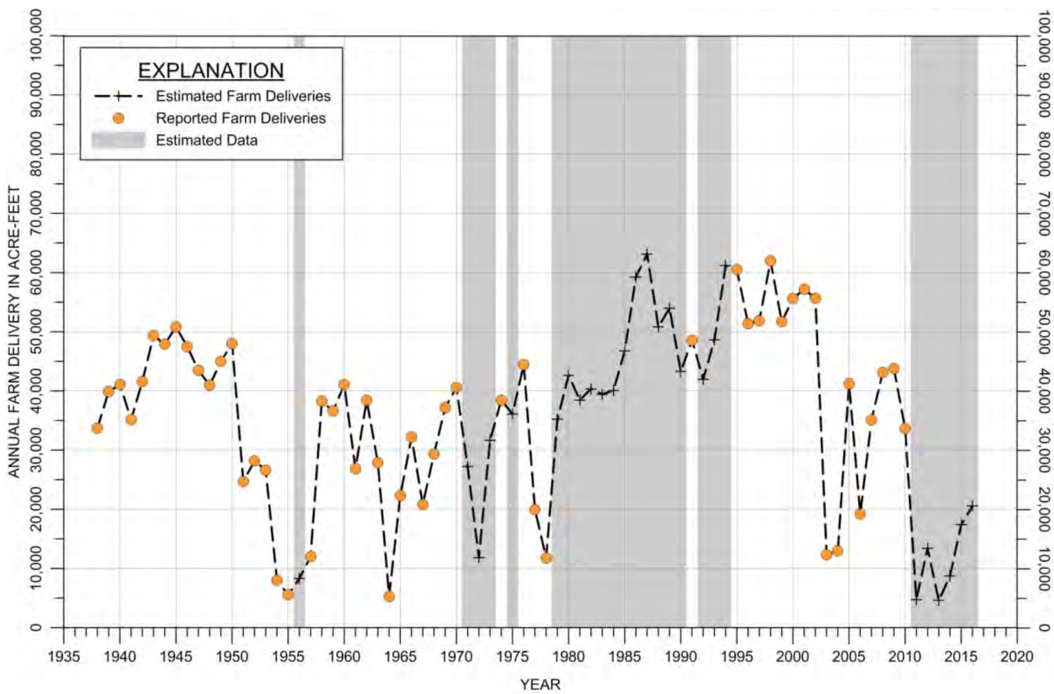

Figure 3.7. Summary of Surface Water Deliveries to Farms in Rincon Basin

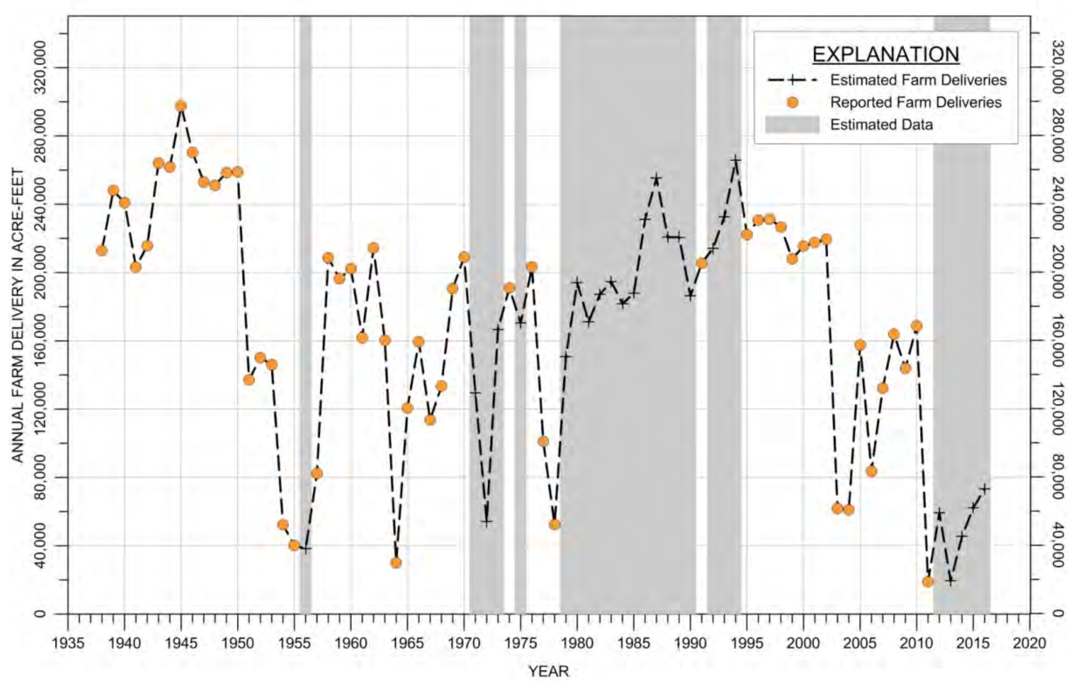

Figure 3.8. Summary of Surface Water Deliveries to Farms in Mesilla Basin

3.2.2.3 Methods for El Paso Valley

El Paso Valley is shown on **Figure 3.6**. The Rio Grande History Reports define El Paso Valley as lands from El Paso to the Hudspeth-El Paso County line. This definition includes only EPCWID#1 lands in El Paso Valley, not Hudspeth County Conservation and Reclamation District 1 (HCCRD1) lands. However, for this report, El Paso Valley includes both EPCWID#1 and HCCRD1 lands because HCCRD1 receives Project water as return flows from EPCWID#1.

For 1938 through 1978, project water deliveries are reported for El Paso Valley (El Paso/Ysleta unit). However, data are missing for 1956, 1971, 1972, 1973, and 1975. A simple regression analysis was conducted to estimate monthly deliveries for these years. The regression equation (Farm Deliveries to El Paso Valley = 0.6105*(Farm Deliveries to Mesilla) + 1458.8; r^2=.92), describes the relationship between reported farm deliveries in El Paso Valley and reported farm deliveries in Mesilla Basin for 1938 through 1978. The equation is used to estimate total monthly farm deliveries in El Paso Valley for the missing years (1956, 1971, 1972, 1973, and 1975) from reported farm deliveries in Mesilla Basin for those same years.

For 1979 through 2008 and 2010, El Paso Valley farm deliveries are estimated based on reported total deliveries to EPCWID#1. Total deliveries to EPCWID#1 are disaggregated based on proportions of total district acreage located in Mesilla Basin and El Paso Valley (**Figure 3.6**). Based on a geospatial dataset provided by EPCWID#1, the total area of the district is 86,929 acres, with 72,596 acres (or 83.5 percent) located in El Paso Valley and 14,343 acres (or 16.5 percent) located in Mesilla Basin. El Paso Valley farm deliveries are estimated as 83.5 percent of total deliveries to the district (farm and non-farm). Non-farm deliveries are reported in EPCWID#1 water distribution tables and presumably represent delivery of project water to the city of El Paso for municipal and industrial use. For this evaluation, non-farm deliveries are considered to be deliveries that would have gone to farms if the associated lands were not urbanized over time. Non-farm deliveries were assigned only to El Paso Valley; thus, for months when EPCWID#1 non-farm deliveries are equal to total district deliveries (no farm deliveries occurred), the entire total district amount is applied to El Paso Valley (no deliveries to Mesilla Basin).

For 2009 and 2011 through 2016, no data are available for deliveries to El Paso Valley or EPCWID#1. The only project delivery data available for this time period are for total annual deliveries to EBID. In the absence of measured data, farm deliveries to El Paso Valley are estimated based on Texas Mesilla estimates from (1) the Mesilla regression method for 2009 and 2011-through 2014, and from (2) reported annual EBID deliveries for 2015 and 2016.

For 2009 and 2011 through 2014, total EPCWID#1 deliveries were estimated by dividing Texas Mesilla deliveries from the Mesilla regression by the percentage of EPCWID#1 land located in Mesilla Basin (16.5 percent). El Paso Valley deliveries were then computed as 83.5 percent of the estimated total EPCWID#1 deliveries.

For 2015 and 2016, following the same methodology previous described for Rincon and Mesilla basins, total EBID deliveries were disaggregated to Rincon and Mesilla basins based on relative proportions of total district acreages. Texas Mesilla deliveries were then estimated to be 13 percent of EBID Mesilla deliveries, based on proportion of land acreage in Mesilla Basin. Total EPCWID#1 deliveries were subsequently estimated using the same proportion methods described above for 2009 and 2011 through 2014.

In addition, surface water is also delivered to Hudspeth County Conservation and Reclamation District 1 (HCCRD1), located in Hudspeth County immediately downstream from the RGP-defined extent of the valley. Surface water deliveries to HCCRD1 are equal to reported "supplemental" deliveries in Rio Grande Project History Report tables. The delivered water is comprised of irrigation return flows, wastewater, and operational spills from upstream water users (EPCWID#1 and City of El Paso). Farm deliveries to HCCRD1 are reported for 1979 through 2006, except for 1990 and 1992. Farm deliveries to HCCRD1 are on average 26 percent of farm deliveries to EPCWID#1 El Paso Valley, based on reported and estimated data for 1979 through 2006. This ratio was applied to the deliveries dataset to estimate HCCRD1 farm deliveries for missing years from 1938 through 2016.

3.2.3 Incidental Depletions

Above-farm incidental depletion is a component of total canal losses, and includes water loss to soil evaporation, and transpiration by vegetation in and surrounding canals. The mechanisms for water loss for below-farm incidental depletion are similar, but apply only to open drains. Above-farm incidental depletions represent water lost to the atmosphere from the surface-water network. Similarly, below-farm incidental depletions from drains consume a portion of groundwater discharge to drains that otherwise would have returned to the main channel Rio Grande. If below-farm incidental depletions are zero, then all groundwater discharge to drains returns to the main channel – if incidental depletions are not zero, then only a portion of groundwater discharge to drains ultimately returns to the main channel.

Above-farm incidental depletion is defined by the NMOSE (Wilson and others, 2003, p. 70) as "evaporation from canals and laterals that convey water from stream or reservoir to the farm headgate; transpiration by phreatophytes along canals and laterals; and evaporation of leakage from off-farm water supply pipelines." Below-farm incidental depletion is defined by the NMOSE as "evaporation of runoff and seepage from irrigated fields; evaporation from open drains and tailwater recovery pits; and transpiration by phreatophytes along drains and below irrigated fields."

A procedure described by the NMOSE was used to quantify above-farm and below-farm incidental depletion of surface water deliveries (Wilson and others, 2003). Monthly consumptive irrigation requirements (CIR) are multiplied by either an above-farm or below-farm incidental depletion factor (IDF). The consumptive irrigation requirement was computed as the portion of crop ET satisfied by surface water deliveries.

Above-farm incidental depletions occur only if water is flowing in the canals. The land-surface water budget assumes that prior to 1951, all crop consumptive use was satisfied by surface water deliveries, or precipitation. The land-surface water budget further assumes that beginning in 1951, crop consumptive use was principally satisfied by a combination of surface water deliveries and supplemental groundwater pumping (**Figures 2.9 and 2.10**). The fraction of crop consumptive use satisfied by surface water is calculated as the monthly farm delivery divided by the monthly crop consumptive water use. During and after 1951, only the portion of crop consumptive use satisfied by surface water (CIR_{SW}) is used to calculate above-farm incidental depletions. The source of irrigation water (groundwater vs. surface water) is not relevant to the magnitude of below-farm incidental depletion. Therefore, below-farm incidental depletion is calculated as the product of the total CIR and the below-farm incidental depletion factor. Above-farm and below-farm incidental depletions are shown on **Figures 3.9a, 3.9b, 3.10a, and 3.10b** for Rincon and Mesilla basins, respectively.

3.2.4 Open-Water Evaporation

A portion of the water conveyed along surface water features, including the main channel of the Rio Grande and agricultural canals and drains, is lost to evaporation. For this evaluation, open-water evaporation is estimated using monthly pan evaporation rates and estimated surface area of the river channel, canals, laterals, and drains.

Monthly pan evaporation from Caballo Reservoir was used for this analysis, with several exceptions. During 1938, monthly pan evaporation rates from Caballo Reservoir were not available, and instead monthly pan evaporation rates from Elephant Butte Reservoir were used. For isolated months with missing data, the average monthly rate over the period of record was substituted.

The evaporation rate, per unit area, was calculated by multiplying the pan evaporation rate by a pan-coefficient of 0.7, as recommended in the JIR. Evaporation volume was calculated by multiplying the monthly evaporation rate by the river surface area. The evaporative surface area was estimated based on stream channel geometry inputs to the OSE Administrative Model (SSPA, 2007) to be about 1,180 acres in the Rincon Basin, and 2,710 acres in the Mesilla Basin. **Figure 3.9c and 3.10c** show estimated open-water evaporation losses in Rincon and Mesilla basins, respectively.

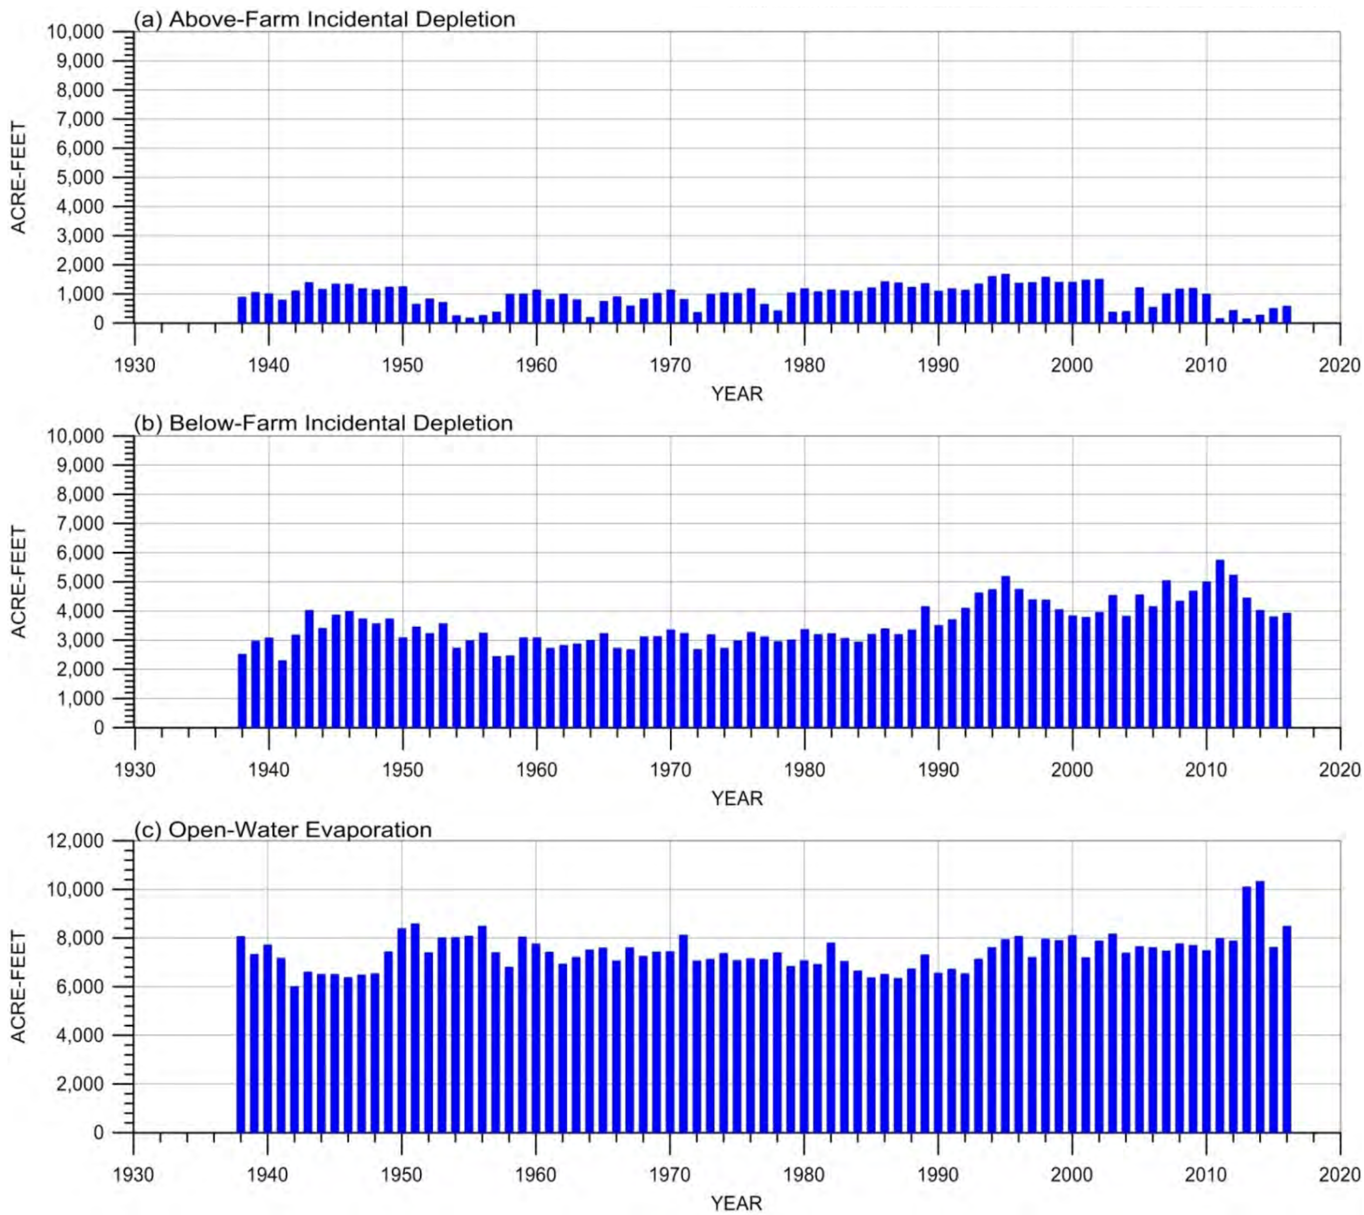

Figure 3.9. Estimated Annual Surface Water Losses in Rincon Valley

US_MSJ_00002000

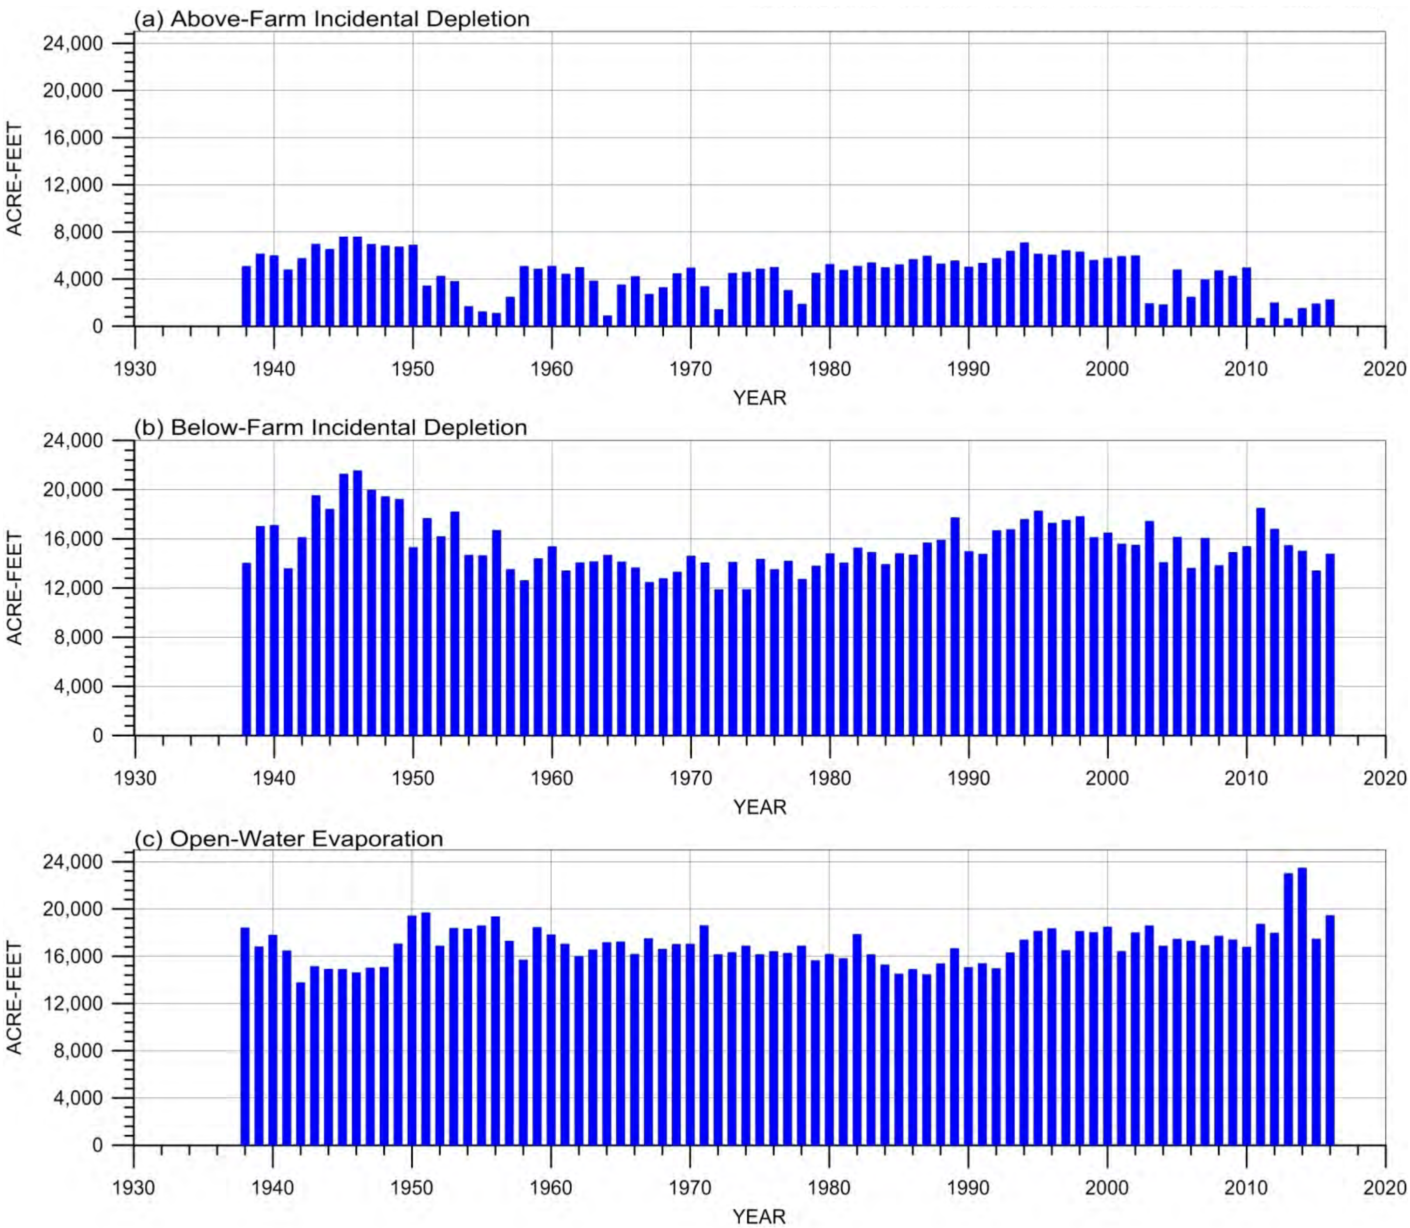

Figure 3.10. Estimated Annual Surface Water Losses in Mesilla Valley

3.3 Surface Water Network Interaction with Groundwater

Monthly exchanges between groundwater and surface water were calculated as the difference between outflows and inflows of the surface water budget, as stated in Equation 36. Estimated annual net groundwater-surface water exchange is shown on **Figure 3.11** for Rincon and Mesilla basins. A positive value of $Q_{GW\text{-}SW}$ reflects monthly net gain to the surface water network from groundwater, whereas a negative value reflects monthly net loss to groundwater from surface water. In Rincon Basin, $Q_{GW\text{-}SW}$ has fluctuated around zero over the study period. In Mesilla Basin, on the other hand, $Q_{GW\text{-}SW}$ has generally fluctuated around annual surface water losses of roughly 50,000 acre-feet per year (AF/year) for almost the entire study period since the 1950s. Prior to 1950, surface water gains occurred at an average rate of approximately 50,000 AF/year. The net loss of groundwater contributions to surface water flows after 1950 coincides with the timing of substantial increase in groundwater withdrawals throughout the study area.

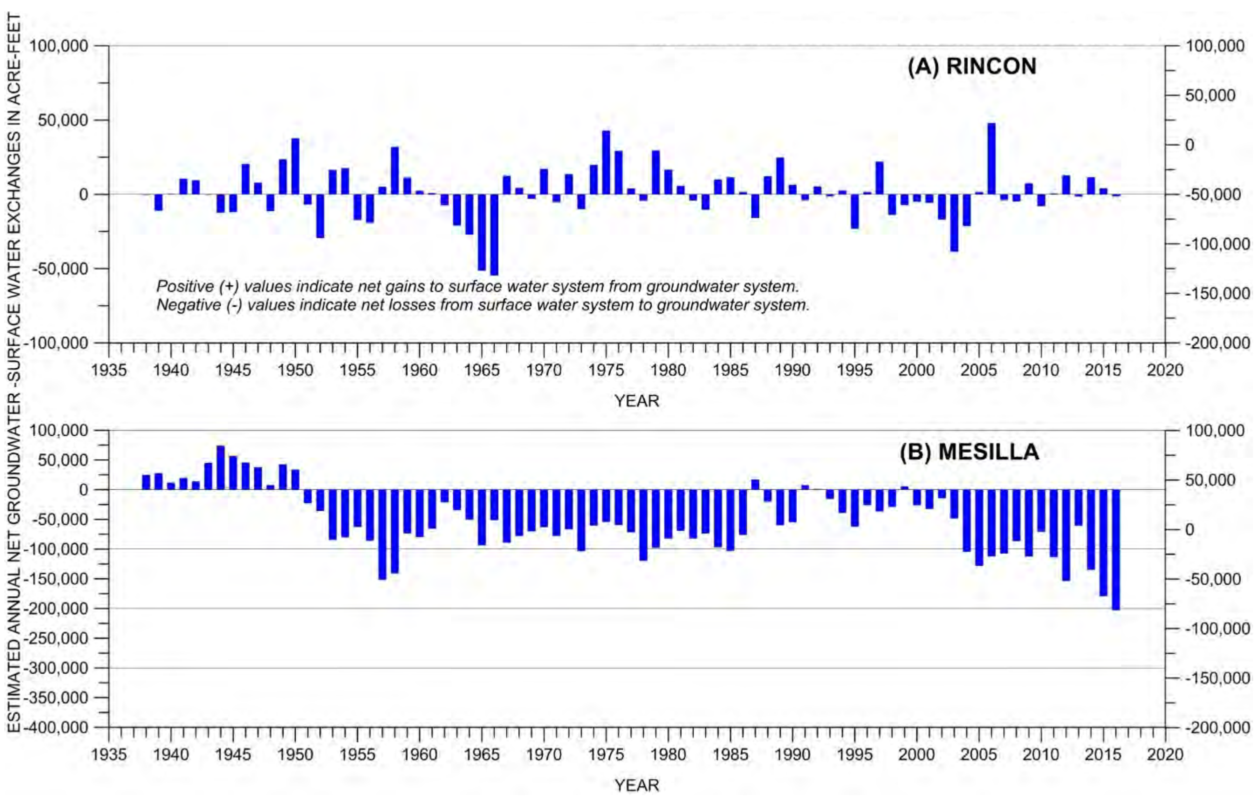

Figure 3.11 Estimated Annual Net Groundwater–Surface Water Exchanges in Rincon and Mesilla Basins

US_MSJ_00002002

4 GROUNDWATER BUDGET

When applied to the groundwater budget, Equation (1) becomes:

$$[Q_{GW\text{-}in}] - [Q_{GW\text{-}out}] = \Delta S_{GW} \quad (47)$$

Where,

$Q_{GW\text{-}in}$ is the sum of land-surface inflows;
$Q_{GW\text{-}out}$ is sum of land-surface outflows; and
ΔS_{GW} is change in soil moisture.

All components of the groundwater budget can be derived from available data or the analysis of available data.

Considering all components of the groundwater budget, Equation (47) becomes:

$$[GW_{IB\text{-}in}+MFR+DP_f+DP_{nf}+Q_{GW\text{-}out}] - [GW_{IB\text{-}out}+ET_{rip}+GW_{app\text{-}f}+GW_{app\text{-}nf}+Q_{GW\text{-}in}] = \Delta S_{GW} \quad (48)$$

Where,

$GW_{IB\text{-}in}$ is Interbasin groundwater inflow from adjacent basins;
MFR is natural recharge (mountain-front recharge);
DP_f is deep percolation to groundwater from farm lands (agricultural);
DP_{nf} is deep percolation to groundwater from non-farm lands;
$Q_{GW\text{-}out}$ is surface water outflow to groundwater;
$GW_{IB\text{-}out}$ is Interbasin groundwater outflow to adjacent basins;
ET_{rip} is riparian evapotranspiration (consumptive use by phreatophytes);
$GW_{app\text{-}f}$ is applied groundwater to farm lands (agricultural pumping);
$GW_{app\text{-}nf}$ is applied groundwater to non-farm lands (urban pumping); and
$Q_{GW\text{-}in}$ is groundwater outflows to the surface water network.

When groundwater inflows are not equal to outflows there is a resulting change in the amount of groundwater stored in the aquifer. The change in groundwater storage is evidenced by a change in groundwater surface levels in an unconfined aquifer or a change in piezometric heads in a confined aquifer. Spatial and temporal distribution of available groundwater level data are not adequate for estimating changes in groundwater storage throughout the basin over time; however, all other components of the groundwater budget can be derived from available data or the analysis of available data. Changes in groundwater storage are estimated as the quantity required to close the groundwater budget.

Figure 4.1 provides a graphical depiction of Equation (48).

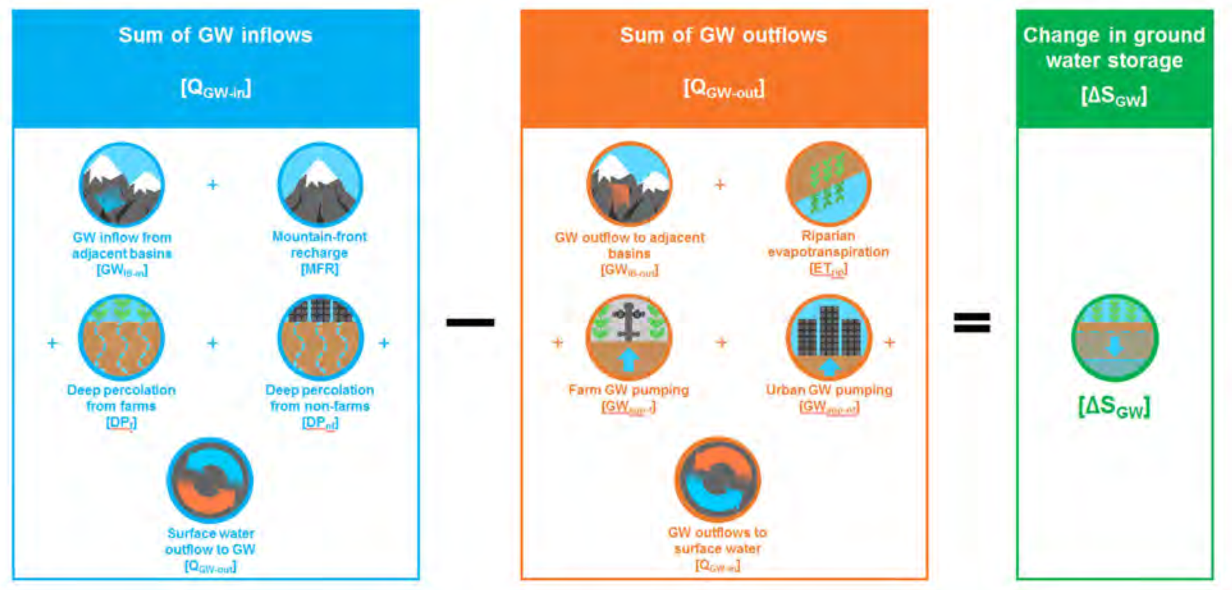

Figure 4.1. Graphical Depiction of Groundwater Budget Equation

The groundwater budget and relationships with the land-water and surface water budgets are shown on **Figure 1.2**. Groundwater pumping is an input to the land-surface water budget.

The monthly, basin-wide groundwater budgets for Rincon and Mesilla basins are summarized in the accompanying dataset named *IntegratedWaterBudgets.xlsx*. Annual groundwater budgets for Rincon Basin and Mesilla Basin are summarized in this chapter of the report and tabulated in **Appendices C1 and C2**.

4.1 Groundwater Inflows

Groundwater inflows to the Rincon and Mesilla groundwater basins include (1) subsurface flow from adjacent groundwater basins, (2) mountain-front recharge, (3) agricultural deep percolation, (4) urban deep percolation, and (5) infiltration from surface water bodies including canals, laterals, and the main-channel Rio Grande. The latter inflow is lumped under a single term representing net groundwater-surface water exchange, as previously described in Section 3.3 of this report, and is included as an outflow component described in Section 4.2. Each of these groundwater inflow components was calculated separately for the Rincon and Mesilla basins.

4.1.1 Interbasin Subsurface Inflows

Groundwater enters Rincon Basin from the adjacent Jornada del Muerto Basin (**Figure 4.2**) through buried basin-fill sediments in vicinity of Rincon Arroyo, located approximately 15 miles

US_MSJ_00002004

upriver from Leasburg Dam. Rincon Arroyo underflow is estimated to be 1,500 AF/year, based on groundwater modeling studies of the Jornada basin (Shomaker & Associates, 1996; Kambhammettu and others, 2007). This annual rate was converted to a constant rate of 125 AF/month for the entire Rincon Basin groundwater budget time period. Groundwater enters Rincon Basin as seepage from Caballo Reservoir and Dam at an estimated rate of 1 AF/year based on input files for the SSPA (2007) groundwater flow model.

Underflow to the Mesilla Valley consists of groundwater flow from the adjacent Jornada del Muerto Basin through buried basin-fill sediments and as flow through relatively shallow, saturated alluvium from Selden Canyon (**Figure 4.2**). Underflow from the Jornada Basin is estimated to be less than 850 AF/year by Hawley and Kennedy (2004), and underflow from Selden Canyon is estimated to be 10 AF/year based on simulation results from the NMOSE administrative groundwater model (SSPA, 2008). Total underflow into the Mesilla Basin is estimated to be 860 AF/year. This annual rate was converted to a constant rate of 72 AF/month for the entire Mesilla Basin groundwater budget time period.

Interbasin subsurface inflows are summarized in **Table 4.1**.

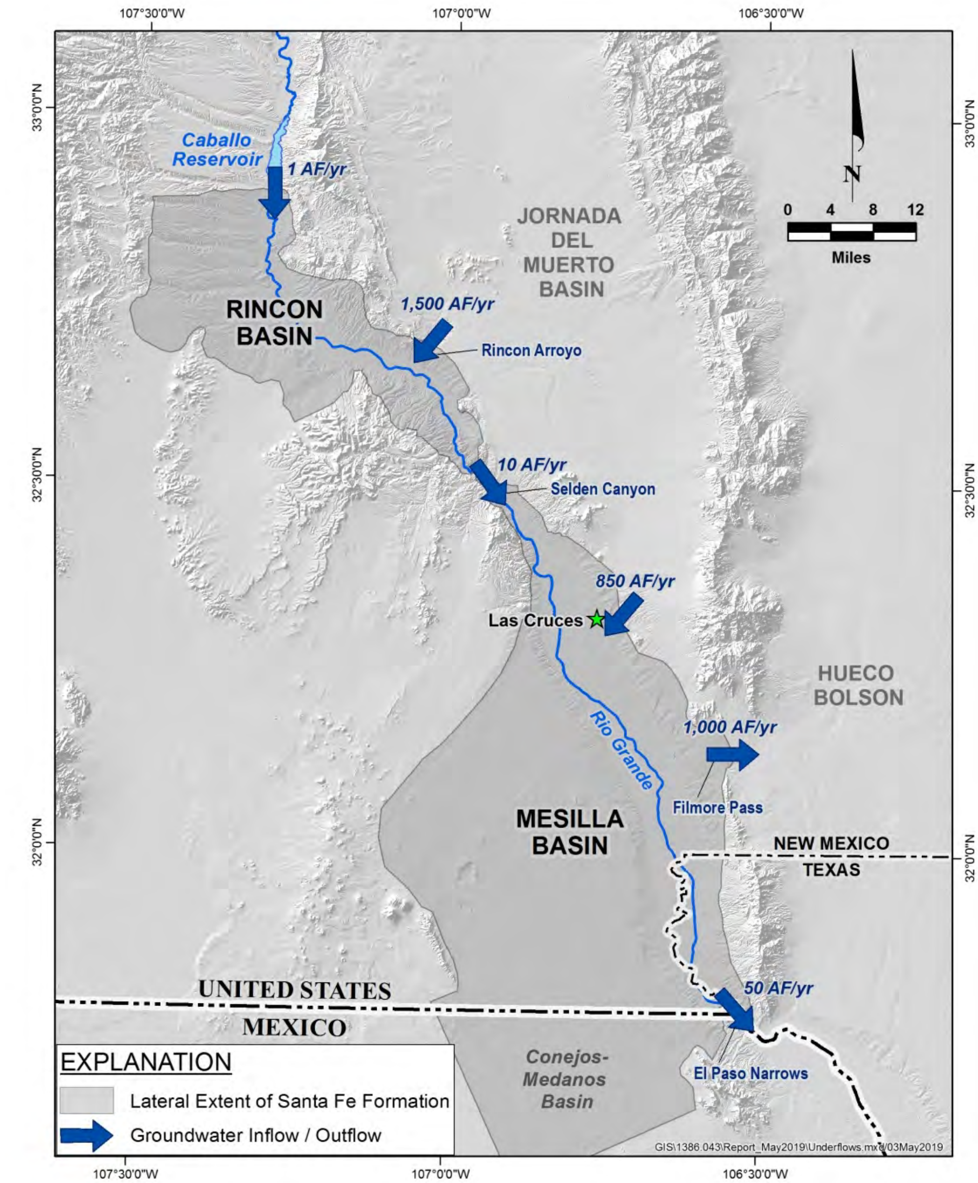

Figure 4.2. Locations of Interbasin Groundwater Flows in Rincon and Mesilla Basins

4.1.2 Agricultural Deep Percolation

Agricultural deep percolation inflows for Rincon and Mesilla basins were estimated as previously described in Section 2.1.3 of this report. Agricultural deep percolation outflows from the land-surface water budgets are inflows to the groundwater budgets.

4.1.3 Urban Deep Percolation

Urban (non-farm) deep percolation inflows for Rincon and Mesilla basins were estimated as previously described in Section 2.2.2 of this report. Urban deep percolation outflows from the land-surface water budgets are inflows to the groundwater budgets.

4.1.4 Natural Aquifer Recharge

Natural aquifer recharge in the Rincon and Mesilla Basins principally occurs as mountain-front recharge along the basin margins near the lateral extent of the Santa Fe Formation. Recharge occurs where runoff from precipitation in the upper portions of the watershed infiltrates into the basin alluvium deposits. Mountain-front recharge in the United States portions of the study area was evaluated using the Hearne-Dewey (1988) regression equation for mean annual recharge of a tributary basin. The Hearne-Dewey regression equation was developed, based on data for 16 basins in northern New Mexico, to estimate average annual basin water yield based on winter precipitation, basin slope, and basin area. The method assumes that recharge occurs solely along ephemeral streams in response to snow melt and local rainfall events. Recharge is estimated using the following equation:

$$Q = (1.074 \times 10^{-5})\, A^{1.216}\, P^{2.749}\, S^{0.535} \qquad (49)$$

Where,
Q is mean annual recharge;
A is area of drainage basin;
P is mean winter precipitation; and
S is slope of basin.

The inputs to the regression equation are mean winter precipitation, basin area, and basin slope. Tributary sub-watersheds that contribute to mountain-front recharge were defined based on the intersection of USGS Watershed Boundary Dataset HU-10 with the lateral extent of the Santa Fe formation. **Figure 4.3** shows the spatial extent of the contributing sub-watersheds for the Rincon and Mesilla basins.

17	3.9

Figure 4.3. Sub-Watersheds Contributing to Mountain-Front Recharge in Rincon and Mesilla Basins North of the International Border with Mexico

Winter precipitation was determined on the basis of historical precipitation surfaces included in the PRISM dataset, previously described in Section 2.1.1 of this report. Winter precipitation was defined as the months October through April, as was done in the original study of Hearne and Dewey (1988). Precipitation data for each contributing sub-watershed were extracted from the nation-wide PRISM dataset. Winter precipitation data were compiled for each year from 1895 through 2010 and used to determine an average winter precipitation value for each contributing sub-watershed (**Figure 4.3**).

The original study of Hearne and Dewey (1988) defines the basin slope by two points along the main stream channel, 10 percent and 85 percent from the lowest point on the channel. A stream order analysis was undertaken within each contributing watershed to identify the main stream channel. Points along the main channel located 10 percent and 85 percent of the total channel length from the basin outlet were then calculated for each contributing watershed, and the channel slope between these two points was calculated.

The Hearne-Dewey (1988) regression analysis yielded mountain-front recharge rates of about 9,360 AF/year and 5,430 AF/year for the Rincon and Mesilla basins respectively. These estimates are compared against previously published estimates of mountain-front and mountain-slope recharge rates in the Rincon and Mesilla Basins in **Table 4.2**, and are generally comparable to those previously estimates. The annual rates determined in this analysis were converted to constant rates of 780 AF/month and about 450 AF/month for the groundwater budgets for the Rincon and Mesilla basins, respectively.

Table 4.2. Comparison of Mountain-Front and Mountain-Slope Recharge Estimates

Rincon Basin	Mesilla Basin	Rincon and Mesilla Basins, Total	Source

NR	NR	10,830[a]	Frenzel and Kahler (1992)
23,910	4,350	28,260	Wilkins (1996)

Mountain-front and mountain-slope recharge rates in acre-feet per year
NR: Not reported
[a] Rates used in groundwater flow model

Mountain-front recharge occurring in the Conejos-Medanos Basin, Mexico, is estimated to be 2,000 AF/year, based on a previous study by CH2MHILL (2013). This annual rate was converted to a constant rate of about 167 AF/month for the Mesilla Basin groundwater budget.

4.2 Groundwater Outflows

Discharge or outflow from the Rincon and Mesilla groundwater basins occurs via: (1) subsurface flow into adjacent groundwater basins (Interbasin outflows), (2) agricultural groundwater pumping, (3) urban groundwater pumping, (4) evapotranspiration (ET) from phreatophytes (riparian vegetation), and (5) groundwater flow into gaining reaches of streams and drains. Groundwater outflows to surface water are lumped under a single term representing net groundwater-surface water exchange. Each of these groundwater outflow components was determined separately for the Rincon and Mesilla basins.

4.2.1 Interbasin Subsurface Outflow

Groundwater underflow from the Rincon Basin occurs as discharge through relatively shallow, saturated river alluvium in Selden Canyon. Underflow through Selden Canyon from Rincon Basin into Mesilla Basin is estimated to be 10 AF/yr, based on simulation output from the NMOSE administrative groundwater model (SSPA, 2007). This annual rate was converted to a constant rate of 0.8 AF/month for the Mesilla Basin groundwater budget.

Groundwater underflow from the Mesilla Basin occurs as discharge to the adjacent Hueco Bolson at Fillmore Pass, and in the saturated river alluvium at the El Paso Narrows (**Figure 4.2**). Underflow at Fillmore Pass is estimated to be 1,000 AF/year, based on groundwater model simulations by Montgomery & Associates (M&A) (2016) for Hueco Bolson. Underflow at the ElPaso Narrows is estimated to be 50 AF/year, based on field studies reported by Slichter (1905). Total underflow from the Mesilla Basin into adjacent basins is estimated to be 1,050 AF/year. This annual rate was converted to a constant rate of about 88 AF/month for the Mesilla Basin groundwater budget.

Interbasin subsurface outflows are summarized in **Table 4.1**.

4.2.2 Agricultural Groundwater Pumping

Irrigation groundwater pumping rates in the Rincon and Mesilla basins were estimated as described in Section 2.1 of this report.

4.2.3 Urban Groundwater Pumping

Urban groundwater pumping in the basins includes three categories of water uses: (1) municipal and industrial (M&I), (2) domestic, and (3) stock. M&I pumping was further partitioned into pumping corresponding to large municipalities, including Las Cruces, Santa Teresa, El Paso (Canutillo wellfield), and the wellfield serving Ciudad Juarez located in the Conejos-Medanos aquifer in the southern portions of the Mesilla Basin. Annual groundwater withdrawals for M&I uses are summarized in **Table 4.3**.

[a] M&I = Municipal and Industrial water use

Information for water production wells located in New Mexico was obtained from records for points of diversion available from the online New Mexico Water Rights Reporting System (NMWRRS) (NMOSE, 2015), which links to New Mexico's Water Administration Technical Engineering Resource System (WATERS) database. The WATERS database includes information on well location, water use, well construction details, pump yield, metered pumping data, and water right information. Individual wells were considered and evaluated for this water budget analysis. Basin-wide pumping was determined by summing pumping rates for individual wells located within each basin and for each water use category. If location coordinates were not specifically reported for a well, then the well was assumed to be located at the center of its reported cadastral location. Wells without reported location coordinates or cadastral location were assumed to not exist and were not included in this analysis.

Information for water production wells in Texas was obtained from the Texas Water Development Board's (TWDB) online Groundwater Database (GWDB) (TWDB, 2015). The Groundwater Database contains information for well construction, water use, depth to water, and estimated pumping rates. Information for water production wells in Mexico includes location, approximate extraction rates, and water use, as reported by the IBWC (2011).

Reported well installation information indicates that relatively few wells existed in the study area prior to 1950 and most were registered as domestic wells. **Figures 4.4 and 4.5** show reported cumulative annual well installation histories by water use for registered water supply wells in New Mexico and Texas, respectively. Wells installations in New Mexico steadily increased from 1950 through the 1970s. After the 1970s, well installation rates increased again through about 2016. The majority of wells installed during the 1980s and 1990s were domestic wells; however, the number of M&I well installations increased as well. An increase in the rate of installation of irrigation wells occurred in the mid-2000's (**Figure 4.4**). M&I wells have been the dominant well type in the Texas portions of Mesilla Basin (**Figure 4.5**). However, irrigation well installations increased in the mid-2000. By 2015, more than 11,500 registered water supply wells (approximately 7,400 urban and 4,100 irrigation) were installed in both basins in the study area. However, these counts do not reflect the total number of potentially active water supply wells. Well installation dates are not reported in the state databases for more than 3,500 wells in New Mexico portions of the study area and 17 wells in Texas portions. Spatial distributions of production wells in 1938 (before Compact) and in 2014 are shown on **Figures 4.6 and 4.7**. The spatial locations of wells are not utilized for the water budgets; instead, well locations are used as inputs to the numerical groundwater flow model developed by William R. Hutchison.

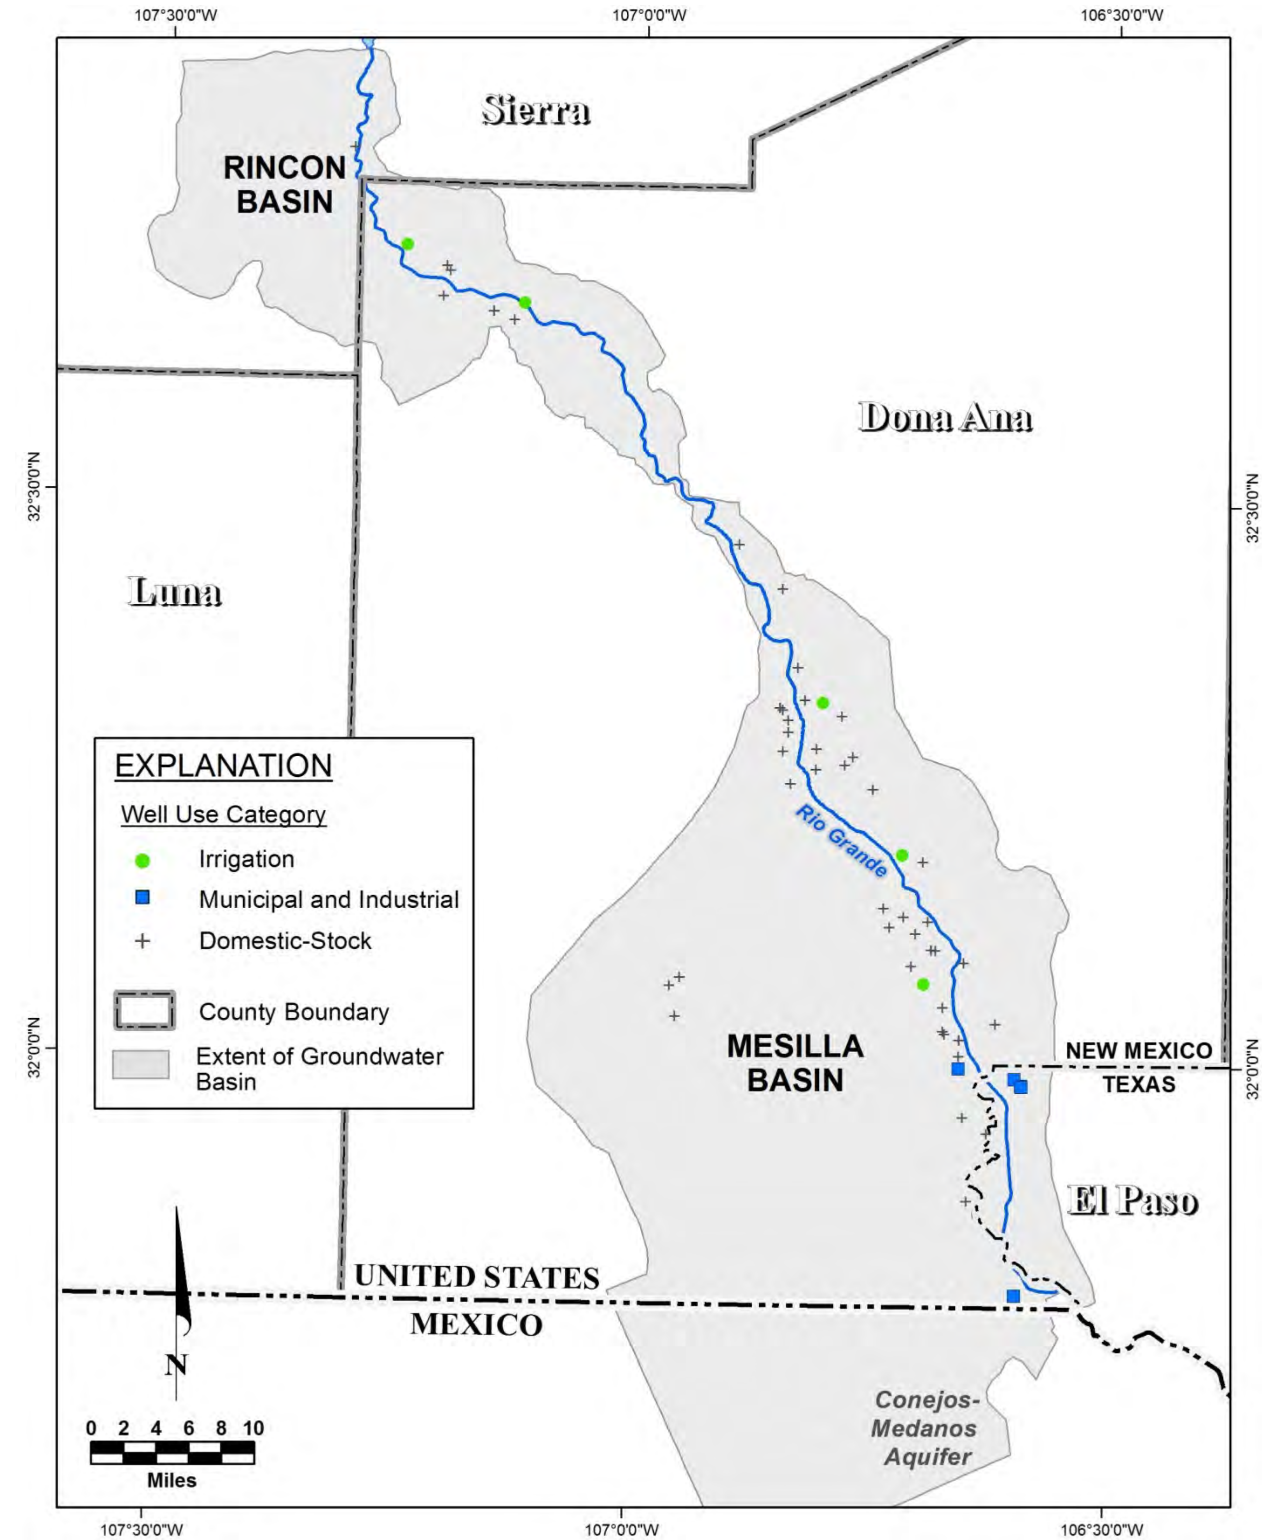

Figure 4.6. Location of Reported Wells in Rincon and Mesilla Basin: 1938

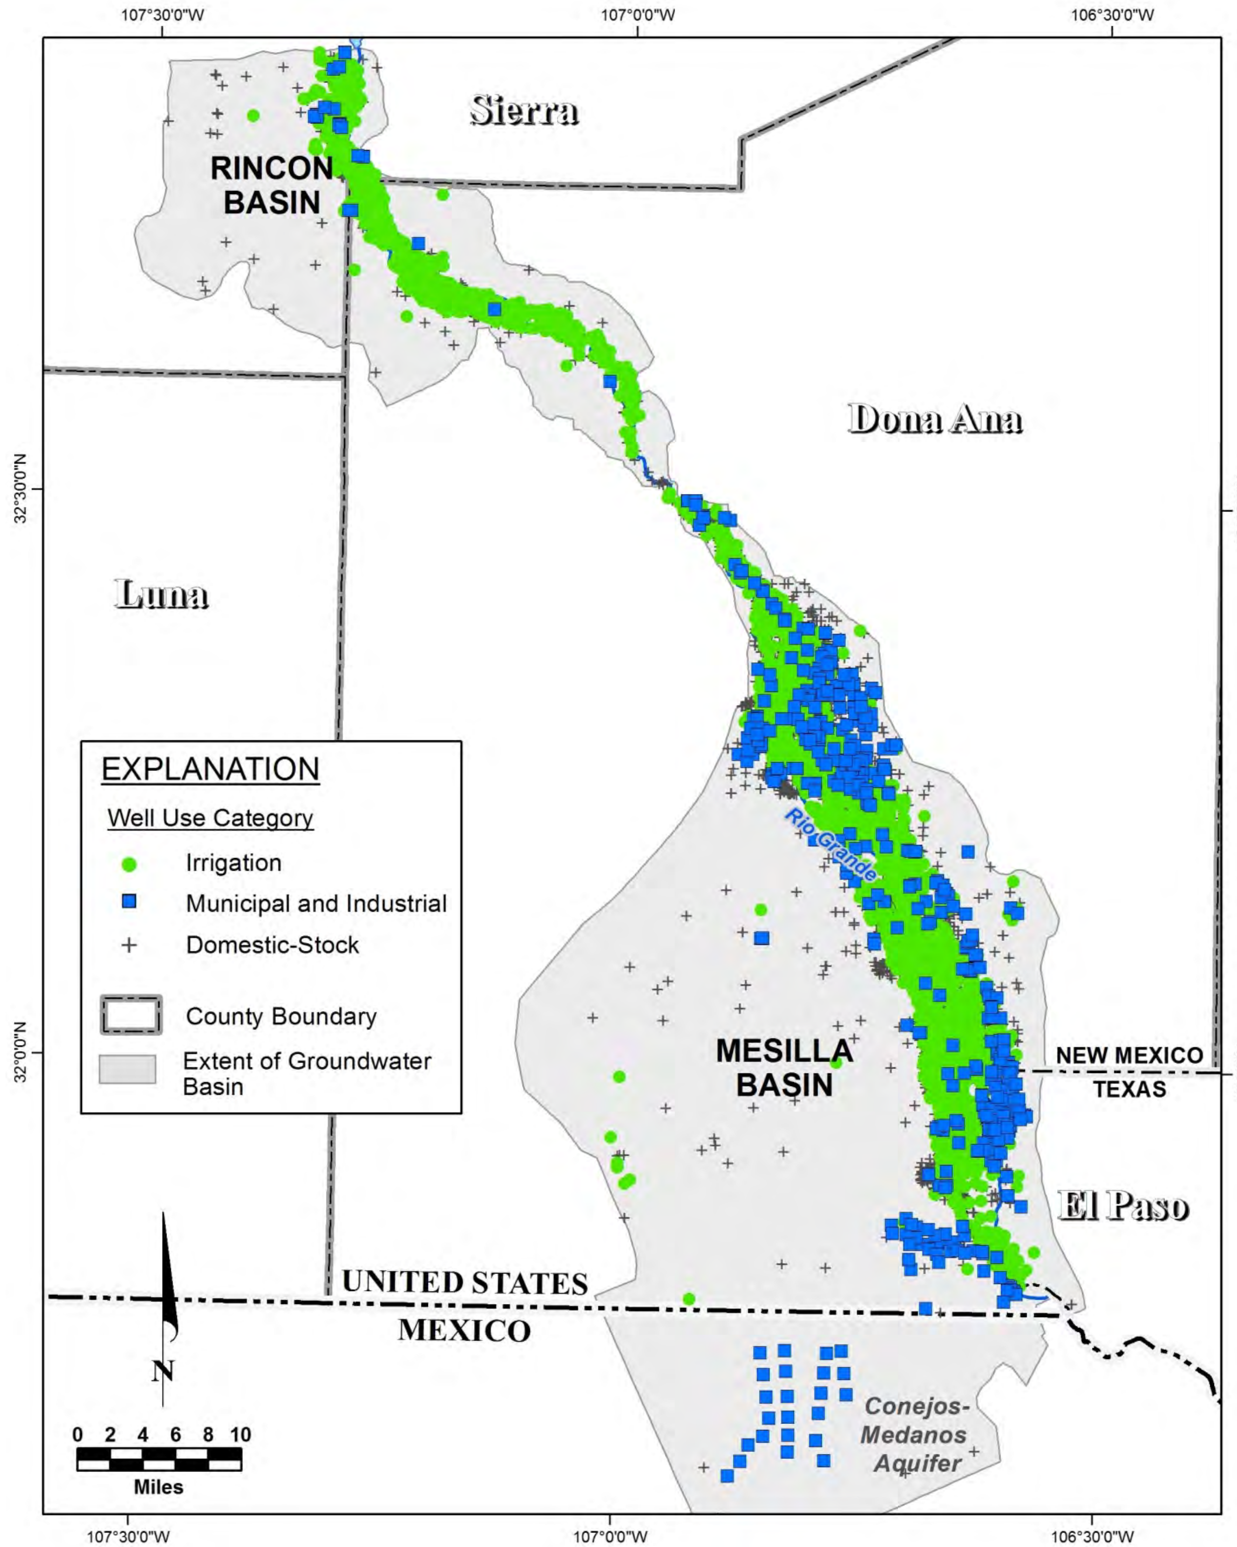

Figure 4.7. Location of Reported Wells in Rincon and Mesilla Basin: 2016

Estimated total historic annual urban groundwater pumping in the study area occurred predominantly in Mesilla Basin and has substantially increased through time since the 1950s. Pumping estimates for each urban water use category (M&I, domestic, and stock) is described in the following sections of this report. Cumulative annual estimated groundwater withdrawals by water use are shown on **Figure 4.8**. The majority of groundwater pumped from the basin aquifers is used for irrigation purposes. M&I groundwater use increased through time as urban areas grew in the basins. Although there are large numbers of domestic wells in the basins, collectively they account for a very small portion of overall estimated groundwater withdrawals. The well registries do not always record when wells are no longer active or were destroyed. It is possible that some wells, especially domestic wells, are no longer used because households connected to municipal water supplies.

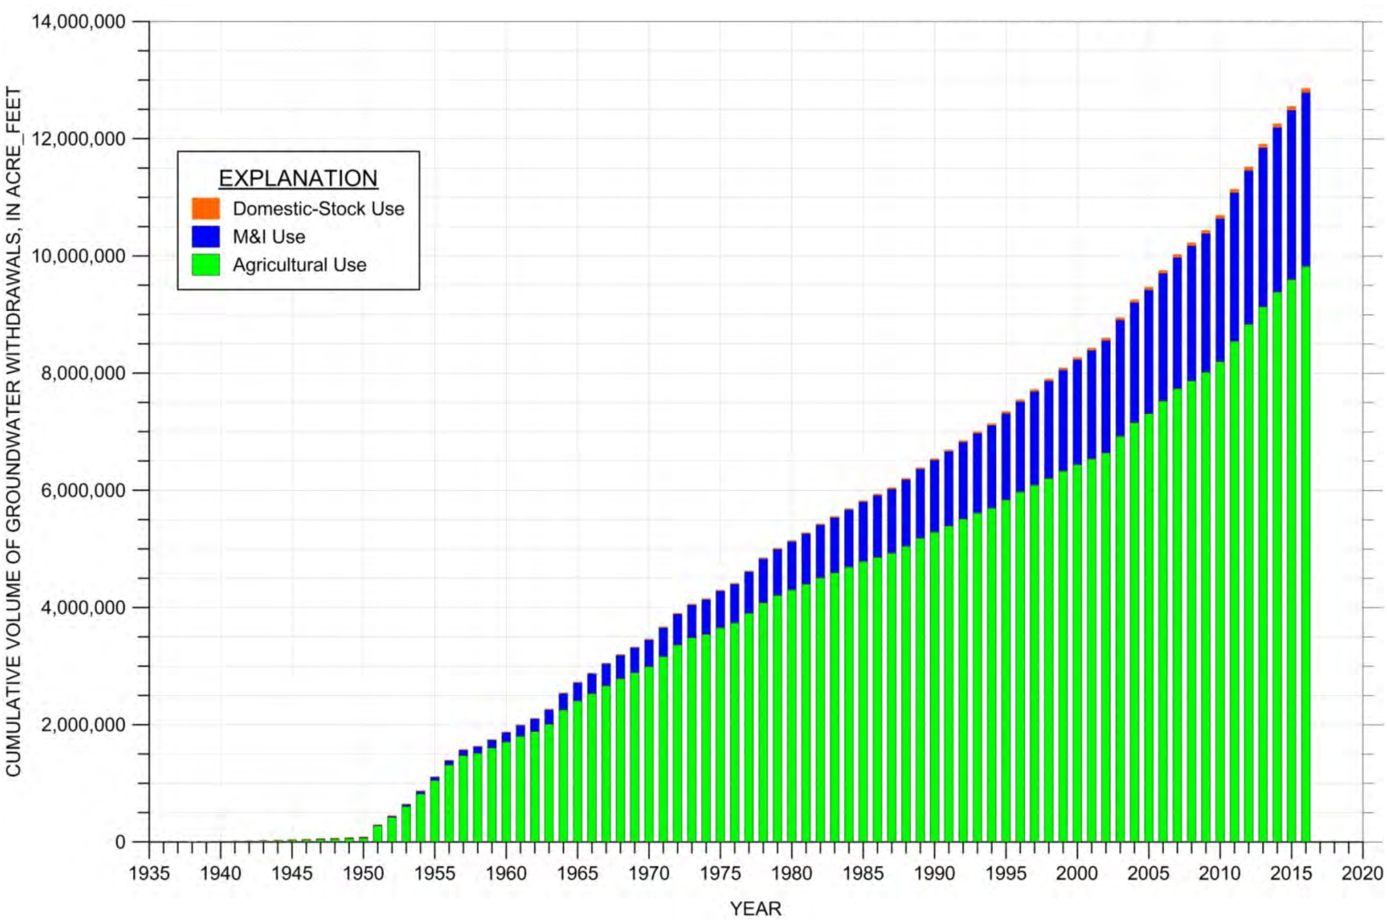

Figure 4.8. Cumulative Estimated groundwater Withdrawals in Rincon and Mesilla Basins in New Mexico, Texas, and Mexico

4.2.3.1 Municipal and Industrial Pumping

The principal sources of information used to develop basin-wide M&I pumping estimates for the water budgets are (1) metered pumping data obtained from the online New Mexico Water Rights Reporting System (NMWRRS), which links to New Mexico's Water Administration Technical Engineering Resource System (WATERS) database, (2) pumping datasets obtained from El Paso Water Utilities for the Canutillo wellfield, and (3) input datasets for the numerical groundwater flow model developed for the New Mexico Office of State Engineer (NMOSE) by S.S. Papadopulos & Associates (SSPA) (2007). For periods when primary source data were not available, pumping estimates were made using available data, as described in subsequent portions of this section.

Information on well location, drill date, and water use was obtained from well records available for active points of diversion from the online NMWRRS and TWDB GWDB. This information was used for (1) determining whether a well is located in Rincon or Mesilla basin, (2) assigning a well to a water use category, and (3) assigning a pumping start date to a well. Wells with no reported drill dates were assumed to be active and were evenly distributed over the study period. Basin-wide pumping was determined by summing pumping rates for individual wells located within each basin. **Figure 4.9** shows the locations of municipal and industrial water supply wells in the study area. The vast majority of M&I wells in the study area are located within Mesilla Basin along the Rio Grande corridor. Estimated historic groundwater pumping by water use sector in Rincon and Mesilla basins is shown on **Figures 4.10 and 4.11**, respectively.

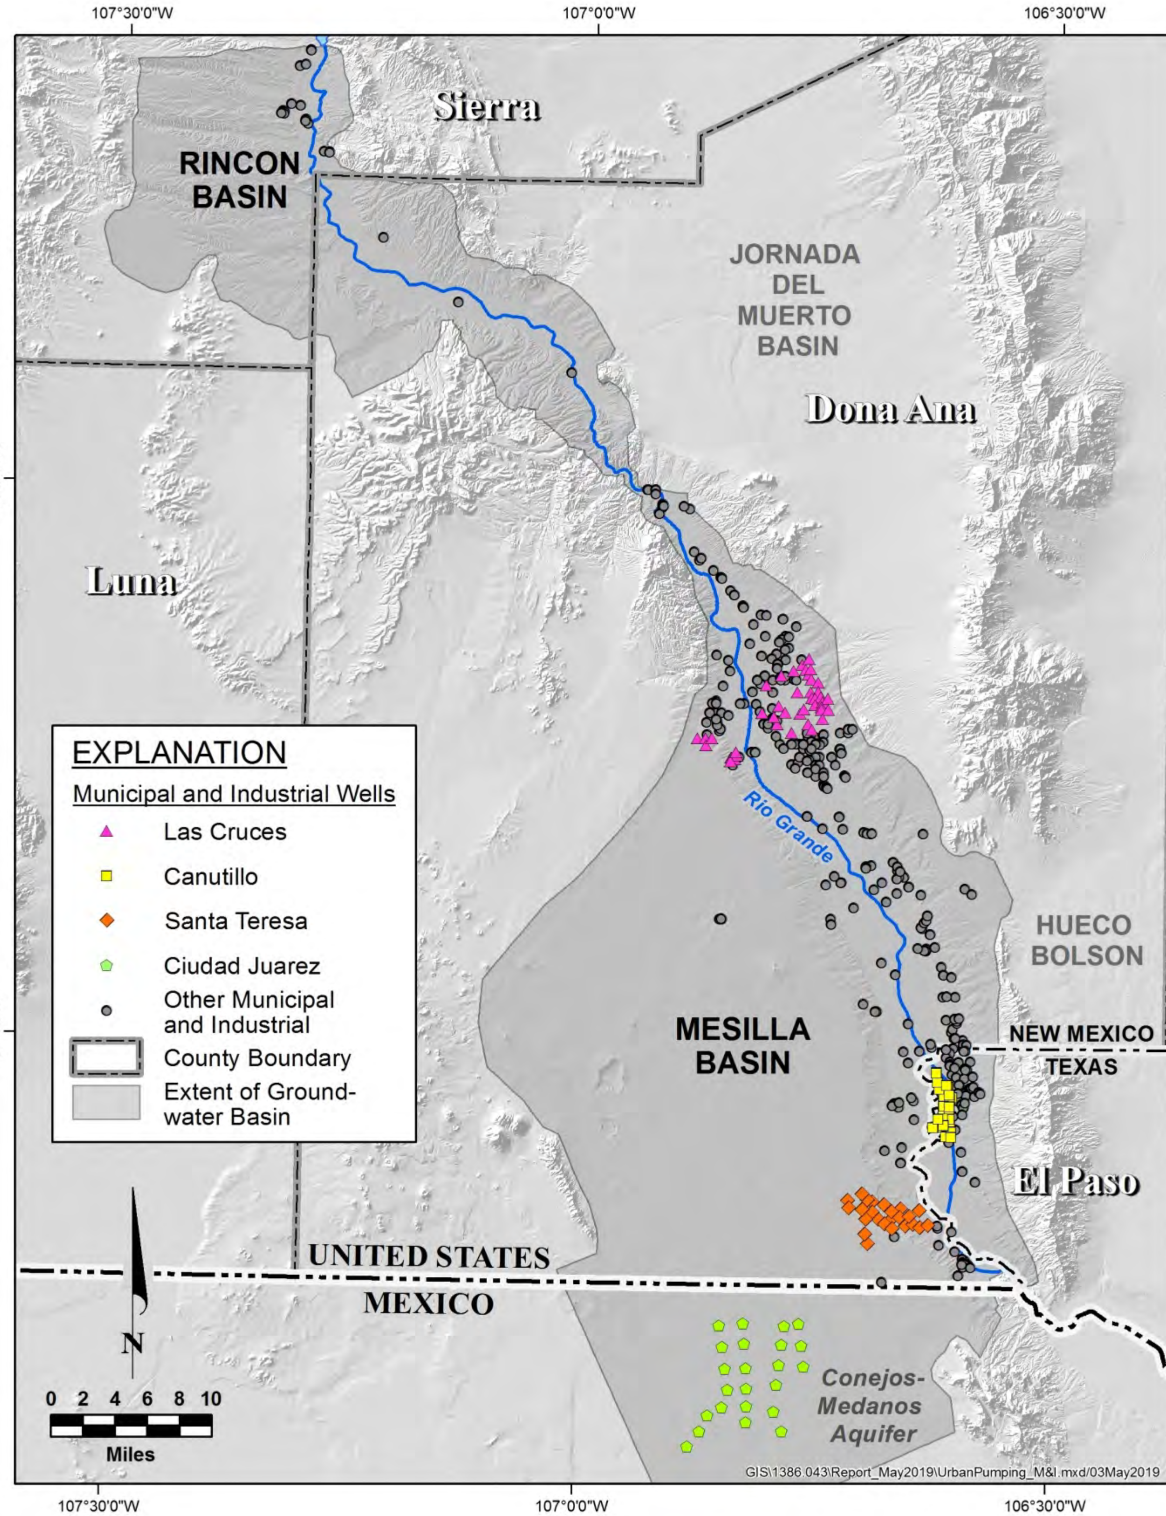

Figure 4.9. Locations of Municipal and Industrial Water Supply Wells In Rincon and Mesilla Basins

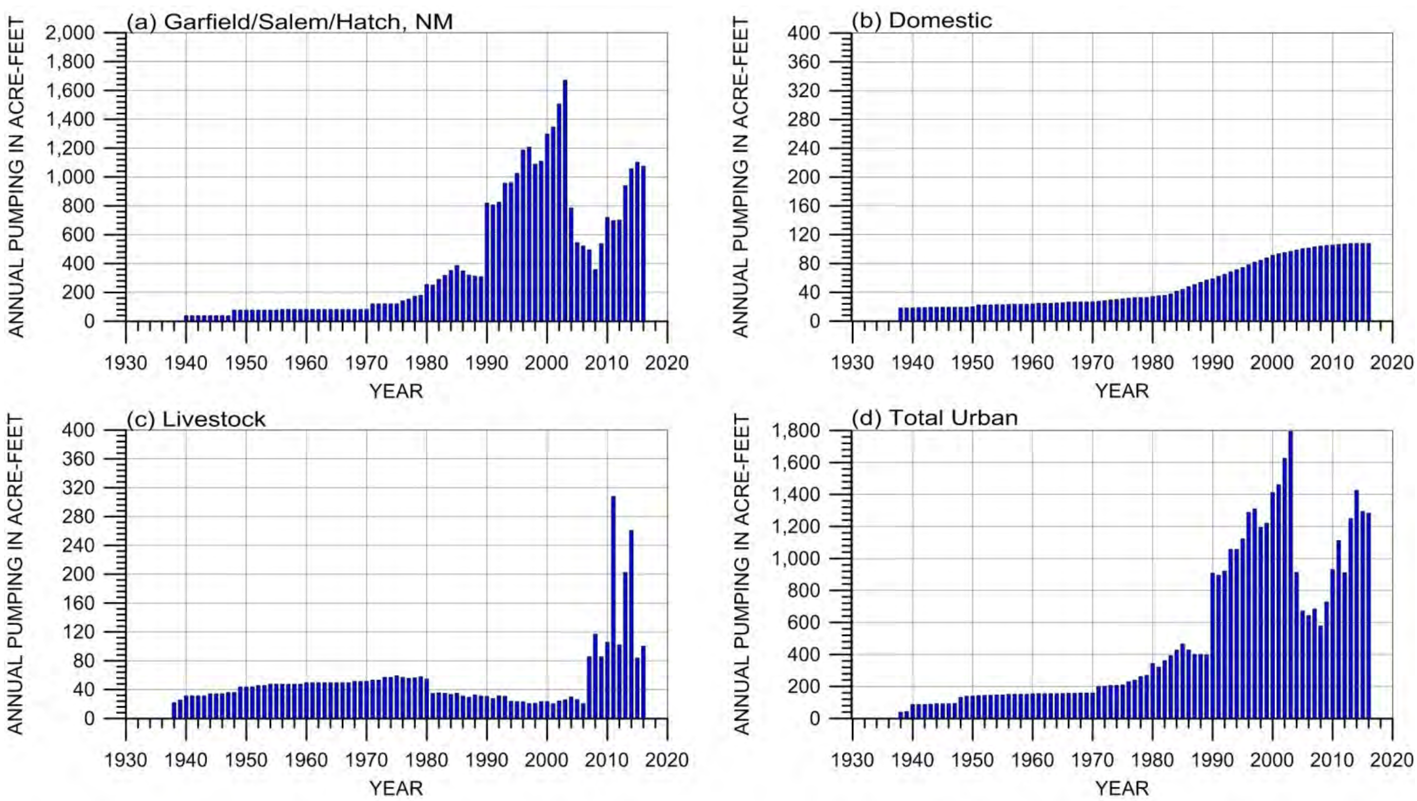

Figure 4.10. Estimated Historic Annual Urban Groundwater Withdrawals by Water Supply Wells in Rincon Basin

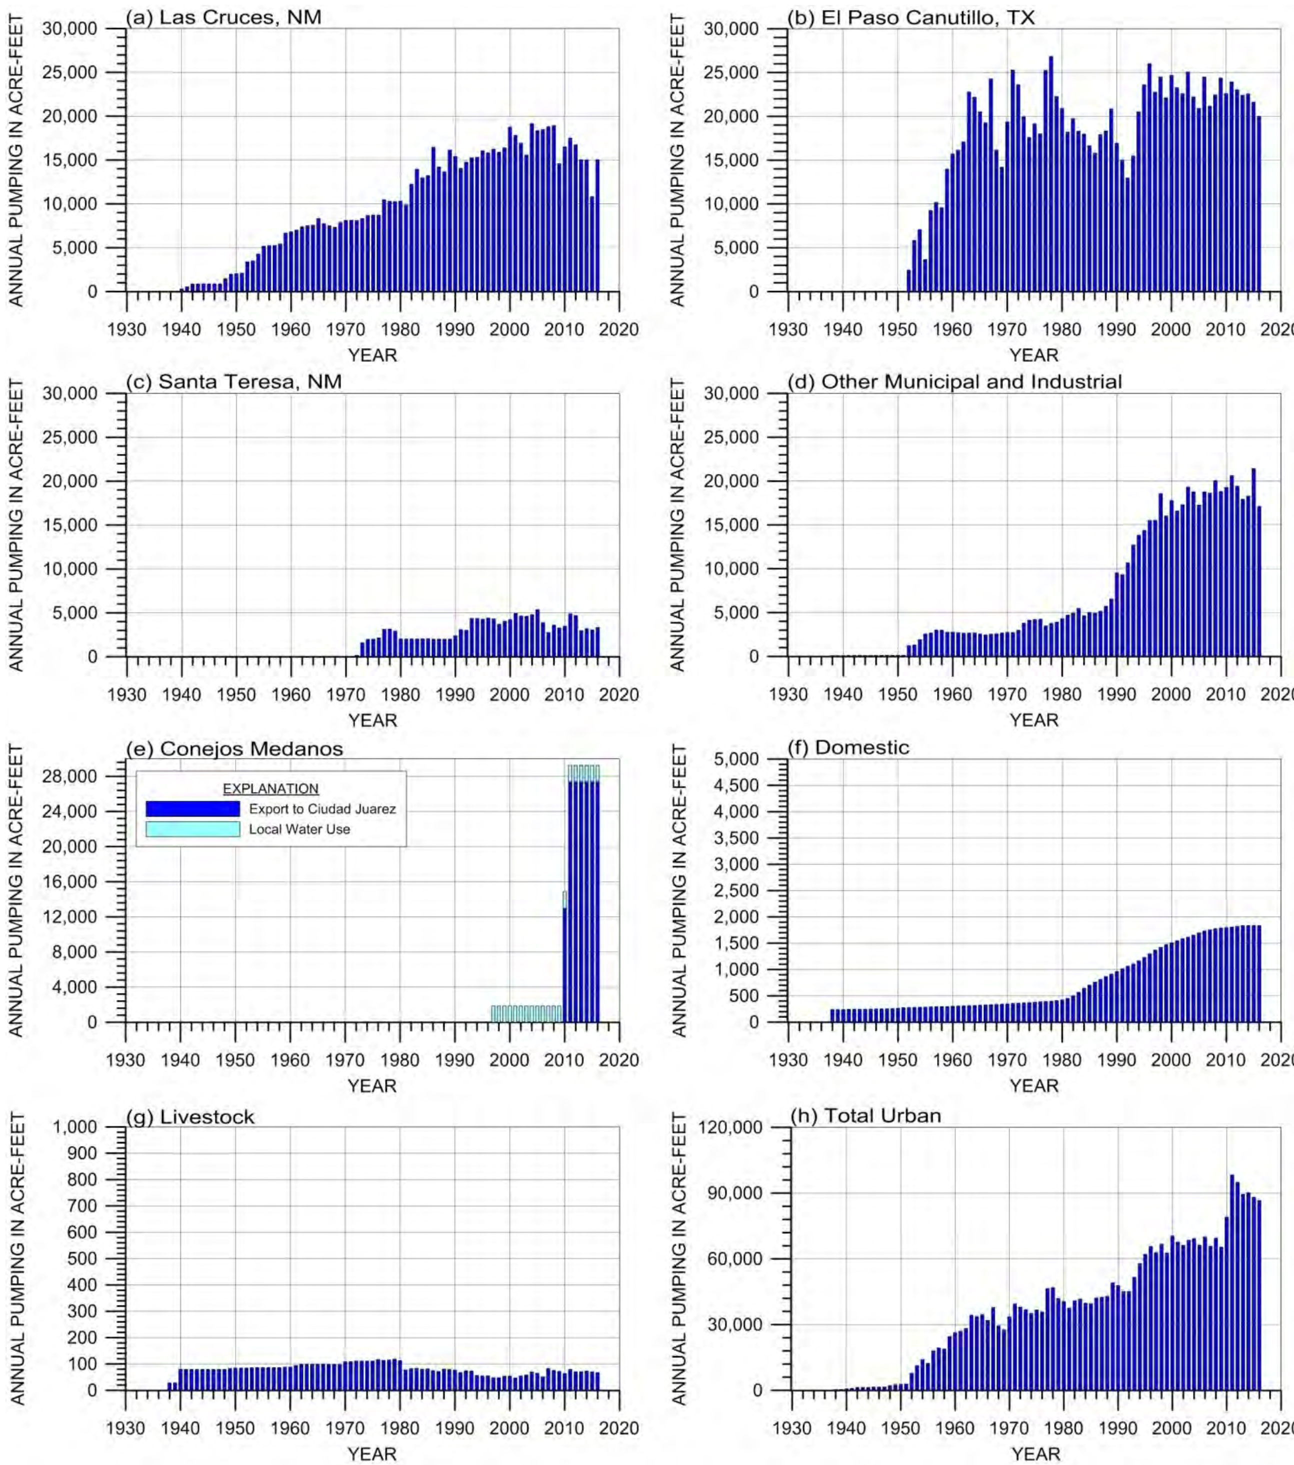

Figure 4.11. Estimated Historic Annual Urban Groundwater Withdrawals by Water Supply Wells in Mesilla Basin

The SSPA (2007) groundwater flow model of the Lower Rio Grande Basin is based on primary data sources on urban groundwater pumping that were unavailable for this investigation. The procedures for determining urban groundwater pumping rates for the SSPA model were reviewed and were determined to be satisfactory for the objective of this analysis. Furthermore, the well input datasets for the model are consistent with available water rights information, as well as regional trends and projections of water use in the basins reported by Terracon and others (2004) and Shomaker & Associates (2008). The SSPA model files for well pumping includes annotation that describes the owner and use of the simulated wells. The SSPA model urban pumping dataset is considered to be a reliable data source for this water budget analysis.

Groundwater pumping information is available for January 1940 through February 2004 from the SSPA (2007) model. It was therefore necessary to extend the period of record on groundwater pumping from 1938 through 2016 for this water budget analysis. This was done individually by well type using a variety of data sources to check estimated values. Non-irrigation well categories specified in the SSPA model include public supply (Las Cruces, Canutillo, and Santa Teresa), New Mexico Municipal and Industrial (NM M&I), Texas Municipal and Industrial (TX M&I), New Mexico Domestic, Sanitary, and Stock, as well as Texas Domestic, Sanitary and Stock. These well types, except domestic and stock, are grouped into the M&I pumping category. Public supply and NM M&I uses constitute the majority of urban groundwater pumping in the basins.

In 2004, the NMOSE imposed metering requirements on wells in the Lower Rio Grande (LRG) Water Master District, which includes the Rincon and Mesilla basins. Meters are required for all wells in the New Mexico portions of the basins, except single-family domestic wells and livestock wells. According to the 2007 LRG Water Master Report, by 2007, about 86 percent of wells were in compliance with the metering requirements (Dorman, 2008). The metering requirements also include reporting monthly data on a quarterly basis. The metered pumping datasets include dates and totalizer readings, which allows for monthly or annual pumping volumes to be estimated. Prior to 2004, if metered data were not available for a particular well, then an annual pumping rate was obtained from the SSPA model for the well. Monthly pumping rates were determined by applying a monthly distribution factor to annual rates. Monthly distribution factors were determined for each well based on available metered data associated with the well; or, if metered data were not available for a well, then an average distribution was applied based on metered data for other wells.

Las Cruces

Las Cruces, New Mexico municipal groundwater pumping data were compiled from a variety of sources. Monthly pumping data for January 1940 through February 2004 were obtained from pumping input datasets for the SSPA (2007) groundwater model. The SSPA model input files are annotated with well identifiers, which were used to match model wells to registered wells from the New Mexico and Texas well databases. Las Cruces production wells in the study area have state registration identifiers starting with “LRG 430”. The pumping time-series data in the model input files were compared to reported drill dates for the individual wells. In some cases, pumping in the SSPA model is assigned to wells before the reported drill dates. In these cases, any pumping rates that were specified before the reported drill date for a particular well were equally distributed and added to wells that had already been drilled.

Monthly Las Cruces well pumping for 2004 through 2016 were estimated following a series of steps using several data sources. First, medium-growth demand projections from the City of Las Cruces 40 year water development plan (Shomaker and Associates, 2008) were evaluated against historical pumping trends shown in model input files for the SSPA (2007) groundwater model, and were found to be in good agreement. Second, the demand projections were compared against available Las Cruces well metered pumping data for 2009 through 2013. The metered groundwater diversions are slightly lower than the projections; further investigation revealed that this is due to the absence of metered data for several public supply wells. Based on these comparisons, the demand projections were determined to be reliable.

Las Cruces water demand projections are available at 5-year intervals starting in 2005 (Shomaker and Associates, 2008). Annual demands between projected years were calculated by linear interpolation. Next, the water demand projections had to be adjusted to remove Las Cruces groundwater pumping from the Jornada del Muerto Basin (**Figure 4.9**) so the water budget considers only Las Cruces groundwater pumping in the Mesilla Basin. Las Cruces groundwater diversion metered data for 2010 through 2013 were examined to determine the average proportion of groundwater diversions that occur in the Jornada Basin. From 2010 through 2013, about 12 percent of total Las Cruces annual groundwater pumping occurred in the Jornada Basin. Annual water demand projections were accordingly multiplied by a factor of 0.88 to represent only water demand satisfied by groundwater diversions from the Mesilla Basin.

The final task for determining Las Cruces groundwater pumping was to down-sample from annual to monthly groundwater diversions. This is necessary because water demand varies seasonally in Las Cruces. Seasonal pumping variations specified in the SSPA (2007) groundwater model were investigated. From 1982 through 2004, the ratio of primary irrigation (PI) to secondary irrigation (SI) groundwater diversions was equal to 3.9. This indicates that 3.9 times as much groundwater was pumped during the PI season (March through October) compared to the SI season (November through February). For consistency with historical SSPA model data, this ratio was used to partition yearly pumping between PI and SI periods, with constant monthly pumping rates within the periods. The resulting calculated values were checked to ensure consistency with projected annual groundwater diversions and then used to complete the groundwater diversion record for the City of Las Cruces.

Historic annual groundwater pumping from Las Cruces water production wells is shown on **Figure 4.10a**. Annual groundwater pumping to supply Las Cruces has increased from less than 3,000 AF/year in the 1950s to nearly 20,000 AF/year by 2004. Annual pumping by Las Cruces decreased slightly after 2010.

El Paso Canutillo

The City of El Paso, Texas extends into the Mesilla Basin. El Paso Water Utilities operates the Canutillo wellfield for municipal supply for users in Mesilla Basin (**Figure 4.8**). Canutillo pumping data were obtained from El Paso Water Utilities for this analysis. Monthly pumping volumes were provided for 1967 through 2016 and annual pumping volumes were provided for 1952 through 1966. The annual volumes were disaggregated to monthly volumes using average monthly distribution fractions. The monthly fractions were estimated using the available post-1966 monthly data. The monthly volumes were directly used in this evaluation.

Reported historic annual pumping from El Paso Water Utilities supply wells in the Canutillo wellfield is shown on **Figure 4.9b**. Annual pumping from the wellfield increased through the 1970s before decreasing steadily during the 1980s and early 1990s. Since 1995, Canutillo pumping has been relatively stable with rates ranging from about 21,000 to 26,000 AF/year.

Santa Teresa

Pumping data for water supply wells that serve the city of Santa Teresa, New Mexico are reported in the SSPA (2007) groundwater model by primary and secondary irrigation stress periods from 1972 through 2004. Metered data for Santa Teresa wells are available from 2004 through 2016. Similar to the procedure used for Las Cruces wells, metered data were analyzed to determine the fraction of total annual pumping that occurs during each month. Those monthly fractions were then used to disaggregate pumping rates from the SSPA model from stress period values to monthly values. **Figure 4.11c** shows annual pumping rates summed over all Santa Teresa wells. Annual pumping rates were less than 3,000 AF/year during the 1970s and 1980s, which then increased to nearly 5,000 AF/year during the 1990s. Pumping rates have subsequently declined during recent years.

Other Municipal and Industrial

In addition to M&I groundwater pumping by specific municipal water providers, M&I pumping by other water users, referred herein as “other M&I” pumping, occurs throughout the Rincon and Mesilla basins (**Figure 4.9**). Other M&I wells are predominantly located in the New Mexico portion of the Mesilla basin, and were identified based on reported water right information associated with wells in this category located in New Mexico. Most of the nearly 400 other M&I wells shown on **Figure 4.9** are associated with municipal water use (55 wells) mobile home parks (53 wells), commercial uses (48 wells), community type uses (48 wells), dairy operations (39 wells), subdivisions (37 wells), and several other categories with smaller number of wells.

Pumping rates corresponding to New Mexico wells in this category have been tabulated as input data to the SSPA (2007) groundwater model for the period from 1940 through 2004. Metered data for some of these wells are available from 1990 through 2016. Metered pumping data for wells in this category were analyzed to determine the monthly distribution of total annual groundwater pumping, and the corresponding fractions were used to disaggregate pumping rates reported in SSPA model input data sets to monthly time series. For the period after 2004, metered pumping rates were assigned to each well, where available.

Groundwater pumping for the other M&I wells in Texas was determined based on records from the Texas Water Development Board (TWDB) database and the OSE-SSPA model (SSPA, 2008). For years 1945-1990, groundwater diversions from the NMOSE administrative groundwater flow model WEL package were used. For 1991-1999, 1990 rates were repeated. For years 2000-2012, TWDB groundwater diversion estimates are used, where available; otherwise, reported rates from the WEL package are used. TWDB records provide annual values for groundwater diversion by well; if monthly diversions were available from the WEL package data, then the annual values were used to rescale the average monthly diversion fractions. Otherwise, annual diversions were distributed equally among months of the year, for each well.

Annual pumping from the other M&I wells in Rincon and Mesilla basins is shown on **Figures 4.10a and 4.11d**. Pumping from these wells increased steadily through time before substantially increasing in the 1990s. Annual rates became more stable after the 1990s, with rates varying between about 16,000 and 20,000 AF/year.

Conejos-Medanos

The Conejos-Medanos Aquifer is located in Chihuahua, Mexico and is the southern portion of the Mesilla Basin aquifer system (**Figure 4.9**). Prior to 2010, groundwater withdrawals in the Conejos-Medanos Aquifer were less than 2,000 acre-feet per year, and were associated with relatively small-scale agriculture, small municipalities, livestock, and utilities water uses (SGM, 2011). Monthly groundwater pumping rates reported by SGM (2011) are used in this study. The earliest water right registry in the Mexican Public Registry of Water Rights (REPDA) occurred in 1997; it is therefore assumed that groundwater pumping prior to 1997 as negligible and is not considered in the water budget. **Figure 4.11e** shows annual groundwater pumping rates in the Conejos-Medanos aquifer. It should be noted that some of the groundwater uses depicted in **Figure 4.11e** correspond to agriculture; however, the pumped volumes are estimated differently from the procedure used to estimate irrigation pumping in the Rincon and Mesilla Basins, and therefore are reported as M&I pumping for this analysis.

In 2010, Ciudad Juarez began pumping groundwater from its constructed wellfield in the Conejos-Medanos aquifer for supplemental municipal water supply. Water is conveyed (exported) from the wellfield to Ciudad Juarez, located approximately 15 miles to the east, via the Conejos-Medanos Aqueduct. Municipal pumping rates in Conejos-Medanos was about 13,000 AF/yr in 2010 and approximately 27,400 AF/yr from 2011 through 2014 (SGM, 2011). Pumping rates for 2015 and 2016 are not available for this analysis; thus, pumping rates for these years were assigned to be the same as in 2014. These pumping rates are shown in **Figure 4.11e**. Groundwater pumping for export to Ciudad Juarez is substantially greater than groundwater pumping to supply local water demands.

Total Municipal and Industrial Pumping

The vast majority of M&I groundwater pumping in the study area occurs within Mesilla Basin, as shown on **Figure 4.9**. Annual M&I pumping in Mesilla Basin substantially increased after the early-1950s, and steadily increased through time to approximately 65,000 AF/year by 2000. In 2010, the Ciudad Juarez wellfield in the Conejos-Medanos aquifer in the southern portions of Mesilla Basin began pumping operations, which resulted in a sudden increase in total M&I pumping in Mesilla Basin (**Figure 4.11h**). From 2000 through 2016, M&I pumping rates in the United States portion of Mesilla Basin (not including Conejos Medanos) ranged from about 65,000 to 69,000 AF/year.

4.2.3.2 Domestic Pumping

Basin-wide groundwater withdrawals from domestic wells were calculated by multiplying the number of domestic wells located within the study area, for each month, by a constant pumping rate. Monthly records of domestic wells were developed based on reported drill date for active points of diversion with specified domestic use in the NMOSE WATERS database. Reported well drill dates were then used to determine the number of wells that existed in the study area each month. Total groundwater pumping by domestic wells was then calculated assuming a constant monthly pumping ("diversion") rate of 0.025 AF/month (0.3 AF/year), as was done in a previous study by the NMOSE regarding groundwater withdrawals for domestic use in New Mexico (NMOSE, 2000).

Records for a portion of domestic wells did not contain information on drill date or well casing information. Those wells were excluded from this water budget analysis.

Historic annual domestic pumping in the Rincon and Mesilla basins is shown on **Figures 4.10b and 4.9f**. Annual pumping rates have increased through time, most dramatically after 1980, to a maximum estimate of about 2,000 AF/year by 2013. However, domestic pumping is a relatively small component of the overall groundwater budget.

4.2.3.3 Livestock pumping

Groundwater pumping to supply livestock water consumption was estimated based on beef cattle livestock water consumption estimates from the National Agricultural Statistics Service (USDA, 2013) for years 1975 through 2013, and estimates of per capita (animal unit or head) water consumption by beef cattle published by the NMOSE (Longworth and others, 2008). Per capita water use by livestock prior to 1975 is assumed to be similar to stock water use in 1975. Annual groundwater diversion rate per stock well was calculated as the total stock water use in Doña Ana County, divided by the number of Doña Ana County stock wells recorded in the NMOSE WATERS database. Calculated values of groundwater diversion per well were then multiplied by the number of stock wells located within each basin to yield a monthly a time series of groundwater diversion for livestock. Annual pumping estimates for stock wells in the Rincon and Mesilla basins are shown on **Figures 4.10c and 4.11g**. Livestock pumping is a small component of the overall groundwater budget for the basins with total pumping rates smaller than 200 AF/year. The noticeable decrease in stock pumping in 1980 occurred as a result of a substantial decrease in the number of cattle in the basins at that time (USDA, 2013).

4.2.4 Riparian Consumptive Use

Consumptive use of groundwater by phreatophyte vegetation (riparian evapotranspiration) in the Rincon and Mesilla basins was analyzed by Land IQ for this water budget analysis. Annual riparian consumptive use was estimated for this analysis using evapotranspiration rates reported by Land IQ , annual acreages of riparian vegetation specified in the SSPA (2007) groundwater flow model prepared for the NMOSE for 1938 through 2009, and annual acreages reported by Land IQ from 2010 through 2016. Annual riparian vegetation consumptive use estimates are shown on **Figure 4.12**. Riparian vegetation acreages are shown in **Table 4.4**. The step-wise changes in total vegetation consumptive use rates through time is a result of limited availability of aerial imagery required for estimating riparian vegetation acreages; changes occur at the mid-point between two available images. Estimated annual rates were converted to monthly rates and equally distributed to each month of the respective year. For this analysis, riparian vegetation consumptive use is assumed to be constant throughout the year. Further refinements might account for seasonal differences in riparian consumptive use.

Bare soil evaporation along the Rio Grande is also included in total riparian evapotranspiration. Since riparian soil evaporation depends on a depth to water through time, this water budget relies on preliminary results from the groundwater flow model developed by William Hutchison.

Riparian evapotranspiration for each basin is summarized in Appendix C. Values represent total riparian evapotranspiration (vegetation and soil). Average annual total riparian evapotranspiration is about 10,200 AF in Rincon Basin and about 11,600 AF in Mesilla Basin. Net Groundwater-Surface Water Exchange

Net groundwater-surface water exchanges for Rincon and Mesilla basins were estimated as previously described in Section 3.3 of this report. Exchanges from the surface water budgets are input to the groundwater budgets. A positive value from the surface water budget reflects monthly net loss of groundwater to the surface water network, whereas a negative value reflects monthly net gain in groundwater from surface water.

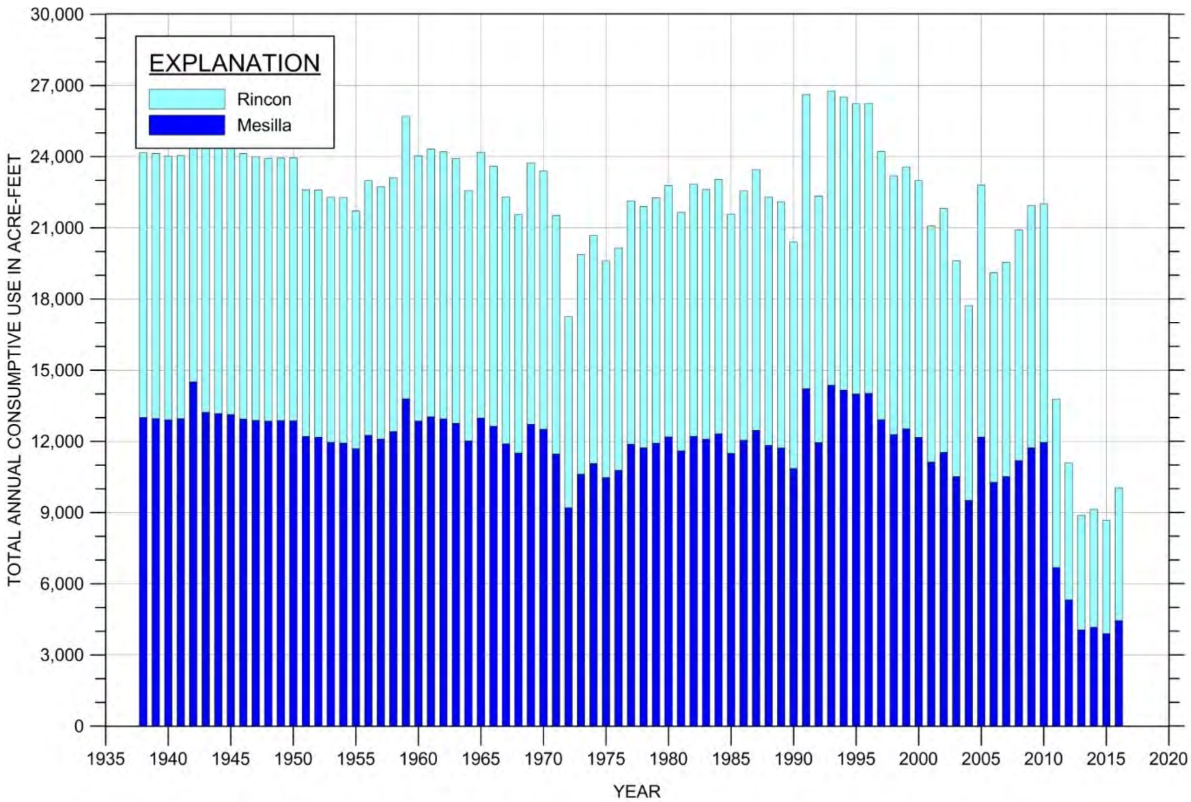

Figure 4.12. Estimated Annual Riparian Consumptive Use in Rincon and Mesilla Basins

Table 4.4. Summary of Riparian Vegetation Acreages in Rincon and Mesilla Basins

	Vegetation Acreage by Plant Group - Rincon (acres)			Vegetation Acreage by Plant Group - Mesilla (acres)										
Year	Riparian Tree	Riparian Shrub	Riparian Herb	Riparian Tree	Riparian Shrub	Riparian Herb	Riparian in Rincon (acres)	Riparian in Mesilla (acres)	Total Area (Acres)	Total Riparian Tree (Acres)	Total Riparian Shrub (Acres)	Total Riparian Herb (Acres)	Total Riparian Vegetation Area (Acres)	Acreage Source

4.3 Change in Aquifer Storage

When groundwater inflows are not equal to outflows there is a resulting change in the amount of groundwater stored in the aquifer. The change in groundwater storage is evidenced by a change in groundwater surface levels in an unconfined aquifer or a change in piezometric heads in a confined aquifer. For this analysis, changes in groundwater storage are estimated as the quantity required to close the groundwater budget shown in Equation (40). Changes in groundwater storage are used as a calibration metric for this analysis. Calibration of the water budgets was accomplished by adjusting various components until the estimated changes in groundwater storage were in reasonable agreement with simulated changes in groundwater storage from the calibrated numerical groundwater flow model developed by William Hutchison for this litigation project.

Estimated annual changes in groundwater storage are shown on **Figure 4.13**. Annual gains and losses of groundwater storage have occurred in both basins through time. Storage gains are shown as positive values on the **Figure 4.13** and storage losses are shown as negative values. It is important to note that estimated changes groundwater storage from this water budget analysis represents total storage change throughout each entire basin. This analysis does not address or identify trends that could occur in localized areas, such as agricultural versus non-agricultural areas. Groundwater storage losses occurred periodically in Rincon Basin, particularly during the 1950s, 1970s, and after 2002. A loss of groundwater storage has occurred in Mesilla Basin during the 1950s and during almost every year between 1986 and 2016. The years with the largest losses in groundwater storage in Mesilla Basin generally coincide with time periods when surface water deliveries to farms were relatively small (**Figures 2.10 and 4.13**), such as in early to mid-1950s, 2003 to 2004, and after 2010. A similar correlation occurs for Rincon Basin, such as in the mid-1950s and after 2010; however, the trends are not as obvious, partly because the magnitude of storage changes is substantially smaller than in Mesilla Basin.

Cumulative estimated annual groundwater storage changes in Rincon and Mesilla basins are shown on **Figure 4.14**. To evaluate calibration results, the cumulative storage change curves from water budget results are plotted with the cumulative curves from numerical model simulation results. Combined cumulative storage changes (both basins combined) have fluctuated above the zero line for most years from 1938 through the mid-1990s. The curve dropped below zero (cumulative loss) during the 1956-1957 and then again after 2002. Periods of gains and losses have occurred in Rincon Basin; however, the general, long-term trend is cumulative loss of groundwater in storage through time after 1975. The cumulative storage change curve for Mesilla Basin shows a similar pattern as the combined curve. A relatively steep rise in cumulative storage occurred during the 1980s when surface water deliveries to farms were relatively high. Cumulative groundwater storage has generally declined since 1986. The dramatic decrease in cumulative storage in Mesilla after 2010 indicates the impacts on the water budgets from Ciudad Juarez pumping in Conejos-Medanos in the southern portions of the basin in Mexico.

Cumulative gains in groundwater storage occurred in both basins from 1938 to about 1950. During this time period, applied irrigation water (farm deliveries) exceeded crop consumptive use estimates and the excess water was routed to deep percolation in the land-surface water budget presented herein. The gain in groundwater storage indicates that an excessive amount of water was applied to crops prior to 1950.

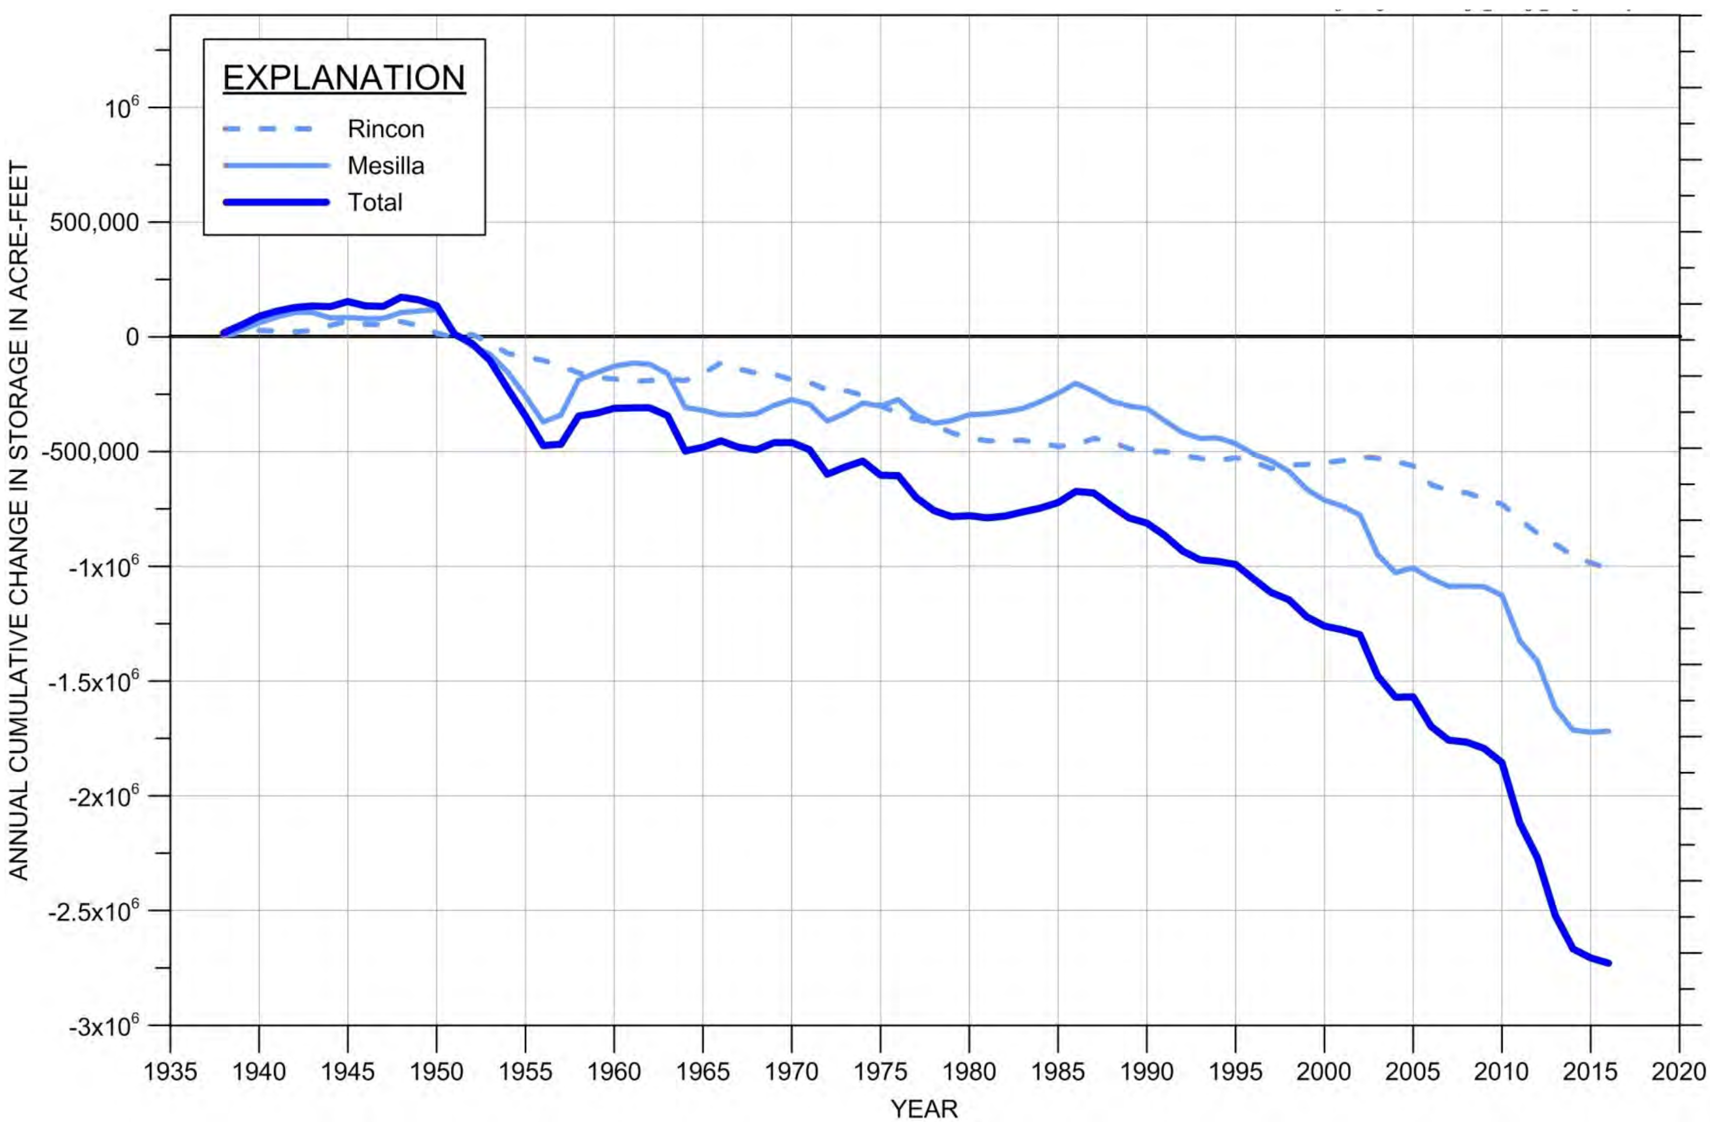

Figure 4.14. Estimated Annual Cumulative Change in Groundwater Storage in Rincon and Mesilla Basins

5 SUMMARY OF WATER BUDGET RESULTS

Monthly, basin-wide land-surface water, surface water, and groundwater budgets were developed for Rincon and Mesilla basins for 1938 through 2016. Water budgets were developed to provide conceptual inputs to other expert analyses, including a numerical groundwater flow model. These water budgets are integrated with multiple components linking to each other.

Water budget patterns were evaluated and compared for wet and dry years. Average annual values for water budget components during wet and dry periods are summarized in **Table 5.1**. Four time periods were selected for this evaluation based on climate and drought history descriptions reported by Terracon and others (2004). Wet periods contain years with above average precipitation. The selected wet periods are 1938 through 1943 and 1990 through 1999. The selected drought periods are 1945 through 1956 and 2009 through 2016. The period from 1945 through 1956 was further divided into two periods to evaluate potential impacts on the water budgets resulting from the advent of substantial groundwater pumping in 1950. The period from 1945 through 1949 represents drought conditions without supplemental irrigation pumping, and the period 1950 through 1956 represents drought conditions with supplemental pumping.

In both basins, agricultural consumptive use remained generally the same during wet or dry years. However, supplemental groundwater pumping substantially increased during drought periods when surface water deliveries were small. The ratio of supplemental groundwater pumping to agricultural consumptive use is used to evaluate irrigation practices during wet and drought years, except for pre-1950 when crop water demands within districts were fully satisfied by applied farm deliveries and precipitation. After 1950, crop water demands are satisfied by farm deliveries, precipitation, and supplemental groundwater pumping. After 1950, the ratios of supplemental pumping to agricultural consumptive use in both basins range from 0.6 to 0.85 during drought periods; the ratio ranges from 0.3 to 0.40 during wet periods. These results indicate that supplemental groundwater pumping is used to maintain agricultural production when surface water allotments are small. Without the availability of supplemental groundwater pumping, crop applied water demands could not be fully satisfied.

Urban consumptive use and urban groundwater pumping in the basins generally increase through time and do not appear to be substantially dependent on climate conditions. Urban applied water demands are met predominantly by groundwater pumping and are not dependent on surface water availability, which varies during dry and wet periods.

The volume of groundwater storage in the Rincon and Mesilla basins aquifers has generally declined since 1938 conditions. Annual gains and losses of groundwater storage have occurred in both basins through time. The years with the largest losses in groundwater storage generally coincide with time periods when surface water deliveries to farms were relatively small, such as in the early-1950s and after 2003. Groundwater storage in Mesilla Basin has declined during most years since 1986. This reduction in groundwater storage is principally attributed to an increase in groundwater withdrawals throughout the basins.

Table 5.1. Summary of Water Budgets for Selected Wet and Dry Periods

	RINCON BASIN					MESILLA BASIN				
	1938-1943	1945-1949	1950-1956	1990-1999	2009-2012	1938-1943	1945-1949	1950-1956	1990-1999	2009-2012

[a] Positive values indicate gains to the surface water system; negative values indicate losses from the surface water system.

APPENDIX D

SUMMARY OF WEB-BASED HYDROLOGIC DATABASE
FOR RIO GRANDE PROJECT DATA ANALYSIS

TECHNICAL MEMORANDUM

DATE:	May 31, 2019
TO:	SOMMACH SIMMONS & DUNN
FROM:	STAFFAN SCHORR Montgomery & Associates
SUBJECT:	SUMMARY OF WEB-BASED HYDROLOGIC DATABASE FOR RIO GRANDE PROJECT DATA ANALYSIS

This technical memorandum summarizes the web-based hydrologic database developed in support of data analysis for the Rio Grande Project litigation. The objective of the database is to store and provide access to public data available for analyses by experts on the project team. The RGP database comprises three components: a database, a website, and a Microsoft Access data management tool. This memorandum describes the database design and provides information on data sources for each data table contained within the database. All source data used to populate the database are included in the primary source data provided to counsel.

1.1 Web-Based Database Design

Project hydrologic data are housed in a secured Microsoft SQL server database hosted by Montgomery & Associates (M&A). The database is accessed using Windows Active Directory Domain User Accounts either via a secure website, or via in-office or remote access by designated M&A project personnel. Programming within the database is responsible for exciting searches and exports. Access to the data is granted based on login credentials.

1.1.1 Database

The SQL server database contains tables for surface water, monthly surface water flows, climate, agricultural water distribution, and metered groundwater withdrawals. Database queries interact with search criteria specified by the user via the website. Solely public-available source data are included in the database. Further processing and manipulation of data could be required for expert analysis; however, those derivative data are not included in this database.

1.1.2 Website

The website is accessed using Secure Sockets Layer (SSL) encryption and requires user authentication. Members of the project team were provided with individual usernames and randomly-generated passwords.

The website is composed of a Common Gateway Interface (CGI) executable (programmed with Delphi), supporting html files, Cascading Style Sheets (CSS) files, and JavaScript files. Through the website, the database is accessed via Microsoft's ActiveX Data Objects (ADO) technology. Links to all the datasets that can be accessed in the database are displayed upon website login, and also across the top of the screen in a menu bar format on the web page. The user can adjust search criteria settings for each dataset, choose the number of resulting rows to display on the screen, and export data to an external file.

1.1.3 Microsoft Access data management user interface

Database updates and modifications are made through a Microsoft Access user interface (UI) created for the database. The interface connects to the database using Open Database Connectivity (ODBC) and Windows accounts. Designated M&A project personnel have access to this interface.

1.2 Database Table Descriptions

The database comprises multiple tables of information related to expert analyses, including:

- Monthly Surface Water Flows
- Daily Surface Water Flows and Reservoirs
- Climate
- Agricultural Water Distribution
- Metered Groundwater Pumping
- Annual Allotments
- Water Quality: Historical (USGS Data Series 499)

This database contains source data accessible to experts for their respective analyses. Additional processing and manipulation of data might be required for analysis; however, those derivative data are not included in this database. Each data table contained in the database is described in the following section.

Table: Monthly Surface Water Flows

Flows along the agricultural water distribution network in the project area, including at the major river diversion head gates, are monitored at many locations. Flows are monitored along numerous canals, laterals, wasteways/spillways, and drains. In cooperation with this data compilation effort, the Elephant Butte Irrigation District (EBID) provided the principal monthly flow dataset included in the database for canals, laterals, wasteways/spillways, and drains in Rincon and Mesilla valleys. The EBID provided data directories compiled by the New Mexico State University (NMSU) containing historic flow data and metadata for individual EBID monitoring stations from the early-1900s through 2003 (2003 dataset). NMSU compiled the data from the U.S. Bureau of Reclamation (USBR), International Boundary and Water Commission (IBWC), U.S. Geological Survey (USGS), EBID, El Paso County Water Improvement District

#1, and "Parson's Data". The EBID also provided a separate data directory containing historical flow data updated from 1975 through 2006 (2006 dataset); however the original source of these data was not documented in the deliverable. Monthly flow data from both the 2003 and 2006 datasets were loaded into the database; however, most data were duplicates of each other. Where duplicate data existed between the 2003 and 2006 datasets, values from the 2006 dataset were kept because that dataset contained a longer period of record. Some stations were included in the 2003 dataset and not included in the 2006 dataset, and vice versa. Collectively, these data are sourced from EBID.

A secondary source of monthly data for flows along the agricultural water distribution networks are historic data files and tables obtained from the irrigation districts and the U.S. Bureau of Reclamation (USBR). These data augment the EBID-provided data (described previously) to construct a comprehensive dataset for monthly flows for the entire study period. Most of the flow data included in this table was extracted from old data files as daily or monthly values. Values included in the database reflect the data received. Monthly flow data at the major diversion canal head gates, at Rio Grande below Caballo Dam, and Rio Grande at El Paso were obtained from the EBID and IBWC to update this table through 2016. Data for 2015 and 2016 were downloaded from the EBID website for the major diversions and were obtained from Rio Grande Compact Commission annual reports for Rio Grande below Caballo Dam.

Flows along the Rio Grande are monitored at numerous locations in the Rio Grande Project area from Elephant Butte Reservoir through El Paso Valley. Historic flow data were downloaded from the International Boundary and Water Commission (IBWC) website for Rio Grande streamflow gages below Elephant Butte Reservoir, below Caballo Reservoir, at El Paso, at Acequia Madre (flows to Mexico), and below American Dam. Historic flow data were downloaded from the U.S. Geological Survey's (USGS) online National Water Information System for three streamflow gages at San Marcial, located upstream from Elephant Butte Reservoir. Data requests to the USBR and IBWC provided data for Rio Grande at El Paso from 2013 through 2016, which were not available from the online sources. Monthly flow data for Rio Grande below Caballo Dam for 2014 through 2016 were obtained from the EBID.

Monitoring stations with monthly flow data are summarized on **Table 1**.

Table: Daily Surface Water Flows and Reservoirs

Daily surface flow data were obtained from a variety of sources and were used as a secondary source of monthly flow data. In many instances, flow data are missing for days during the non-irrigation season when the distribution system was not active. Although flows were likely zero during these times, the database reflects missing or blank values as received in the source data. Daily data were not available for all stations for all time during the study period.

Reservoir information is also included in this daily surface water table. The Reservoir data can be queried separately from flow stations on the web-based interface. Daily water elevations and storage volumes, as well as monthly surface area and total evaporation, for Elephant Butte and Caballo reservoirs were obtained from the USBR for 1938 through 2014. Monthly pan evaporation and precipitation at both reservoirs, and monthly inflows to Elephant Butte Reservoir, were obtained from tables included in annual reports by the Rio Grande Compact Commission (RGCC) for 1940 through 2012. The monthly values are included in the database on the last day of each month with zeroes entered for all other days of that particular month.

Table: Climate

Daily climate data for weather stations in the region are included in the database for the period 1900 through 2013. The data were downloaded from the National Oceanic and Atmospheric Administration's (NOAA) National Centers for Environmental Information website [https://www.ncdc.noaa.gov/]. Twelve weather stations are included in the database. These stations were selected because they (1) are located within or adjacent to the project area and (2) have a long period of record for climate data. The weather stations included in the database are summarized in **Table 2**.

Each weather station monitors for numerous parameters on a daily basis, including: average cloudiness, average wind speed, pan evaporation, maximum temperature in evaporation pan, precipitation, percent possible sunshine, minimum and maximum soil temperature, snowfall, snow depth, minimum and maximum temperature, temperature at time of measurement, daily total sunshine, and 24-hour wind movement. These datasets use codes for parameter names and flags for measurement notes, causes for failure to record data, and sources for raw data. A separate file containing descriptions of these codes and station information can be downloaded along with the climate data.

Table: Agricultural Water Distribution

Data for monthly agricultural water distribution within irrigation district boundaries in Rincon and Mesilla basins were obtained from summary tables from annual Rio Grande Project history reports, the U.S. Bureau of Reclamation (USBR), and the irrigation districts in the basins. Water distribution data include diversions, canal losses, canal wastes, farm deliveries, deliveries to non-agricultural entities, and other reported quantities. Farm deliveries were the principal component of interest from these summary tables. Monthly data were tabulated from annual Rio Grande history reports for 1938 through 1980. Data were generally reported as project totals and inconsistently aggregated for a variety of subarea-groupings in the Rio Grande Project area. The project history reports are not available after 1988. Data for after 1988 were obtained from the USBR and El Paso County Water Improvement District #1 (EPWCID#1).

Availability of water distribution data, including surface water deliveries to farms, is summarized in **Table 3**.

Table: Metered Groundwater Pumping

New Mexico Office of the State Engineer (NMOSE) records groundwater pumping (withdrawal) data for metered water production wells in the state. Well information, including measured groundwater withdrawals, are available from the NMOSE's online New Mexico Water Rights Reporting System (NMWRRS) [*http://nmwrrs.ose.state.nm.us/index.html*], which links to the Water Administration Technical Engineering Resource System (WATERS) for well reports and well permit information. Well information and pumping records were obtained from the NMWRRS for wells listed as being located in the Lower Rio Grande ("LRG") basin, which includes areas outside the basins of interest for this project. Wells are referred to as "points of diversion" (POD) in the NMWRRS. A Point of Diversion Summary was downloaded in html format for each well in the basin. The Point of Diversion Summary provides POD number, location coordinates, drill date, basic well constriction information, and metered pumping data. Pumping data include a "meter reading" and a "meter amount" for each well. The meter reading is the total volume of water that has flowed through the meter since installation. This is often called the totalizer reading. The meter reading value gradually increases during pumping and resets (or flips) when the meter reading reaches the maximum value on the gage, similar to a car odometer. The meter amount value is the volume pumped since the previous reading. The totalizer meter readings are reported as gallons with a reported multiplier of 10, 100, or 1000; multipliers are reported for each well and flow meter. The meter amount values are reported in acre-feet units. The information from each html file was extracted and compiled into a database for this project.

Groundwater withdrawals are reported to the NMOSE periodically by well owners. Withdrawal data are available from 1987 through 2016. The number of wells with reported pumping data increased through time as the NMOSE implemented its well metering program.

Reported pumping records obtained from the NMOSE Point of Diversion Summary sheets were evaluated to identify any issues with the data that could result in inaccurate estimates of total pumping. The majority of reported pumping data appeared to be adequately formatted and organized. However, several instances of duplicate or suspect data suggest that there are uncertainties inherent in the dataset. Apparent discrepancies could be a result of erroneous reporting by the well owner or errors in data management by the NMOSE.

Table: Annual Allotments

Annual allotments for Project water were provided by the EBID in cooperation with this data compilation effort. Allotments (in feet) were provided for 1950 through 2015.

Table: Water Quality (USGS Data Series 499)

Water quality data contained in this database table are from USGS Data Series 499, Design and Compilation of a Geodatabase of Existing Salinity Information for the Rio Grande Basin, from the Rio Arriba-Sandoval County Line, New Mexico, to Presidio, Texas, 2010 (Shah and Maltby, 2010). The data are shown as received from John Walton. Definitions for fields or flag codes were not received with the dataset.

Table 1. Summary of Stations and Years with Available Monthly Flow Data

APPENDIX E

SUMMARY OF MODEL INPUT DATASETS
PREPARED IN SUPPORT OF
NUMERICAL GROUNDWATER FLOW MODEL DEVELOPMENT

TECHNICAL MEMORANDUM

DATE:	May 31, 2019
TO:	SOMMACH SIMMONS & DUNN
FROM:	STAFFAN SCHORR Montgomery & Associates
SUBJECT:	SUMMARY OF MODEL INPUT DATASETS PREPARED IN SUPPORT OF NUMERICAL GROUNDWATER FLOW MODEL DEVELOPMENT

This technical memorandum summarizes the conversion of water budget information to model input datasets in support of the numerical groundwater flow model for the Rincon and Mesilla basins being developed by William R. Hutchison. Source data and methods used to estimate water budgets for the basins are described in detail in the water budgets report for Rincon and Mesilla basins. The information herein summarizes the datasets provided to Mr. Hutchison for model development. For this task, Montgomery & Associates assigned model boundary condition values to grid cells based on the spatial distribution of the various water budget components for each basin.

1.1 Model Grid

The model grid was generated using AlgoMesh software. The grid design was developed by Montgomery & Associates with oversight from Mr. Hutchison. The model grid was vertically discretized into four model layers as described in a separate memorandum prepared by Montgomery & Associates. Each grid grid was then populated with unique identifiers (cell IDs), model layer elevations, preliminary values for aquifer properties, and initial water levels. Aquifer property values from the SSPA (2007) groundwater model were assigned to the AlgoMesh grid as preliminary values for starting model calibration.

Initial water levels assigned to the grid are based on water level contours prepared by M&A using USGS water level data from the National Water Information System (NWIS). No measurement data are available for the start of the model simulation period, 1938. 81 measurements were selected from available USGS data to represent initial water level conditions in the basins: 35 measurements for 1945 through 1949, 39 measurements for 1950 through 1959, and 8 measurements for 1960 through 1969. The data for the 1960s were used for areas at the margins of the basin where no other data exist and water levels likely had not substantially changed over time. The vast majority of measurement data are from wells located along the Rio Grande corridor. In addition to measurement data, control points were used to guide contouring in areas missing actual measurement data and to maintain interpolated water levels at or below land surface along the river. Initial groundwater level elevation contours are shown on **Figure 1**.

Deliverables:

- *AlgoMesh.zip* containing numerous text files, shapefiles, and tables related to the properties of the model grid.

1.2 Groundwater Pumping

Groundwater pumping data sources and methods for estimating historical withdrawals are described in detail in the water budgets report. Information for active water production wells in the Rincon and Mesilla basins were compiled from websites for the New Mexico Office of the State Engineer and the Texas Water Development Board. Relevant information preserved from the state well databases for each well include well identifier, spatial location coordinates, installation date, well use, well depth, and screened casing depths. Each well was assigned the cell identifier of the grid cell it is located within. Model layers were assigned to each well based on well construction information and the model layer elevations at the respective grid cell. Adjustments were made to grid cell and layer assignments based on feedback from Mr. Hutchison during model construction, principally to avoid assigning a well to inactive grid cells.

For this model, urban wells include all water production wells not categorized as irrigation use. Urban wells are as Municipal and Industrial (M&I) or domestic-stock wells. There are 7,181 urban wells included in the model dataset. Monthly urban pumping rates for individual wells were assigned based on (1) model inputs prepared by SSPA (2007) for a previous groundwater flow model for the Lower Rio Grande Basin, (2) measured pumping data, and (3) estimates from published hydrologic reports. Estimated monthly groundwater pumping for water user groups defined in the water budgets report were distributed to individual well locations based on reported well owner information and well use. A monthly pumping rate was assigned to each well from January 1938 through December 2016. A pumping value of zero is assigned to a well for months prior to when the well started pumping groundwater, as well as for months after pumping stopped at the well.

Total estimated agricultural pumping in the basins is summarized in the water budgets report. The model input dataset for irrigation wells was not populated with monthly agricultural pumping rates because pumping data are largely unknown for irrigation wells in the basins. There are 3,951 irrigation wells reported as being located in the model area. Monthly agricultural pumping estimates from the farm water budget will be distributed to individual irrigation wells by Mr. Hutchison during model construction and calibration.

Deliverables:

- *Urban_Pumping_ft3_for_WEL.xlsx*
- *WEL_global_ID_list.xlsx*
- *WEL_IRR_global_ID_list.xlsx*

1.3 Streamflow Routing

Datasets were prepared to conform to the MODFLOW Streamflow-Routing package (SFR2), which is designed to route flow through a network of channels representing a variety of rivers, streams, canals, laterals, and farm drains. The SFR package uses two components to define the stream network: reaches and segments. A reach defines (1) the routing order from upstream to downstream within a segment, (2) the model cell location of the reach, and (3) the length of the channel reach contained in each model grid cell. A segment is a group of reaches that defines (1) the tributary and diversion flows, (2) the streambed hydraulic properties, and (3) the channel geometry (streambed elevation and slope, streambed thickness, and channel depth and width).

A streamflow-routing dataset was developed for this model using two principal sources of information for locations and geometry of the network: (1) a geospatial dataset for the agricultural water conveyance network provided by the Elephant Butte Irrigation District (*EBID_Conveyances*, dated 4/28/2014), and (2) the streamflow-routing model input file (LRG_2007.sfr) prepared by SSPA (2007) for a previous groundwater flow model for the Lower Rio Grande Basin. A database was prepared to facilitate the management of the SFR data from the SSPA (2007) model and the development of the current SFR dataset.

The same streamflow-routing network (segment numbers, divisions, connections, and geometry) that was simulated in the SSPA (2007) model is included in the input datasets for the current model. The main conveyance features are included in the model dataset; some smaller conveyance features are not included. Conveyance features were selected from the EBID conveyance dataset, divided into reaches and segments as defined by the SSPA (2007) model, and attributed with the respective segment information from the SSPA (2007) model files. The network was then overlain by the current model grid to assign reach numbers, model grid cell identifier, and reach length within each grid cell representing the streamflow-routing network in the model. A generalized diagram of the streamflow-routing network for the current model is included in **Figure 2**.

Locations of segment inflows, diversions, and farm deliveries were assigned based on the SSPA (2007) model files. Monthly flow values for each inflow and diversion were assigned from the project's online database, which was developed by Montgomery & Associates and described in a separate memorandum.

Historical flows at Rio Grande below the Caballo Reservoir Dam provide the primary inflow of water to the simulated stream network. These flows are specified at the beginning of the first segment (segment 1) of the streamflow-routing network. Flow data were obtained from the project's online database, as described in a separate memorandum.

Diversions from the Rio Grande principally occur at five locations: Arrey Canal (segment 2), Percha Lateral (segment 3), Leasburg Canal (segment 76), Eastside Canal (segment 143), and Westside Canal (segment 195). Diversion flows at these locations are specified as monthly rates. Diversion flows were measured as flows near the main diversion headgate in the respective canal.

Surface water deliveries to farms (farm deliveries) are specified in the SFR datasets as a percentage of available flow from the upstream segment. The flow percentages are initially specified to be equal to the values included in the SSPA (2007) model input files. The percentages specified for these farm delivery outflows could change during model calibration to match measured water levels, flows, and farm deliveries.

Tributary inflows to the river are specified in the SFR network. These are flows from ephemeral streams to the river in response to runoff from rainfall events in the watershed. Contributing watersheds were assigned to a SFR river segment based on location. For each basin, the amount of inflows received by each selected river segment was computed by dividing the total contributing watershed area for each segment by the total contributing watershed area for the entire basin. **Table 1** summarizes the relative proportions of contributing watersheds to SFR river segments for each basin. The basin-wide monthly tributary inflows will be distributed during model construction based on these relative proportions.

Table 1. Summary of contributing watersheds for distributing tributary inflows

SFR River Segment	Basin	Contributing Watershed Area (acres)	Proportion of Basin Area
17	Rincon	72625	0.303
35	Rincon	78311	0.326
18	Rincon	43579	0.182
26	Rincon	26246	0.109
58	Rincon	2859	0.012
75	Rincon	16343	0.068
84	Mesilla	2759	0.119
90	Mesilla	2229	0.096
102	Mesilla	2531	0.109
116	Mesilla	565	0.024
142	Mesilla	2588	0.112
372	Mesilla	9773	0.422
373	Mesilla	1938	0.083
430	Mesilla	797	0.034

In addition to natural surface water flows in the stream network, discharges from major wastewater treatment facilities and urban return flows are included in the streamflow-routing dataset. Locations of wastewater discharges were selected based on the approximate location of the respective facility. Each facility discharges treated wastewater to the Rio Grande. Wastewater discharges are specified at four locations: Hatch/Salem (segment 26), Las Cruces (segment 102), Anthony (segment 326), and Sunland Park/El Paso Electric (segment 430). Wastewater discharges from the City of El Paso's Hickerson treatment facility into Rio Grande occur downstream from the outlet of the groundwater model and, thus, are considered as exported groundwater in the water budgets and are not included in the model inputs dataset. Historical discharges from the main wastewater treatment facilities in the model area are described in the water budgets report. Monthly discharge rates were assigned to the respective segment of the streamflow-routing network.

Monthly urban return flows will be distributed to SFR river segments that intersect or are nearest to mapped urban areas in each basin. The discharge points for urban return flows to the surface water network are unknown for this analysis. For simplicity, all monthly urban return flows are assigned to river segments associated with Hatch, Las Cruces, Anthony, or El Paso. Estimated urban return flows for Rincon Basin will be assigned to the river segment at Hatch. Estimated urban return flows for Mesilla Basin will be assigned to river segments at Las Cruces, Anthony, and El Paso. Mapped urban areas in vicinity of each of these municipalities are grouped and assigned to a specific SFR river segment. Small urban areas located between Las Cruces and Anthony and between Anthony and El Paso were assigned to one of these groups based on their relative locations. **Table 2** summarizes the relative proportions of urban areas contributing urban return flows to SFR river segments. The basin-wide monthly urban return flows will be distributed during model construction based on these relative proportions.

Table 2. Summary of grouped urban areas for distributing urban return flows

SFR River Segment	Basin	Grouped Urban Area	Contributing Urban Area (acres)	Proportion of Basin Area
26	Rincon	Hatch	1020.76	1
116	Mesilla	Las Cruces	27966.86	0.501
371	Mesilla	Anthony	2618.992	0.0470
373	Mesilla	El Paso	25195.53	0.452

Deliverables:

- *SFR_AM600.accdb*
- *SFR_diagram.pdf*
- *AM600_monthly.sfr* (preliminary)
- *AM600_yearly.sfr* (preliminary)
- *TribInflows_UrbRetFlows.xlsx*

1.4 Riparian Evapotranspiration

Model input data for riparian vegetation was prepared using information prepared by Land IQ, as summarized in the water budgets report. Land IQ mapped the extents of riparian vegetation for 1955, 2005, and 2014 and determined plant distributions for each mapped year. Model input datasets were prepared by selecting the model grid cells that intersect the mapped vegetation polygons. Vegetation distributions within each grid cell for each mapped year were determined from the Land IQ datasets. The model input dataset for each mapped year comprises a cell identifier, cell area, percent bare ground in the cell, percent tree-shrub in the cell, and basin identifier. Evapotranspiration rates for riparian vegetation will be assigned by Mr. Hutchison during model construction.

Deliverables:

- *ET_GridCells_RipExtents_1955_2005_2014.xlsx*

1.5 Mountain-Front Recharge and Transbasin Boundary Flows

Methods for estimating mountain-front recharge and transbasin boundary flows are described in the water budgets report. The volume of estimated mountain-front recharge from a contributing watershed was evenly distributed to model grid cells along the active model boundary at the interface with the respective watershed. The volume assigned to each grid cell was divided by the cell area to determine a recharge flux for each cell. The sum of recharge at the designated recharge cells is equal to the total recharge estimate reported in the water budgets report.

Similarly, transbasin inflows and outflows were evenly distributed to model grid cells along the model boundary at the location of the boundary flow. The boundary flow volume assigned to each grid cell was divided by the cell area to determine a flux for each cell. The sum of flow at the designated boundary flow cells is equal to the total estimated boundary flow reported in the water budgets report.

Recharge and boundary flow grid cells were attributed with model grid cell identifier, model layer, flux rate, and initial water level elevation.

Deliverables:

- *MntF_Underflow_Recharge.accdb*
- *MntFront_Recharge.xlsx*
- *Underflow.xlsx*

1.6 Urban Recharge

Urban recharge is specified at model grid cells that intersect mapped urban areas within the basins. Urban areas are represented as the maximum extent of high-density urban lands as mapped by Land IQ and described in the water budgets report. Model cells that intersect mapped urban lands were selected to represent urban recharge. Monthly estimates of urban recharge for each basin were distributed evenly among the selected urban recharge cells in the respective basin. The estimated monthly basinwide urban recharge volumes from the water budgets were divided by the total urban gridded acreage in each basin, as represented by the sum of grid cell acreages that represent urban lands, to determine a total recharge rate in acre-foot per acre units. This rate was multiplied by the acreage (acres) of each grid cell to determine a volumetric monthly recharge rate for each cell through time.

Deliverables:

- *Recharge_Urban_gridcentroids.xlsx*

1.7 Model Calibration Data

The groundwater flow model will be calibrated to measured surface water flows and groundwater levels at locations throughout the model area. Each flow or groundwater monitoring station was assigned to a model grid cell based on the spatial location of the station. Monthly flow data were obtained from the project's online database, which was developed by Montgomery & Associates and described in a separate memorandum.

Groundwater level measurements for the study area were obtained from the United States Geological Survey's (USGS) online National Water Information System (NWIS). Groundwater level measurements were assigned to representative model layers based on reported well construction and layer elevations at the assigned grid cell.

Deliverables:

- *CalibrationData_CanalDrainsWasteways.xlsx*
- *USGS_WLs.accdb*

1.8 Farm Budget Summary

A farm water budget dataset was prepared for each basin to facilitate model development. The farm budget simplifies the overall integrated water budget for the basin into components that are most important for the groundwater flow model. Farm water budget inflows include farm deliveries, effective precipitation, infiltration of excess precipitation, and applied groundwater. Farm water budget outflows include potential crop consumptive use, actual consumptive use by soil evaporation on non-cropped lands, deep percolation at agricultural fields, and deep percolation of agricultural conveyance losses. The residual of the water budget is net change in soil moisture. Results of the farm budget are consistent with the integrated water budgets for the basins, as reported in the water budgets report. Like the water budgets, the farm water budget comprises lands inside irrigation district boundaries and lands outside irrigation district boundaries. Crop lands outside the districts are assumed to receive only groundwater for irrigation.

Deliverables:

- *FarmBudget_RinMes.xlsx*
- *FarmBudget_RinMes _in.xlsx*
- *FarmBudget_RinMes_out.xlsx*

SUMMARY OF HYDROGEOLOGIC FRAMEWORK
FOR NUMERICAL GROUNDWATER FLOW MODEL DEVELOPMENT

TECHNICAL MEMORANDUM

DATE:	May 31, 2019
TO:	SOMMACH SIMMONS & DUNN
FROM:	STAFFAN SCHORR Montgomery & Associates
SUBJECT:	SUMMARY OF HYDROGEOLOGIC FRAMEWORK FOR NUMERICAL GROUNDWATER FLOW MODEL GRID DEVELOPMENT

This technical memorandum summarizes the geologic framework developed for the numerical groundwater flow model for the Rincon and Mesilla basins being developed by William R. Hutchison. Information provided herein includes data sources, methodology for developing a three-dimensional geologic model, and the hydrostratigraphic framework used for developing the layers for the groundwater model.

BACKGROUND

The numerical model will incorporate two groundwater basins: Rincon Basin and Mesilla Basin. Rincon Basin is the southern portion of the larger Palomas Basin. The Rincon and Mesilla basins are topographic depressions in the regional bedrock surface that are generally bounded by high-angle faults and physically separated by intervening bedrock highs. These geologic faults and uplifted areas are important controls on the groundwater flow of the basin aquifer systems. As is typical in the Basin and Range Province, the principal aquifers in the basins comprise the non-consolidated to weakly consolidated sediments that have been deposited within the structural basin areas. These "basin-fill" deposits are chiefly of alluvial origin. The bedrock complex is the principal source of the sediments that comprise the basin-fill deposits. In general, the bedrock units are crystalline to strongly lithified, resulting in low permeability and limited aquifer potential. The basin-fill deposits and valley-fill alluvium (along the Rio Grande corridor) comprise the principal aquifer systems in the basins and provide the vast majority of groundwater supplies to wells in the region.

GEOLOGIC HISTORY AND SETTING

The geologic history of the project area summarized herein is based chiefly on information provided in reports by the New Mexico Water Resources Research Institute (Hawley and Kennedy, 2004; Hawley and others, 2005; and Hawley and others, 2017), which has conducted extensive research on the geology and aquifer systems in the region.

The hydrostratigraphic layering scheme used for this analysis is based on interpretations from these studies.

The project area lies within the southern reach of the Rio Grande rift tectonic province which is a north-trending continental feature that separates the regional Colorado Plateau physiographic region on the west from the Great Plains region on the east. The Rio Grande rift feature extends from central Colorado through central New Mexico to the northern part of Chihuahua, Mexico. The basins in the project area are part of a series of basins and adjacent mountain uplifts within this rift zone. The rift zone, including the basin and uplift areas, began forming 25 to 30 million years ago (Ma). During the rifting process, the Earth's crust was stretched and pulled apart by extensional forces, resulting in the formation of large fault blocks that were rotated, uplifted and/or down-dropped. The movement and rotation of the fault blocks resulted in the formation of north-trending intermontane half-graben to full-graben structures within the rift zone. The upper surfaces of the fault blocks were chiefly volcanic-tectonic features, and it is on these surfaces that basin-fill deposits accumulated. The basin-fill deposits are chiefly of alluvial origin, although some facies are of lacustrine, eolian, and colluvial origin. In addition, some basaltic flows, pyroclastic deposits, and other volcanic rocks are interbedded with the basin-fill at some locations in the project area. These volcanic rocks are associated with features such as feeder dikes, sills, and breccia pipes (Hawley and Kennedy, 2004).

During and after the formation of the basins, sediments eroded from the adjacent uplifted areas were deposited in the half-graben basins. This basin-filling continued until approximately 670,000 to 700,000 years ago (0.67 to 0.70 Ma), as indicated by the subsequent entrenchment of the Rio Grande channel. These basin-fill deposits are the lower and middle hydrostratigraphic units of what is presently known as the Santa Fe Group.

The basin-fill deposits in the Rincon and Mesilla basins are comprised of Santa Fe Group hydrostratigraphic units which have been informally subdivided into lower, middle, and upper units on the basis of their lithologic properties, depositional origin, and post-depositional lithification. These units range in age from 23 to 0.7 Ma. They are chiefly alluvial in origin. Generalized geology of the study area is shown on **Figure 1**.

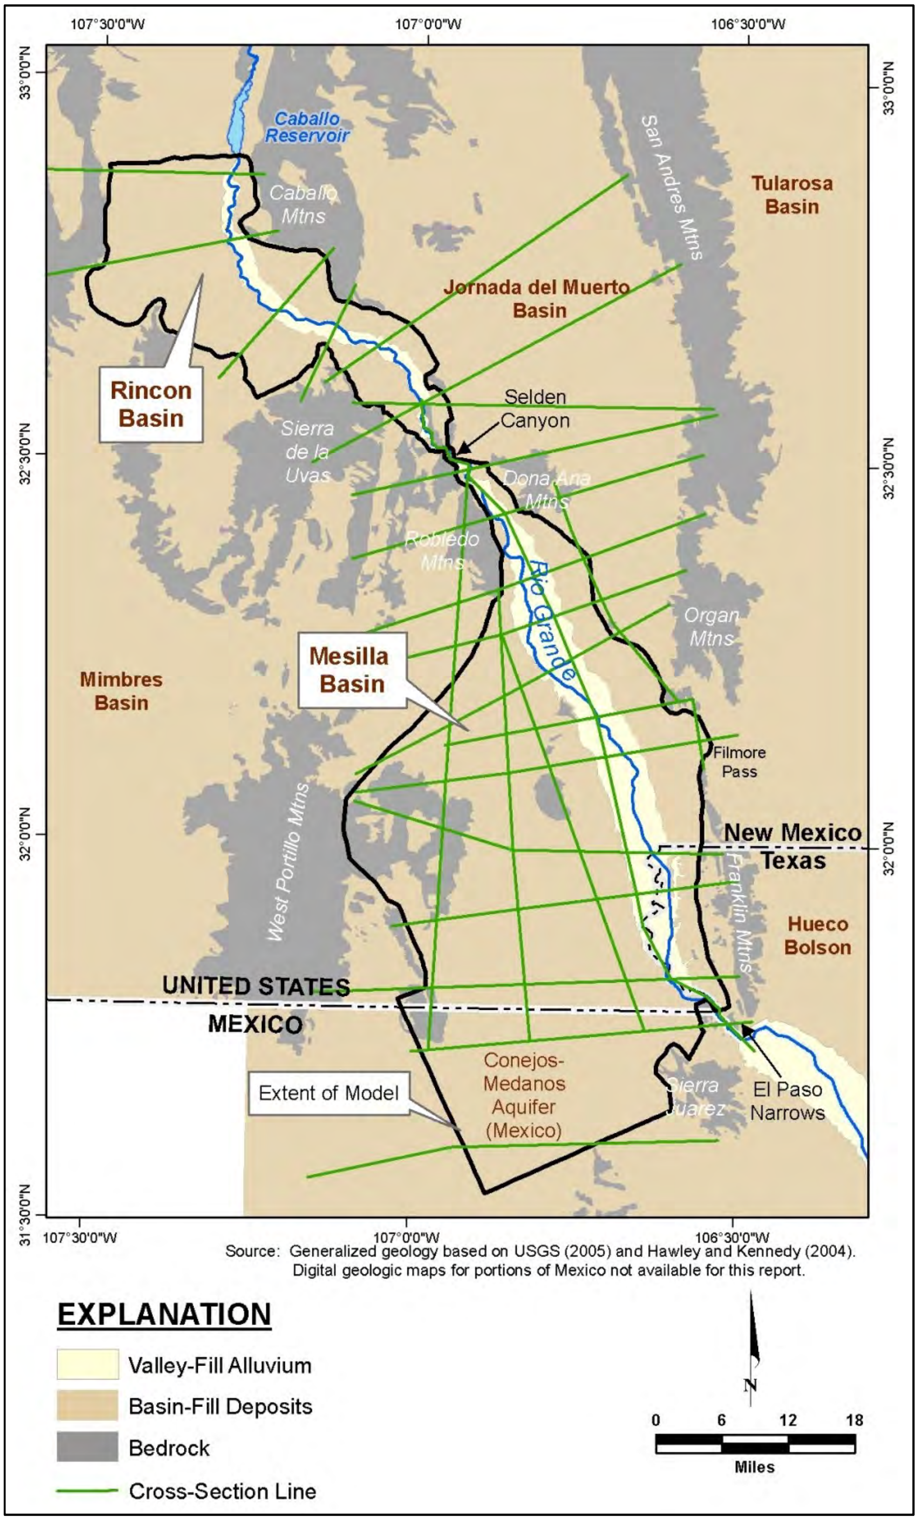

Figure 1. Generalized geology in Rincon and Mesilla Basins, with locations of cross-sections from New Mexico Water Resources Research Institute reports used to develop the aquifer framework.

Hydrostratigraphy and Layering Framework

Geologic units in the project area are listed below in order of increasing depth and age.

- Rio Grande valley-fill/river alluvium deposits
- Santa Fe Group basin-fill deposits
    - Upper Santa Fe Unit (USF) – Camp Rice & Palomas Formations
    - Middle Santa Fe Unit (MSF) – Fort Hancock & Rincon Valley Formations
    - Lower Santa Fe Unit (LSF) – Hayner Ranch Formation
- Bedrock Complex
    - Volcanic, sedimentary, igneous, and metamorphic rocks

The groundwater aquifer(s) in the basins consist of the lower, saturated intervals of the valley-fill alluvium, along with the underlying Santa Fe Group basin-fill units.

Valley-Fill/River Alluvium Deposits

The valley-fill (or river) alluvium occurs in and beneath the Rio Grande river channel and floodplain along the valley floors in the Rincon and Mesilla basins. It also occurs along the river channel in the intra-basin areas including Selden Canyon (between Rincon and Mesilla basins) and El Paso Narrows (between Mesilla Basin and Hueco Bolson) (**Figure 1**). Valley-fill alluvium is also present in the channels and floodplains of the major tributary arroyos of the Rio Grande, although they tend to be unsaturated and therefore do not comprise a substantial aquifer. For this model, the valley-fill unit solely comprises deposits along the Rio Grande and its floodplain. The valley-fill sediments are generally coarse-grained, but range from sand and gravel to silt and clay in texture. The deposits range in width from about 1 to 2 miles in Rincon Valley, and 2 to 5 miles in Mesilla Valley. Along the river channel in the shallow, intra-basin areas (e.g. Selden Canyon and El Paso Narrows), the width of the valley-fill deposits are approximately equivalent to the width of the river channel itself, which ranges from about 50 to 200 feet.

The average thickness of the valley-fill alluvium deposits is on the order of 60 to 80 feet.

Santa Fe Group Basin-Fill Deposits

The basin-fill deposits of the Santa Fe Group collectively comprise the vast majority of the groundwater flow system in the study area. The Santa Fe Group has been subdivided into five separate geologic units based on their relative ages and lithologies. From youngest to oldest, these units are the Camp Rice, Palomas, Fort Hancock, Rincon Valley, and Hayner Ranch Formations (Hawley and Kennedy, 2004). Overall thickness of the basin-fill deposits varies substantially throughout each basin. Maximum thickness of basin-fill is about 500 feet in Rincon Basin and about 2,500 to 3,000 feet in Mesilla Basin.

Hawley and Kennedy (2004) grouped these geologic units of the Santa Fe Group into three hydrostratigraphic units. The groups were determined based on age, lithology, and hydraulic properties of the deposits. The upper Santa Fe Group unit (USF) consists of the Camp Rice and Palomas Formations which are comprised chiefly of unconsolidated sand and gravel with minor lenses of silt and clay. Locally, it can include basalt flows. The USF is the most productive aquifer zone, but only the lower portions of the unit are saturated. The middle Santa Fe Group unit (MSF) consists of the Rincon Valley Formations which tend to be more fine-grained than the USF and consist of floodplain, alluvial flat, and playa deposits, but also includes extensive clean sand layers interbedded with silt and clay. Because the MSF is up to 2,000 feet thick, it is considered the principal aquifer zone. The lower Santa Fe Group unit (LSF) consists of the Hayner Ranch Formation which is chiefly comprised of fine-grained sediments similar to the MSF but locally more cemented. The LSF is an important aquifer zone in the lower Mesilla Basin from near Mesquite to Canutillo and La Union where a substantial thickness of eolian sand occurs (Hawley and Kennedy, 2004).

Bedrock Complex

The bedrock complex includes all intrusive and extrusive consolidated rock units. In the basin areas, the bedrock complex generally occurs beneath the alluvial and basin-fill deposits, except those which intruded and/or are interbedded with the basin-fill deposits. Surface exposures of bedrock are chiefly in the mountain and highland areas. However, bedrock outcrops do occur in isolated areas within the alluvium basin boundaries, such as north of Selden Canyon and west of Vado, New Mexico (**Figure 1**). These outcrops are based on mapping by Hawley and Kenney (2004) and USGS (2005). The various rock units that comprise the bedrock complex include, from youngest to oldest in age:

- Basalt flows, maar deposits (breccias and airfall units), and cinder cones
- Basalt and andesite flows, silicic volcanic flows (rhyolite, latite, and dacite), andesitic to dacitic flows, ash flow tuffs, sandstone, mudstone, conglomerate, and undifferentiated sedimentary rocks
- Quartzite, limestone and other carbonate rocks
- Limestone and other carbonate rocks, sandstone, shale, gypsite, and other undifferentiated sedimentary rocks
- Granitic and undifferentiated metamorphic rocks

STRUCTURAL FEATURES AND CONTROLS

Bedrock configuration and geologic structural features that affect groundwater movement in the project area include mountains and other geologic uplift areas, configuration of bedrock surface, fault zones and flexures within and adjacent to basin boundaries, and intrusive and extrusive rocks that penetrate or interbed with the basin-fill deposits. Impacts on groundwater flows from faults in the non-consolidated to weakly consolidated Santa Fe units are unknown.

MODEL LAYERING

Layering in the numerical model will be based on the principle hydrostratigraphic units. Hydrostratigraphy refers to the layering of aquifers and associated confining units of a study area. Hydrostratigraphic units are geologic sub-units with similar hydrogeologic properties or geologic units with distinct hydrogeologic properties. The hydrostratigraphic framework of an aquifer system is the elevation surfaces of the top and bottom of each hydrostratigraphic unit.

The hydrostratigraphic framework for the aquifer systems in the Rincon and Mesilla basins is based on geologic interpretations by Dr. John Hawley and the New Mexico Water Resources Research Institute. The aquifer framework for the basins was originally developed based on geologic information and cross-sections reported by Hawley and Kennedy (2004) and Hawley and others (2005). The framework was subsequently updated with new geologic interpretations delineated in cross-sections reported by Hawley and others (2017).

A continuous three-dimensional (3D), volumetric representation of the hydrostratigraphic framework for the aquifer system in Rincon and Mesilla basins was prepared using the geologic modeling software Leapfrog® Geo, developed by Seequent. The Leapfrog geologic model was prepared by importing a series of 23 cross-sections prepared by Hawley and Kennedy (2004) and Hawley and others (2005, 2017) into the Leapfrog 3D model space and digitizing (or drawing lines in digital format) the contacts between adjacent hydrostratigraphic units as delineated on the cross-sections. Mapped faults on the cross-sections are represented as offsets along the contacts or changes in thickness in layers. The software interpolates elevation surfaces, with a specified resolution of 500 feet, for the top and bottom of each hydrostratigraphic unit using the digitized contact lines along the length of each cross-section, coupled with control features to guide interpolations between cross-sections or in areas not included in the cross-sections. The cross-sections cover the entire model area from below Caballo Dam in northern Rincon Basin to the southern portions of Mesilla Basin in northern Chihuahua, Mexico, as shown on **Figure 1**. The framework is bounded on the top by the land surface and on the bottom by the bedrock surface. An example cross-section used to construct the 3D geologic model is shown on **Figure 2**.

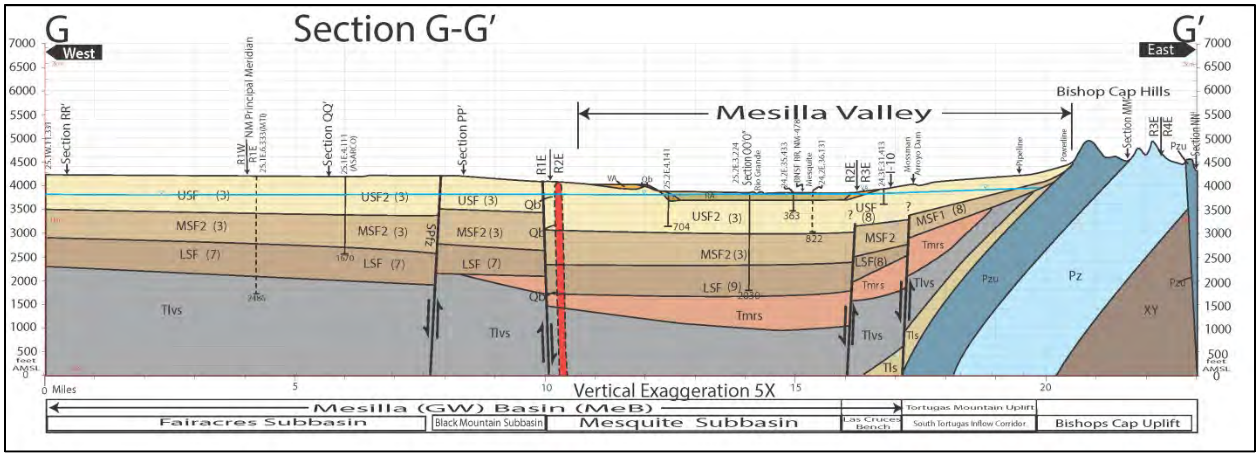

Figure 2. Example geologic cross-section for the Mesilla Basin from Hawley and others (2017). RA is valley-fill/river alluvium (greenish-tan); USF is upper Santa Fe unit (light tan); MSF is middle Santa Fe unit (tan); LSF is lower Santa Fe unit (brown); and bedrock units (various other colors).

The groundwater system in the Rincon and Mesilla basins groundwater model is represented as a four-layer aquifer system. The active portions of the model layers are bounded by the bedrock units that are assumed to be impermeable. Model layers are delineated as follows:

- Model layer 1 comprises the valley-fill/river alluvium deposits
- Model layer 2 comprises the upper Santa Fe unit
- Model layer 3 comprises the middle Santa Fe unit
- Model layer 4 comprises the lower Santa Fe unit

Thicknesses of each aquifer layer were determined from the 3D geologic model. The average thickness of model layer 1 (river alluvium) is about 85 feet, with a maximum thickness of about 150 feet. Average thickness of model layer 2 (upper Santa Fe) is about 500 feet, with a maximum thickness of about 1,100 feet. Average thickness of model layer 3 (middle Santa Fe) is about 640 feet, with a maximum thickness of about 1,985 feet. The average thickness of model layer 4 (lower Santa Fe) is about 560 feet, with a maximum thickness of about 2,240 feet.

Model grid layers were generated by importing elevation surfaces from the 3D geologic model into the MODFLOW grid generating software AlgoMesh. Model layer top and bottom elevations are consistent with the corresponding layers of the geologic model (hydrostratigraphic framework). Model grid datasets were then provided to William H. Hutchison for model development.

APPENDIX G

FARM WATER BUDGETS FOR IRRIGATION DISTRICTS IN EL PASO VALLEY, TEXAS
1938 THROUGH 2016

TECHNICAL MEMORANDUM

DATE:	May 31, 2019
TO:	SOMMACH SIMMONS & DUNN
FROM:	STAFFAN SCHORR Montgomery & Associates
SUBJECT:	FARM WATER BUDGETS FOR IRRIGATION DISTRICTS IN EL PASO VALLEY, TEXAS: 1985 THROUGH 2016

1.1 Objective and Scope

I was asked by counsel to develop farm water budget for two agricultural districts located in El Paso Valley, Texas to support economic analyses by Dr. David Sunding and Dr. Lydia Dorrance. The two districts are El Paso County Water Improvement District #1 (EPCWID#1) and Hudspeth County Conservation and Reclamation District 1 (HCRRD1). EPCWID#1 has lands in both Mesilla Basin and El Paso Valley; this farm budget considers only the portion of EPCWID#1 located in El Paso Valley. For the analysis, a farm water budget was developed for agricultural lands in EPCWID#1 and HCRRD1 with the principal goals of estimating (1) agricultural groundwater pumping for irrigation and (2) deep percolation beneath agricultural fields. Due to the lack of historic direct measurements of agricultural applied groundwater (pumping) and agricultural deep percolation, soil water balance models were used to estimate these components, along with surface runoff and soil moisture changes on agricultural lands. The soil water balance models were developed and implemented using GoldSim simulation software. Model results were used to prepare the farm water budgets for EPCWID#1 and HCRRD1.

El Paso Valley is an alluvial valley along the Rio Grande, extending from the El Paso Narrows to Fort Quitman (**Figure 1**). The valley extends across the Hueco Bolson groundwater basin. The river flows from Mesilla Basin into El Paso Valley at the Narrows. Farm lands across the river in Mexico are not included in this analysis. Urban lands, including the City of El Paso and Ciudad Juarez, and their associated water budgets are also not included in this analysis.

A soil water balance model was developed for each district to estimate agricultural groundwater pumping and deep percolation over the time period of interest, 1985 through 2016. The models tracks soil moisture within the maximum extent of cropped areas of EPCWID#1 and HCRRD1 on a monthly time step. The farm soil water balance models for El Paso Valley follow the same governing equations and framework as the models previously developed for the Rincon and Mesilla basins. The farm soil water balance model framework, design, and implementation are described in detail in the separate water budget report submitted for Rincon and Mesilla basins.

1.2 Model Inputs

Crop lands in EPCWID#1 and HCRRD1 were mapped by Land IQ for several years during the study period. The EPCWID#1 and HCRRD1 farm budgets encompasses a maximum crop area of 68,704 acres (about 107 square miles) and 17,752 acres (about 28 square miles), respectively. All crop lands are located within the districts' boundaries and irrigation demand is supplied by both surface water deliveries and supplemental groundwater pumping.

Tabular crop distribution and evapotranspiration (ET) (crop consumptive use) datasets for EPCWID#1 and HCRRD1 prepared by Land IQ were used in this farm water budget analysis. The Land IQ datasets contain annual acreages and monthly ET data for nineteen crop categories, along with annual ET adjustment factors computed based on analysis of historic crop yield. Theoretical crop ET rates were computed by dividing adjusted crop ET by the corresponding crop ET adjustment factor. The adjusted Land IQ adjusted ET (AET) rates are referred to herein as target AET rates, meaning that they reflect the best available estimates, and should be reproduced by the soil water balance model to the extent possible. This analysis assumes that irrigation practices and irrigation non-uniformity are the same as in Mesilla Basin; however, double-cropping is not incorporated into the El Paso Valley models due to lack of data. The soil water balance model simulates total ET from all the crops, and so target AET was calculated as an area-weighted average over the different crop types over the study period. Crop acreages for EPCWID#1 were adjusted for pre-irrigation of cotton and pecans by one month, consistent with the Rincon and Mesilla models; However, HCRRD1 was modified to have pre-irrigation of all crops by two months to also represent leaching of salts from the fields prior to planting. The application of water for leaching is seen in available data when surface water deliveries are reported during winter months when crop ET values are zero. EPCWID#1 personnel verified in an interview on April 23, 2019 that more salt leaching is required in HCCRD1 than in EPCWID#1 due to the higher salinity of the available irrigation water in HCCRD1.

The soil water balance model for each district tracks all root zone soil moisture, including in cropped and non-cropped areas. For non-cropped area, this requires the computation of bare soil evaporation. The method for estimating bare soil evaporation is described in the water budget report for Rincon and Mesilla basins. For this analysis, precipitation is specified to be the same as in Mesilla Basin.

Soil properties required for the soil water balance model include the residual moisture content, permanent wilting point, critical soil moisture, field capacity, total porosity, pore size distribution index, and saturated hydraulic conductivity (K_{sat}). Because soil types are similar in Mesilla and the two El Paso Valley districts, soil properties specified in the EPCWID#1 and HCRRD1 models are the same as in the Mesilla Basin model.

The soil water balance model simulates total ET from all the crops, and so effective root zone depth was calculated as an area-weighted average over the different crop types over the study period. Crop rooting depths are described in the water budget report for Rincon and Mesilla basins.

The applied water demand by crops is satisfied by surface water deliveries and supplemental groundwater pumping. The farm soil balance model provides an estimate for total applied water to meet the target crop ET. Applied surface water deliveries are reported for most years; however, supplemental agricultural groundwater pumping is not reported. Supplemental pumping is estimated as the quantity of applied water required to achieve the target crop ET estimated by Land IQ in addition to surface water deliveries.

Data for surface water deliveries to farms are available from USBR crop report water distribution tables for 1985 through 2008 for EPCWID#1 and for 1985 through 2006 for HCCRD1. Data sources and methods used for estimating deliveries to farms when data are missing are described in the water budget report for Rincon and Mesilla basins.

1.3 Results

The annual farm budgets for EPCWID#1 lands in El Paso Valley and for HCRRD are summarized in **Tables 1 and 2, respectively**. Estimates for total applied agricultural water, farm deliveries, and supplemental groundwater pumping for the two districts are shown on **Figures 2 and 3**.

Surface water deliveries to farms in EPCWID#1 in El Paso Valley were generally larger than 100,000 acre-feet per year (AF/yr) from 1985 through 2002, with an average of about 129,000 AF/yr. A substantial reduction in deliveries to EPCWID#1 in El Paso Valley occurred in 2003 and again in 2011, when average deliveries were about 95,000 AF/yr and 27,000 AF/yr, respectively, during these time periods. Surface water deliveries to HCCRD1 farms were generally larger than 40,000 AF/yr from 1985 through 2002, with an average of about 48,000 AF/yr. Similar to EPCWID#1, a substantial reduction in deliveries to HCCRD1 farms occurred in 2003 and again in 2011, when average deliveries were about 28,000 AF/yr and 7,000 AF/yr, respectively, during these time periods.

Crop acreage within both EPCWID#1 farms in El Paso Valley and HCRRD1 farms has declined since 1985, based on data provided by Land IQ. In EPCWID#1 in El Paso Valley, for example, average cropped acreage from 1985-2002 was about 50,000 acres, whereas average cropped acreage from 2003-2016 was about 34,000 acres. In HCRRD1, average cropped acreage from

1985-2002 was about 15,000 acres, whereas average copped acreage from 2003-2016 was about 8,000 acres.

According to model results, supplemental groundwater pumping occurred in EPCWID#1 and HCRRD1 each year during the study period. As expected, groundwater pumping has an inverse relationship with farm deliveries, where pumping increases as farm deliveries decrease. In years with reduced surface water availability, groundwater is required to satisfy crop demand. Average annual supplemental groundwater pumping for EPCWID#1 farms in El Paso Valley from 1985 through 2016was about 79,000 AF/yr. Average annual supplemental groundwater pumping for HCCRD1 farms from 1985 through 2016 was about 19,000 AF/yr.

In contrast to similar analyses conducted for the Rincon and Mesilla Valleys, agricultural groundwater pumping data are not available to validate simulated results from the EPCWID#1 and HCRRD1 soil water balance models.

Within the soil water balance model, monthly deep percolation is calculated as the sum of on-farm conveyance losses and field losses. Estimated annual agricultural deep percolation for EPCWID#1 farms in El Paso Valley and HCRRD1 farms is shown on **Figure 4a** and **Figure 5a**. Field losses account for soil moisture derived from both applied irrigation water and precipitation; however, the contribution from applied irrigation water is substantially greater than contributions from precipitation. Similar to the Mesilla farm soil water model, 10 percent of reported farm deliveries are assigned to deep percolation from infiltration along on-farm water conveyance features. Average annual estimated deep percolation is approximately 42,000 AF in EPCWID#1 farms in El paso Valley and 18,000 AF in HCRRD1 farms.

The soil water balance model computes evapotranspiration rates based on theoretical crop evapotranspiration rates and simulated soil moisture conditions. For this analysis, the monthly theoretical evapotranspiration rates are from crop consumptive use datasets prepared by Land IQ. Estimates of crop consumptive use for El Paso Valley are shown on **Figures 4b and 5b** for EPCWID#1 and HCRRD1 respectively. For reference, **Figures 4b and 5b** also show target adjusted crop consumptive use, or AET, developed by Land IQ for EPCWID#1 and HCRRD. AET simulated by the EPCWID#1 and HCRRD1 soil water balance models closely follows the target AET values from Land IQ.

Mean annual crop AET for 1985 through 2016 is about 155,000 AF for EPCWID#1 as simulated by the model, compared to about 154,000 AF as estimated by Land IQ. Mean annual crop AET for 1985 through 2016 is about 43,000 AF for HCRRD1 as simulated by the model, compared to about 42,000 AF as estimated by Land IQ.

TABLE 1. ANNUAL FARM WATER BUDGET FOR EL PASO COUNTY WATER IMPROVEMENT DISTRICT #1 LANDS IN EL PASO VALLEY: 1985 THROUGH 2016

APPENDIX H

PROFESSIONAL RESUMES

Staffan W. Schorr, Hydrogeologist / Principal

Office: TUCSON

Years Experience

Total: 20 | M&A: 12

Education

M.S., Hydrology, University of Arizona (2005)

B.S., Geology, University of Arizona (1997)

Key Areas of Expertise

Regional hydrogeologic characterization

Flow and transport modeling

Development of geologic models

Integration of GIS and conceptual models for numerical model construction

Database development and management

Aquifer test design, implementation, and data analysis

Staffan Schorr specializes in regional hydrogeologic characterization in support of groundwater modeling. He applies his background in numerical and analytical groundwater flow modeling to a variety of M&A projects to simulate the effects of long-term pumping, mine dewatering, and managed aquifer recharge and recovery. He has extensive experience using GIS methods to develop numerical model inputs, display model results, and develop geospatial databases for conceptual hydrogeologic models. He also manages M&A's GIS and 3D modeling services, and specializes in the use of Leapfrog software to develop volumetric geologic and geochemical interpolation models. His other interests include characterizing the interactions between groundwater and surface water along riparian corridors. Prior to joining M&A, Staffan worked for 8 years in watershed planning at Pima Association of Governments, a regional agency that facilitates coordination among local jurisdictions.

Representative Projects

Groundwater Modeling | Groundwater Resource Development

Groundwater Flow Model • Hueco Bolson • El Paso Water Utility
Updated hydrogeologic sections with new borehole data and geophysical logs, evaluated data from the Texas Water Development Board's groundwater database, developed a 3D geologic model, and constructed and calibrated a numerical groundwater flow-and-transport model to support the management of brackish groundwater resources and wellfields [EL PASO COUNTY, TX]

Groundwater Flow Model • Lower Rio Grande Valley • Texas Water Development Board
Developed a conceptual hydrogeologic model, relational database, and geodatabase to provide input for a groundwater flow-and-transport model used to evaluate future desalination operations [SOUTHERN TX]

Groundwater Flow Model • Northern Portions of Queen City, Sparta, and Carrizo Wilcox • Texas Water Development Board
Developed a conceptual hydrogeologic model, relational database, and geodatabase to provide input for a groundwater flow model used to evaluate regional groundwater availability. [NORTHEASTERN TX]

Groundwater Flow Model • Kinney County • William R. Hutchison, Independent Groundwater Consultant
Supervised development of MODFLOW USG model grid using AlgoMesh software [KINNEY COUNTY, TX]

Groundwater Flow Model • Bluebonnet Groundwater Conservation District • William R. Hutchison, Independent Groundwater Consultant
Provided support for numerical model development: evaluated previous aquifer layer interpolations, updated aquifer layering using available well borehole geophysical logs, and supervised development of a geologic model that

combines all aquifer layers from existing Groundwater Availability Models in vicinity of the District [NORTH-CENTRAL, TX]

Groundwater Modeling | Hydrologic Impact Analysis

Environmental Impact Analysis • Arivaca Groundwater Flow Model • Pima County Regional Flood Control District
Projected changes in groundwater levels and potential impacts to environmentally sensitive areas related to pumping in a hydrologically isolated basin [PIMA COUNTY, AZ]

Groundwater Modeling | Tailings Water Management

Water Balance • Sierrita Mine • Freeport-McMoRan Corporation
Developed and updated spreadsheet water budget models for tailings impoundments at the Sierrita open-pit copper mine [PIMA COUNTY, AZ]

Groundwater Modeling | Mine Dewatering

Dewatering & Impacts Modeling • Collahuasi Mine / Rosario Pit • Compañía Minera Doña Inés de Collahuasi SMC
Designed and constructed a groundwater flow model to support dewatering operations and predict the environmental impacts associated with a large, open-pit mine in a complex mountain aquifer system [NORTHERN CHILE]

Groundwater Modeling | Managed Aquifer Recharge

Water Level / Quality Projections • Tonopah Desert Recharge Project • Central Arizona Water Conservation District
Developed flow and solute-transport models to project changes in nitrate concentrations and groundwater levels associated with recharge and future recovery operations [WESTERN AZ]

Water Level / Quality Projections • Central Avra Valley Storage & Recovery Project • Central Arizona Water Conservation District
Updated flow and solute-transport models to project groundwater level rise and changes in concentrations of total dissolved solids resulting from recharge operations [PIMA COUNTY, AZ]

Water Level Projections • Superstition Mountains Recharge Project • Central Arizona Water Conservation District
Updated a groundwater flow model to evaluate recharge rates and predict the rise in groundwater levels associated with recharge operations [MARICOPA COUNTY, AZ]

Permit Support • Willow Springs South Ranch Village Project • ANAM, Inc.
Developed an analytical model to support regulatory permitting requirements for recharging treated effluent [PINAL COUNTY, AZ]

GIS & 3D Geologic Modeling

Geospatial Model Development • Various Sites • Various Clients
Developed or supervised the development of dozens of 3D geospatial models for hard-rock and basin-fill groundwater systems using Leapfrog® software [U.S., PERÚ, CHILE]

GIS Development & Application • Various Sites • Various Clients
Developed GIS inventories of wells, infrastructure, water use, land use, and other related features; prepared cartographically correct maps, figures, and 3D geologic models for many investigations and modeling projects [U.S., CHILE, PERÚ, ARGENTINA, BOLIVIA]

Managed Aquifer Recharge

Hydrogeologic Characterization • Recovery Wellfield Siting Study (Phase 1) • Central Arizona Water Conservation District
Conducted a hydrogeologic assessment, well inventory, and wellfield analysis for recovering stored CAP water [PINAL COUNTY, AZ]

Groundwater Modeling | Mine Water Supply

Groundwater Flow Model • Confidential Site • Confidential Client
As part of due diligence efforts, designed and implemented a model to project groundwater level impacts associated with potential future pumping for a new water supply; constructed a 3D geospatial model of an alluvial groundwater system using Leapfrog Hydro [WESTERN AZ]

Mine Water Supply

Aquifer Testing & Analysis • Proposed Copper Mine Reopening • Freeport-McMoRan Corporation
Planned and implemented an aquifer testing program; analyzed test data to evaluate groundwater resources [PIMA COUNTY, AZ]

Aquifer Testing & Analysis • Big Sandy Valley • Freeport-McMoRan Corporation
Analyzed long-term test data from a confined aquifer to evaluate potential groundwater resources, impacts to environmentally sensitive areas, and hydraulic connectivity between aquifers [MOHAVE COUNTY, AZ]

Water Policy & Planning

Hydrogeologic Characterization • Regional Water Plan • Confidential Client
Evaluated hydrogeologic data and supervised the development of a 3D data model to support the initial phases of a regional water plan [PIMA COUNTY, AZ]

Hydrogeologic Characterization • Various Sites • Pima County Regional Flood Control District
Conducted basic hydrogeologic investigations using publicly available data sources for Aguirre Valley, Altar Valley, and the Ajo-Why area to support an amendment to Pima County's Water Resources Comprehensive Plan [PIMA COUNTY, AZ]

Colin P. Kikuchi, Ph.D., Groundwater Hydrologist

Office: TUCSON

Years of Experience

Total: 10 | M&A: 5

Education

Ph.D., Hydrology & Water Resources, Minor in Agricultural and Resource Economics, University of Arizona (2015)

M.S., Hydrology & Water Resources, University of Arizona (2011)

B.A., Environmental Studies and Geography, Middlebury College (2005)

Key Areas of Expertise

Groundwater flow modeling

Quantitative uncertainty prediction for hydrologic simulations

Analysis of groundwater / surface water interactions

Agricultural water balance

Design of hydrologic monitoring networks

Colin Kikuchi joined M&A in 2014, bringing a background in quantitative hydrology and groundwater-surface water interaction. He has developed conceptual hydrogeologic models in a variety of environments for M&A clients, and routinely uses analytical and numerical modeling tools to evaluate groundwater systems. Prior to joining M&A, Colin worked on projects evaluating groundwater and groundwater-surface water interactions for the USGS Alaska Science Center. From 2012–2013, he served as the lead instructor for the Alaska Section of American Water Resources Association's workshop series on groundwater and surface-water interactions.

Representative Projects

Recharge Analysis

Recharge Analysis • Salar de Lagunillas • Compañía Minera Cerro Colorado
Designed and installed a streambed and borehole temperature monitoring network; analyzed the statistical uncertainty of natural groundwater recharge [CHILE]

Recharge Analysis • Salar de Punta Negra • Compañía Minera Escondida Ltda.
Analyzed the statistical uncertainty of natural groundwater recharge [CHILE]

Recharge Uncertainty Analysis • San Pedro – Inacaliri Basin • CODELCO
Evaluated hydrogeologic and geochemical data to develop alternate conceptual models; quantified the uncertainty of groundwater budget components, including natural recharge and underflow in and out of basin. Provided technical guidance to monitoring station design and installation, analyzed streambed and borehole temperature data to estimate natural recharge [CHILE]

Groundwater Modeling

Agricultural and Surface Water Budgets • Paso Robles Sub-Basin • City of Paso Robles
Prepared historical agricultural and surface water budget components using daily soil-water balance and surface water models; conducted numerical model simulations to evaluate streamflow depletion; developed future projected water budgets incorporating climate change impacts [SAN LUIS OBISPO COUNTY, CALIFORNIA]

Mine Dewatering Feasibility • Cove Project • Au-Reka Gold Corporation
Evaluated hydrogeologic data and existing numerical models to support underground mine dewatering estimates; led preparation of a new groundwater model [LANDER COUNTY, NEVADA]

Groundwater-surface water interactions • Upper Verde Watershed • The Nature Conservancy
Developed summary narrative of hydrogeologic and surface water studies and data on the Verde River; conducted numerical simulations to evaluate streamflow depletion; analyzed historical data to develop conceptual model of future streamflow under climate and watershed management scenarios [YAVAPAI COUNTY, ARIZONA]

Groundwater Flow Model Simulation • Bingham Canyon Mine • Rio Tinto / Kennecott Utah Copper
Conducted numerical simulations of perched groundwater flow; developed refined grid model using MODFLOW-USG to facilitate use of regional groundwater flow model to evaluate pressure heads along geotechnical sections [SALT LAKE COUNTY, UT]

Scenario Analysis • Santa Margarita Basin • Hydrometrics, WRI
Conducted numerical simulations and analyzed results to evaluate hydrogeologic impacts of managed aquifer recharge projects in a sedimentary rock aquifer; prepared water budgets to support Groundwater Sustainability Plan development [SANTA CRUZ COUNTY, CALIFORNIA]

Numerical Groundwater Flow Simulation • Salares de Centenario & Ratones • ERAMET SA
Conducted probabilistic lithium reserve estimate using numerical flow and transport model [ARGENTINA]

Water Quality Data Compilation • Hueco Bolson • El Paso Utilities
Organized water quality data and prepared maps and time-series plots of chloride concentrations as data inputs for a groundwater flow and transport model [EL PASO COUNTY, TX]

Contaminant Investigation

Capture Analysis • Inactive Rancho Cordova Test Site • The Boeing Company
Conducted probabilistic numerical modeling analysis of capture/hydraulic containment of extraction wells downgradient of plume, evaluated impact of extraction wells on migration of contaminants originating off-site [SACRAMENTO COUNTY, CA]

Analysis of Aquifer Test Data • Inactive Rancho Cordova Test Site • The Boeing Company
Compiled data on groundwater pumping rates and water levels; developed a conceptual model of an unconsolidated, multiple-aquifer system; used analytical and numerical solutions to infer aquifer hydraulic properties based on aquifer test data [SACRAMENTO COUNTY, CA]

Statistical Analysis of Water Quality Data • Former Lisbon Mine & Mill • Rio Algom Mining LLC
Analyzed groundwater quality data to assess the suitability of multiple sampling methods to characterize long-term trends [SAN JUAN COUNTY, UT]

Feasibility Studies

Aquifer Testing & Hydrologic Analysis • Apache Leap Tuff Aquifer & Queen Creek Corridor • Resolution Copper Mining
Analyzed aquifer test data to infer the saturated and unsaturated hydraulic properties of intact rock mass; analyzed streamflow and surface water quality data to support a baseflow characterization and develop hydrographs [PINAL COUNTY, AZ]

Adjudication & Water Rights

Litigation Support • Confidential Site • Confidential Client
Evaluated numerical model and conducted predictive simulations to evaluate drawdowns due to well-field operation [NM]

Litigation Support • Confidential Site • Confidential Client
Evaluated methodology and proof-of-concept study developed by Arizona Department of Water Resources for quantifying subflow capture and prepared recommendations for improvements to modeling approach [AZ]

Other Experience

USGS Experience

Conducted hydrologic/hydrodynamic simulations of groundwater–surface water interactions in riparian wetlands

Served as a technical review team member for aquatic and riparian instream flow studies, Susitna–Watana Hydroelectric Project, as part of the FERC licensing process

Performed field investigations and hydrologic simulations for a permafrost-affected boreal catchment

Worked as lead scientist for regional-scale groundwater availability study

Developed conceptual hydrogeologic model and a numerical groundwater flow model for the Matanuska-Susitna Valley

Used a land-surface modeling code to estimate spatially distributed groundwater recharge

Investigated groundwater–surface water interactions using temperature data

Performed routine groundwater and surface water measurements

Collaborated with state agency personnel to conduct a 2-week synoptic measurement of groundwater levels

1.0 QUALIFICATIONS AND SUMMARY OF OPINIONS

1.1 Overview of Qualifications of Gregory K. Sullivan, P.E.

My name is Gregory K. Sullivan, and I am a principal and senior water resources engineer at Spronk Water Engineers, Inc. ("SWE") in Denver, Colorado. I have Bachelors of Science degree in Civil Engineering from Colorado State University (1985) and a Master of Science Degree in Civil Engineering from the University of Colorado (1990). I am a registered professional engineer in Colorado, New Mexico, Idaho, and Nevada.

After receiving my undergraduate degree in 1985, I took a job with J.W. Patterson & Associates in Denver where I performed work in water supply planning, water rights analysis, surface water and ground water analysis and modeling, and hydrology. In 1990, I accepted a position at SWE as a staff engineer, became a shareholder in 1992, and am currently one of two majority shareholders. SWE is a consulting firm in areas of water resources engineering and water rights. We work for federal, state, and local governments and other water providers; commercial and industrial water users; and farmers, ranchers and other individuals. Most of our work is in the areas of water supply planning, municipal water supply modeling, surface water and ground water modeling, water rights engineering, and conjunctive management of ground water and surface water.

During my 35-year career in water resources and water rights engineering I have worked on numerous projects involving analyses of historical irrigation water use, municipal water use, and surface water and ground water modeling, primarily in Colorado, Idaho, and New Mexico. Among these efforts was my work in the use and modification of the H-I Model of the Arkansas River in Colorado that was used in the original jurisdiction lawsuit filed in 1985 by the State of Kansas against the State of Colorado in the U.S. Supreme Court. The model simulates daily operation of irrigation water uses under approximately two dozen canal systems along the Arkansas River in Colorado between the City of Pueblo and the Colorado-Kansas state line from 1950 to the present. I testified as expert in the case on several occasions before Special Master Littleworth.

My work on the Rio Grande in New Mexico began in the 1990s when I assisted in the development of the original farm budget model of the Rincon and Mesilla basins that was later used in development of the 2007 S.S. Papadopulos & Associates ("SSPA") ground water model of those basins. Since that time, I have worked on various Rio Grande matters leading up to the development and application of the models described in this report.

My professional resume is provided in **Appendix 1A** to this report along with a list of cases in which I have testified as an expert during the past four years. SWE is being compensated at a rate of $200 per hour for my work on this case, and this compensation is not dependent on the outcome of the case.

1.2 Overview of Qualifications of Adelheid M. Welsh

My name is Adelheid (Heidi) M. Welsh. I am a senior watershed scientist and partner at Spronk Water Engineers, Inc. ("SWE") in Denver, Colorado. I have Bachelors of Science degree in Watershed Science from Colorado State University (2007). I am a registered professional hydrologist through the American Institute of Hydrology.

During college, I took a hydrology internship at the Teton Science School (summer 2006) and worked for the U.S. Forest Service Arapahoe-Roosevelt National Forest (Fall 2006 - Spring 2007) in Fort Collins. After receiving my undergraduate degree in 2007, I worked for the U.S. Forest Service Back Hills National Forest in Sundance, WY. In Fall 2007, I took a job with AATA, Inc. in Denver, where I conducted work in environmental consulting which included data analysis, report writing, and GIS applications.

In 2009, I took a job at SWE as a watershed scientist and became a shareholder in 2017. During my 10-year career in water resources and water rights engineering I have worked on numerous projects involving analyses of historical water use, surface water and ground water modeling, and water accounting. I have extensive experience in compilation and analysis of hydrologic and spatial data.

My work on the Rio Grande in New Mexico began in the 2012 when I assisted in the development of the surface water and accounting dataset and the updated farm budget model of the Lower Rio Grande basin, including the Rio Grande Project, Juarez Valley, and Hudspeth.

My professional resume is provided in **Appendix 1B** to this report. SWE is being compensated at a rate of $150 per hour for my work on this case, and this compensation is not dependent on the outcome of the case.

1.3 Assignments

SWE has contracted for its consulting work on this case through the New Mexico Interstate Stream Commission ("NMISC") and the New Mexico Office of the Attorney General ("NMAGO"). Our assignments on this case were developed in discussions with legal counsel for the State of New Mexico. We were asked by legal counsel to develop analyses and expert opinions in the following areas:

- Compilation and analysis of historical records on the hydrology and use of water under the Rio Grande Project ("Project") and nearby areas.
- Development of Canal and Farm Budget Models ("CFB Models") of the major irrigation users between Elephant Butte Reservoir and Fort Quitman Texas, including the Elephant Butte Irrigation District ("EBID"), the El Paso County Water Improvement District No. 1 ("EPCWID"), the Hudspeth County Conservation and Reclamation District No. 1 ("HCCRD"), and the Juarez Irrigation District ("JID").
- Coordination of development of integrated surface water and ground water models of the area along the Rio Grande from San Marcial, New Mexico ("San Marcial") to Fort Quitman, Texas ("Ft. Quitman").
- Analysis of historical Project operations.
- Analysis of the impacts of ground water pumping in New Mexico, Texas, and Mexico on streamflows and water deliveries to the major irrigation water users and El Paso Water ("EPW" a.k.a. "EPWU") in the study area.
- Analysis of the impacts of the 2008 Operating Agreement ("2008 OA") on deliveries of water to the major irrigation water users.
- Review of expert reports and supporting data, analyses, and modeling submitted by experts for the State of Texas and the United States.

Summaries of the opinions that were developed by Ms. Welsh and Mr. Sullivan for this case follow.

1.4 Summary of Opinions of Adelheid M. Welsh

Ms. Welsh prepared and is responsible for the opinions in Section 3 and Section 4 which are summarized below. In addition, she was also involved in compiling the data used in the CFB Models described in Section 6, disseminating data for use in the New Mexico models, and in post-processing the model output files into summary tables and graphs.

<u>Section 3 – Lower Rio Grande Hydrologic Data</u>

1. Data from various sources were reviewed and compiled into an Excel database identified as the SWDataSet. The data in the SWDataSet are organized by flow type and annotated with site information such as the location information, period of record, and metadata reference.

2. The data in the SWDataSet are well documented. Detailed metadata has been prepared and is provided with each data entry and includes contact names, originator

information, supporting files, descriptions, processing notes, spatial domain, data quality, time period of content, and other information.

3. The SWDataSet is the best available compilation of surface water and other data for the Lower Rio Grande Area ("LRG Area"), and the information contained in the database is suitable for use in hydrologic modeling and analyses.

4. The data in the SWDataSet have undergone extensive review and quality assurance and quality control ("QA/QC") consistent with industry standards. This includes double checking all data entry against the source information and preparation of tabular, graphical, and statistical summaries that were prepared for each data site to assess the data for consistency.

5. Despite extensive efforts over several years to obtain all available flow records in the Lower Rio Grande basin, there remained missing data that needed to be estimated for technical analysis and modeling purposes. Over a relevant time period, correlations were derived from two sets of available data. The missing data were estimated using the correlation equation and available data. The estimates of these missing data in the SWDataSet are reasonable and suitable for use in modeling and analysis.

Section 4 – Rio Grande Project Accounting Data

6. The Project records, including Water Distribution Reports, Bureau of Reclamation ("Reclamation") tables, accounting reports, and allocation records, were compiled. Information from these reports was added into two Excel spreadsheets that comprise the Accounting DataSet.

7. The Accounting DataSet is comprehensive and is comprised of the best available Project data. In addition to our review, these data have been reviewed by employees in the New Mexico Office of the State Engineer ("NMOSE") and/or the NMISC for consistency and accuracy. All the data in the Accounting DataSet have undergone QA/QC by two or more water resources professionals.

1.5 Summary of Opinions of Gregory K. Sullivan

Mr. Sullivan prepared Section 2 and Sections 5 through 15, and is responsible for the opinions presented in those sections, which are summarized below.

Section 5 – Historical Water Supply and Water Use

8. Most of the water supply for the Lower Rio Grande below Caballo Reservoir originates as Rio Grande flow passing the San Marcial gage and entering Elephant Butte Reservoir. Annual San Marcial gage flows averaged approximately 890,000 AF during the 1890 - 2017 period of record. The flows have been cyclical, with 10-year average flows generally above average through the 1940s, below average during the 1950s - 1970s, above average in the 1980s and 1990s, and below average thereafter. (Figure 5-1).

9. The average annual inflow available to the Project at San Marcial was estimated in the Rio Grande Joint Investigation ("RGJI") as 1,031,000 AF based on flows for the period from 1890 - 1935 adjusted for upstream development. Annual San Marcial flow since that time has averaged 754,000 AF. (Table 5-1).

10. The annual reservoir release necessary to supply the Project was estimated in the RGJI as 773,000 AF. This was increased to the "normal annual release" of 790,000 AF described in Rio Grande Compact ("Compact"). In the generally wet period following the RGJI analysis (1936 - 1950) annual reservoir releases averaged 845,000 AF. Since then annual reservoir releases have averaged only 607,000 AF (1951-2017). (Table 5-1).

11. Average annual depletions of Rio Grande flow between the Caballo Reservoir outlet and the El Paso gage are at approximately the same level now as they were at the time of the Compact (250,000 AF/y). (Figure 5-2).

12. The total annual Project irrigated area contemplated in the RGJI totaled 145,000 acres, while acres that were actually authorized to be irrigated totaled 159,650 acres (155,000 acres plus an additional 3%). The reported actual irrigated area peaked at approximately 160,000 acres in the early 1950s. Since then, the irrigated area has declined, largely due to urbanization, and currently stands at approximately 105,000 acres. (Figure 5-4)

13. Average annual farm headgate deliveries ("FHG deliveries") of Project water were relatively steady from the 1950s - 1970s, increased during the 1980s and 1990s, and have declined since then due to the recent drought. (Figure 5-10, Figure 5-12, Figure 5-14).

14. The total applied water in EBID, including deliveries of Project water and supplemental pumping, has declined slightly since the 1980s. Conversely, the total

applied water in EPCWID, including deliveries to EPW, has remained steady through time. (Figure 5-15 and Figure 5-19).

15. Project operational waste in EBID typically comprised roughly 10% of canal heading diversions from the 1940s and 1950s and thereafter declined to less than 10% in most years. Operational waste in EPCWID followed a similar pattern in the early years with the waste exceeding 10% in the 1940s, and then declining to roughly 10% or less during the 1950s - 1970s. However, when EPCWID took over water distribution within the district in 1980, operational waste increased substantially to an average of approximately 25% of canal diversions until the recent drought. The increased EPWID waste has resulted in a substantial increase in flows to HCCRD. The excess waste in EPCWID has impacted Project water allocations and deliveries to EBID. (Figure 5-20 through Figure 5-23).

16. The NMOSE has required all well users in the LRG basin within New Mexico to measure and report ground water pumping since 2009. During the relatively dry decade that the measuring requirement has been in effect (2009-2018), annual LRG irrigation pumping in New Mexico has averaged 219,000 AF. New Mexico pumping during this period has been affected by the reduction in Project water allocations to EBID as a result of the 2008 OA. Unlike in New Mexico, there reportedly are no requirements in Texas or Mexico to measure and report pumping, and no records of LRG irrigation pumping are available for those areas. (Figure 5-25).

17. Non-irrigation pumping, primarily for municipal uses, has increased substantially throughout the LRG Area, most notably in the El Paso and Juarez areas. Annual non-irrigation pumping in New Mexico increased to an average of approximately 38,000 AF during the last ten years. This is much less than the non-irrigation pumping that has averaged approximately 82,000 AF in Texas and 144,000 AF in Mexico during the last ten years. (Figure 5-26 through Figure 5-28).

Section 6 – Lower Rio Grande Canal and Farm Budget Models

18. Monthly CFB Models were prepared to simulate irrigation water use in LRG Area during the period from 1938 - 2017. The models were developed to assess the historical use of surface water and ground water in the LRG Area, and specifically to compute:

    - Crop-weighted consumptive use of applied water for the irrigation units in the LRG Area;
    - FHG deliveries for periods when records were not available; and

- Supplemental pumping for all areas, and the primary (ground water only) pumping in New Mexico.

Separate models were developed for four subareas in EBID (Rincon, Leasburg, Mesilla Westside, and Mesilla Eastside), three subareas in Texas (Mesilla Westside, Mesilla Eastside, and El Paso Valley), three subareas in Mexico (JID Units 1, 2, and 3), and the HCCRD.

19. Annual CFB Models were prepared for the portions of the Texas and Mexico irrigation districts that overlie the Hueco Bolson during 1903 - 1939 for the purpose of developing certain input data used in the Hueco Ground Water Model ("Hueco Model") developed by McDonald-Morrisey Associates, LLC ("MMA").

20. The monthly and annual CFB Models that were developed to simulate irrigation water use in the LRG Area are based on commonly used water budget analysis techniques and procedures. Similar water budget analyses are routinely used in the analysis of historical use for changes of irrigation water rights before the Colorado Water Courts.

21. The monthly CFB Models for the LRG Area irrigation units are reasonable representations of the historical irrigation operations during the 1938 - 2017 study period. The simulated consumptive use of applied surface water and ground water, conveyance losses, and on-farm losses are reasonable and representative of the variable water supply and hydrologic conditions that occurred over the 80-year study period.

22. The monthly supplemental ground water pumping and primary ground water pumping computed in the CFB Models are reasonable estimates of the amounts of pumping that were historically required to meet the unmet irrigation demands considering the historical surface water supplies. The simulated pumping for EBID during 2009 - 2017 was within 1% of the reported values. (Figure 6-5).

Section 7 – Need for Modeling Analysis of Claims and Counterclaims

23. Due to the complex effects that Project operations and LRG Area irrigation operations have on the amount and timing of surface water flow, ground water flows and their interaction, a simulation model is useful and necessary to understand and quantify these effects. The model should be reasonably calibrated over a representative historical period and be capable of simulating appropriate dynamic responses of Project and irrigation operations to variations in water supply in historical and alternative scenarios.

24. A simulation model of the LRG Area should reasonably simulate important physical processes and management processes that affect the occurrence, movement, and use of ground water and surface water. Important physical processes include surface water flow, ground water flow, surface water and ground water interactions, evaporation, and evapotranspiration. Important management processes include Project water allocation, reservoir operations, canal operations, and on-farm irrigation operations. (Table 7-1).

Section 8 – Overview and Assessment of Integrated LRG Model

25. The Integrated LRG Model ("ILRG Model") consists of a RiverWare Model that simulates the LRG Area from the Rio Grande at San Marcial gage upstream of Elephant Butte Reservoir to the Rio Grande at Ft. Quitman Gage in Texas. The RiverWare Model is linked to two ground water models - the New Mexico Rincon-Mesilla Ground Water Model ("NMR-M Model") that simulates ground water flow in the Rincon and Mesilla basins between the Caballo Reservoir outlet and the El Paso Narrows, and the Hueco Model that simulates ground water flow in the El Paso and Juarez Valleys from the El Paso Narrows to Ft. Quitman. The ILRG Model simulates the period from 1940 - 2017 and operates using monthly stress periods.

26. The RiverWare Model component of the ILRG Model simulates the surface water and shallow ground water systems of the LRG Area and is the principal vehicle for computing the impacts of pumping and the effects of operational changes on surface water flows. It employs rule-based processes that simulate the essential functions of the Project and operations of the LRG Area irrigation systems. It is through these rule-based processes that the simulated systems are re-operated in alternative scenarios in a manner that reflects the real-world response to changes in conditions.

27. The NMR-M Model and the Hueco Model simulate the hydraulic effect of ground water pumping on surface flows and the effect of drains on ground water flows. The ground water models are linked to the RiverWare Model through certain data that are passed between the models in successive iterations.

28. The RiverWare Model and the ground water models of the ILRG Model have been calibrated to simulate historical surface water and ground water flows during the 1940 - 2017 study period using historical data for reservoir releases, canal operations, and FHG deliveries. The calibrated models reasonably replicate the seasonal, annual, and inter-annual variations in surface water and ground water flows.

29. In order to simulate the human-influenced management processes of the Project and LRG Area irrigation systems, the ILRG Model employs rule-based simulation processes

to simulate reservoir operations, canal diversions, FHG deliveries, and other processes. These rules were tuned in a calibration-like process to reasonably match historical records of reservoir releases, canal diversions, FHG deliveries, streamflows, and the simulated pumping in the calibration run.

30. The calibrated and tuned ILRG Model is the best available tool for evaluating claims, counterclaims, and answering questions about the effects of certain actions on Project operations and deliveries of water to LRG water users. The ILRG Model is superior to the ground water model of the Rincon and Mesilla basins developed by the Texas experts ("Texas Model") for use in the litigation because (a) it simulates the entire LRG Area between the El Paso Gage and Fort Quitman, (b) it employs monthly stress periods that allow it to simulate the important seasonal variations in ground water and surface water flows, and (c) it is capable of simulating the dynamic response of Project operations to changes in flow through rule-based simulation processes.

31. Post-processing spreadsheets were prepared to summarize outputs from the ILRG Model to illustrate the model results and to verify the models are correctly functioning. Tables and charts depicting the model results are presented in Section 9 for the Historical Base Run, in Section 10 for the Alternate Scenario Runs, in Section 13 in responses to the Hutchison Report, and in Section 14 in the responses to the Dorrance Report.

Section 9 – Historical Base Run of Integrated LRG Model

32. The tuned version of the ILRG Model was used to simulate the historical period from 1940 - 2017, including Project operations, to develop the Historical Base Run. The Historical Base Run was compared to alternative runs of the tuned model that simulated various no-pumping and alternative operating scenarios. Project water allocations were simulated using the D1/D2 allocation procedure from 1940 - 2005, the D3 allocation procedure without carryover in 2006 and 2007, and the D3+Carryover procedure in the 2008 OA from 2008 - 2017. Irrigation pumping coverage in EBID, EPCWID, and HCCRD was specified to increase linearly from 0% in 1947 to 100% in 1955, and in JID from 0% in 1939 to 100% in 1954. Non-irrigation pumping and return flows were specified and simulated based on historical records and estimates.

33. The simulated outputs for the Historical Base Run reasonably match the results from the historical records and the historical calibration run of the ILRG Model. Based on this match and the dynamic functionality of the ILRG Model, the Historical Base Run represents a reasonable baseline for comparison to alternative scenarios with reduced pumping, or other changes in model inputs.

Section 10 – Alternative Runs of Integrated LRG Model

34. Thirteen runs were made of the ILRG Model including the Historical Base Run (Run 1), nine no-pumping runs (Runs 2 - 10), and three alternative operations runs (Runs 11 - 13). All runs were made with the tuned version of the ILRG Model in which rules are used to compute Project water allocations, reservoir releases, canal diversions, and FHG deliveries. Changes in model inputs cause dynamic responses of all simulated processes as the changed conditions ripple spatially and temporally through the model, just as they would in the real world. Model outputs from the alternative scenarios were compared to the outputs from the Historical Base Run or another scenario and the differences were computed and summarized in tables and charts.

35. In the no-pumping runs, all pumping or just non-irrigation pumping was turned off in all areas (Run 2) or in certain geographic areas (Runs 3 - 10). When non-irrigation pumping was turned off, so were the associated wastewater treatment plant discharges and urban deep percolation. Because the Project is operated as a single system, any effects of pumping on surface water supplies that are upstream of points of delivery affect Project operations. The model results show that pumping in Texas and Mexico affects Project water deliveries to EBID water users in New Mexico.

36. A run of the ILRG Model was made in which all irrigation and non-irrigation pumping in the Rincon and Mesilla basins in New Mexico was turned off (Run 3). Comparison of the results from this run against the Historical Base Run show that without New Mexico pumping, annual FHG deliveries during the period from 1985 - 2016 would increase by an average of 26,200 AF to EBID and 8,200 AF to EPCWID. (Table 10A-3a).

37. A run of the ILRG Model was made in which all irrigation and non-irrigation pumping in Texas was turned off (Run 4). Comparison of the results from this run against the Historical Base Run show that without Texas pumping, annual FHG deliveries to EBID during the period from 1985 - 2016 would increase by an average of 5,100 AF, with a maximum annual increase of 32,500 AF. (Table 10A-4a and Table 10A-4b).

38. A run of the ILRG Model was made in which all irrigation and non-irrigation pumping in Mexico was turned off (Run 5). Comparison of the results from this run against the Historical Base Run show that without Mexico pumping, annual FHG deliveries during the period from 1985 - 2016 would increase by a maximum of 3,900 AF to EBID, 3,400 AF to EPCWID, and 9,400 AF to HCCRD. (Table 10A-5b).

39. In addition to the simulated effects on FHG deliveries in the no-pumping runs, turning off pumping in the ILRG Model results in simulated impacts to Project storage (including releases, evaporation, and spills), riparian evapotranspiration, river and

canal evaporation, incidental canal losses, and ground water storage. These impacts are reasonable and consistent with the interconnected nature of the Project and the LRG Area irrigation systems.

40. Two runs of the ILRG Model were made to evaluate the effect of the 2008 OA on Project operations. In Run 11, the D1/D2 allocation procedure was simulated to allocate Project water during the period from 1948 - 2017, and in Run 12 the D3+Carryover accounting was simulated during this 70-year period. Comparison of the results showed that the 2008 OA caused annual EBID FHG deliveries to be (a) reduced by an average of approximately 69,100 AF during periods with low diversion ratios (55 years) and (b) increased by an average of 56,900 AF during periods with high diversion ratios (15 years), for an overall decrease in annual EBID FHG deliveries over the 70-year period averaging 42,100 AF. The results also showed that the 2008 OA increased FHG deliveries to EPCWID in most years with an overall average annual increase of 14,700 AF. (Table 10A-12b).

41. A run of the ILRG Model was made to evaluate the effects of reducing Project operational waste. Run 13 limits waste in EBID and in EPCWID to the lesser of the historical amounts or 10% of diversions. The results show that reducing excess operational waste would have resulted in increases in annual Project water deliveries during 1985 - 2016 averaging 28,600 AF to EBID and 12,700 AF to EPCWID. (Table 10A-13).

Section 11 – Response to Brandes Report

42. Based on review of the expert report by Dr. Robert Brandes, his backup files and references, and attending his deposition, I developed the responses to his report that are presented in Section 11. The following is a summary of certain of the responses:

    a. Dr. Brandes attributed all changes in flows after 1950 to pumping in the Rincon basin and Mesilla basin based on single- and double-mass curve analyses. These simple graphical techniques can be useful in identifying changes in flows, but they are not useful or reliable in determining what caused the changes in flows. For complex interconnected systems like the Rio Grande Project and LRG Area, a robust simulation model capable of simulating the dynamic responses of the simulated systems to changes in condition is needed to reasonably determine the effects of certain actions, like the effects of pumping, on Project operations and deliveries to LRG Area water users; and to distinguish these effects from other factors that may have contributed to changes in flows or deliveries.

b. The annual changes in El Paso gage flows and deliveries to Texas and New Mexico water users that are computed by Dr. Brandes occur in virtually all years, including years of full Project water allocations. This does not make sense considering how the Project operates in years with full allocations. In these years, if there was an increase in supply because pumping was reduced, then Reclamation would adjust reservoir releases in order to deliver the same amounts of water to the Project water users, and therefore no significant changes in irrigation season flows and deliveries would be expected to occur in these years.

c. Dr. Brandes' analyses of changes in the flow of the Rio Grande at El Paso are not relevant to this litigation because this is neither a point of compliance for the Compact, nor a point of delivery for the Project.

d. Dr. Brandes incorrectly states that the available Project supply is solely determined by the volume of water either in or projected to be in Project storage each year. In reality, Project releases are affected by (i) the amount of water available in storage at the beginning of the irrigation season, (ii) the inflows to storage during the irrigation season, (iii) the gains and losses between the Caballo outlet and the downstream delivery points, and (iv) the demands of the Project water users.

Section 12 – Response to Montgomery and Associates Report

43. Based on review of the expert report by Mr. Staffan Schorr and Dr. Colin Kikuchi of Montgomery and Associates ("M&A"), their backup files and references, and attending their depositions, I developed the responses to their report that are presented in Section 12. The following is a summary of certain of the responses:

a. While M&A developed comprehensive surface water and ground water budgets for the LRG Area, only a few of the outputs from those analyses were used in the Texas Model and in the Texas analyses of impacts from pumping.

b. M&A performed monthly historical farm budget analyses to (i) estimate supplemental pumping and deep percolation in the Rincon and Mesilla basins for use in the Texas Model, and (ii) to estimate pumping in the El Paso Valley and HCCRD for Texas' analysis of damages from New Mexico pumping. The results from these analyses are unreliable because the soil-water balance model that is central to the farm budget analyses is deeply flawed and produces nonsensical results that are physically impossible and contrary to conditions that would be expected to exist in productive and generally well-managed irrigation districts.

c. Notwithstanding the flaws in M&A's farm budget analysis procedures, the estimates of pumping computed by the M&A analysis in New Mexico and Texas appear to be overstated, largely because of because of differences in irrigated area, crop ET, and FHG deliveries compared to the data used in in SWE's CFB Models

Section 13 – Response to Hutchison Report

44. Based on review of the expert report by Dr. William Hutchison, his backup files and references, and review of portions of his deposition transcript, I developed the responses to his report that are presented in Section 13. The following is a summary of certain of the responses:

   a. New Mexico's legal counsel have advised that Dr. Hutchison's definition of a 1938 condition is not appropriate for characterizing the water entitlements of the states. Moreover, it would be inappropriate to define a 1938 condition on the basis of historical operations in a single year as Dr. Hutchison did in his analyses.

   b. The Texas Model developed by Dr. Hutchison is inappropriate for use in analyzing the effects of pumping on Project operations and deliveries of water to LRG water users because:

      i. The model does not employ rule-based simulation processes that allow the model to appropriately respond to changes in surface water flows when pumping is reduced.

      ii. The model does not simulate Project operations and uses of water between the El Paso gage and Ft. Quitman.

      iii. The annual stress periods in the model do not allow distinction of the significant differences in Project operations and river conditions between the irrigation season and non-irrigation season.

   c. The lack of re-operation in the Texas Model is evident in the relatively steady computed annual impacts of Rincon-Mesilla pumping on Rio Grande at El Paso flows, including in years of full Project water allocations. In years with full Project water allocations, it is expected that the irrigation season flow at El Paso would not be appreciably different without pumping because

Reclamation would adjust Project releases to deliver the same amount of water to Project water users.

d. Dr. Hutchison's modeling analyses of Alternative Consumptive Use scenarios and Conjunctive Use scenarios are of little use because the Texas Model lacks any capability to simulate the Project re-operation that would occur in these scenarios.

Section 14 – Response to Dorrance Report

45. Based on review of the expert report by Dr. Lydia Dorrance, and her backup files and references, I developed the responses to her report that are presented in Section 14. The following is a summary of certain of the responses:

a. Dr. Dorrance's analysis to disaggregate the changes in El Paso gage flow simulated by the Texas Model is oversimplified and not a substitute for a fully functional dynamic simulation model of the area between the El Paso gage and Ft. Quitman.

b. Dr. Dorrance's disaggregation analysis is flawed and inappropriate because (i) it relies on results from a flawed model, (ii) it assumes the increased flows would occur in historical monthly proportions, and (iii) all of the increased flow is assumed available for allocation to Texas water users without diminishment by transit losses or operational inefficiencies.

c. Dr. Dorrance's flawed disaggregation analysis resulted in incorrect and inflated estimates of the effects of New Mexico pumping on deliveries to Texas water users.

Section 15 – Response to Sunding Report

46. Based on review of the expert report by Dr. David Sunding, and his backup files and references, I developed the responses to his report that are presented in Section 15. The following is a summary of certain of the responses:

a. Dr. Sunding's analyses are flawed because they rely on unreasonable and unreliable analyses by Dr. Hutchison and Dr. Dorrance of the effects of New Mexico pumping on Texas water users.

b. Dr. Sunding unreasonably assumes that shortages in EPW surface water supply were caused solely by New Mexico pumping and not by other factors, including drought.

c. The damages analysis by Dr. Sunding is based on simulated impacts on El Paso gage flows from all pumping throughout the Rincon and Mesilla basins and therefore implicitly includes impacts of pumping in the Texas portion of the Mesilla basin.

2.0 BACKGROUND

2.1 Study Area

The Rio Grande begins in headwaters in the San Juan Mountains in Colorado that flow east and join other tributaries in the broad and agriculturally productive San Luis Valley of Colorado. The river flows south out of the San Luis Valley and into New Mexico where it picks up considerable flow from the mountains of northern New Mexico and continues in a generally southerly direction through mostly incised canyons past Taos and Santa Fe before reaching the Middle Rio Grande Valley that extends from Cochiti Lake to San Marcial, about 25 miles south of Socorro.

San Marcial is situated at the northern end of Elephant Butte Reservoir, the primary source of water for the Project that serves lands in the Rincon, Mesilla, and El Paso Valleys in southern New Mexico and western Texas. Additional lands are irrigated west of the Rio Grande in the Juarez Irrigation District in Mexico and further to the southwest in Hudspeth County, Texas down to Ft. Quitman.

The study area for this report is primarily the areas tributary to or hydraulically connected to the Rio Grande between San Marcial and Ft. Quitman. This includes the ground and surface water irrigated lands that are part of the Project, the JID, the HCCRD, and the non-irrigation water uses for the towns and cities in the study area. A map depicting the study area is included as **Figure 2-1**.

2.2 Rio Grande Compact

This section provides a brief overview of certain aspects of the Rio Grande Compact ("Compact"). More detailed information on the Compact is provided in the report of Estevan Lopez (2019). The States of Colorado, New Mexico, and Texas agreed to the Compact in March 1938 to equitably apportion the Rio Grande upstream of Ft. Quitman. The Compact was ratified by Congress and became effective on May 31, 1939.

The annual delivery obligations for Colorado are provided in Article III and New Mexico's delivery obligations are provided under Article IV. In 1948, the Rio Grande Compact Commission ("RGCC") changed New Mexico's Article IV delivery obligation from a nine-month schedule of delivery at San Marcial to an annual delivery determined based on the computed annual inflow to Elephant Butte Reservoir. The RGCC also adopted a new Otowi Gage index table for computing New Mexico's delivery obligation.

Article VI sets out long-term average delivery requirements through a system of debits and credits that allow the states to deviate from the annual obligations based on certain criteria. Annual compact accounting, including these debits and credits, commenced in 1940. The Compact is administered by the RGCC, which is comprised of one voting representative from each of the three States, and a non-voting representative from the United States acting as chair of the Commission.

2.3 Rio Grande Project

The remainder of this section provides an overview of the Rio Grande Project and its operation. More detailed descriptions of the historical operation of the Project and its water allocation and accounting mechanisms is provided in the Barroll Report (2019).

The Rio Grande Project is one of the first large-scale irrigation project developed by Reclamation. It was authorized by Congress in 1905 and construction commenced in 1907 (USNRC, 1938). The Project was developed to improve and expand the existing irrigation systems in the Rincon, Mesilla, and El Paso Valleys, as well as deliver water to Mexico. Elephant Butte Reservoir began storing water in 1915 and was completed in 1916. The major diversion dams and canals for the Project were completed by 1919, and most of the lateral distribution systems and irrigated lands were developed by 1929. High water table conditions caused by irrigation necessitated construction of drainage systems that were largely completed by 1925 (USNRC, 1938). Caballo Reservoir was constructed downstream of Elephant Butte Reservoir for flood control and to conserve winter hydropower releases from Elephant Butte Reservoir for subsequent irrigation use, and the reservoir began operation in 1938. This work, as well as construction of the American Diversion Dam and American Canal, was done as part of the International Boundary and Water Commission's ("IBWC") Canalization Project, which, along with the IBWC's Rectification Project, also realigned the river and adjacent irrigation infrastructure in many areas between Caballo Dam to Fort Quitman (IBWC, 1938; Reclamation, 1938; and IBWC, 1943).

The total irrigated area under the Project was originally planned to total 155,000 acres with 88,000 acres (57%) within EBID in New Mexico and 67,000 acres (43%) within EPCWID in Texas (USNRC, 1938). Of these amounts, about 16,000 acres were in the Rincon Valley, 82,000 acres were in the Mesilla Valley (10,000 acres in Texas), and 57,000 acres were in the El Paso Valley. A 1938 contract between EBID and EPCWID approved by the United States increased the original acreage allotted to the two districts by 3% resulting in a total area authorized to be irrigated of 90,640 acres in EBID and 69,010 acres in EPCWID (EBID, 1938).

The reported actual irrigated area varied through the years as lands were brought in and out of production. The reported actual irrigated area peaked at approximately 160,000 acres in the early 1950s and has generally declined since that time due mainly to urbanization, largely in and around Las Cruces and El Paso. The normal annual release from Project storage to satisfy Project irrigation demands was specified in the Compact as 790,000 AF, including 60,000 AF delivered to the Republic of Mexico at Juarez to satisfy a 1906 Treaty obligation (Reclamation, 1985).

Prior to construction of Elephant Butte Reservoir, the Rio Grande flow available for irrigation in southern New Mexico and western Texas was characterized by highly variable annual and seasonal flows depending mostly on the snowpack accumulation and subsequent snowmelt runoff from the upper portions of the Rio Grande watershed in southern Colorado and northern New Mexico. The original storage capacity in Elephant Butte Reservoir was about 2,274,000 AF, which was sufficient to store almost three years of the normal annual Project release and was essential for controlling and regulating the large fluctuations in Rio Grande flow (USNRC, 1938).

Completion of Caballo Reservoir in 1938 added 346,000 AF of Project storage, however the total Project storage capacity has declined through time due to silt accumulation in the reservoirs. The total combined storage capacity in Elephant Butte Reservoir and Caballo Reservoir declined from 2,570,000 AF in 1940 (Reclamation, 1940) to about 2,000,000 AF in the late 2000's (RGCC, 2017).

The current major diversion structures for the Project include the following:

Diversions Structures
Rio Grande Project

<table>
<tr><th>Region</th><th>Dam</th><th>Canal(s)</th></tr>
<tr><td>Rincon Basin</td><td>Percha Dam</td><td>Arrey Canal</td></tr>
<tr><td rowspan="2">Mesilla Basin
(NM & TX)</td><td>Leasburg Dam</td><td>Leasburg Canal</td></tr>
<tr><td>Mesilla Dam</td><td>Eastside Canal
Westside Canal</td></tr>
<tr><td>El Paso Valley</td><td>American Dam</td><td>Franklin Canal
Riverside Canal
Tornillo Canal</td></tr>
<tr><td>Juarez Valley</td><td>International Dam</td><td>Acequia Madre</td></tr>
</table>

Portions of the southern Mesilla basin extend into Texas, and diversions at the Mesilla Dam into the Eastside Canal and Westside Canal are delivered to Project lands in both New Mexico and Texas.

At present, all Project water deliveries to Project lands in the El Paso Valley originate as diversions from the Rio Grande at the American Dam into the American Canal which delivers water to the Franklin Canal and Riverside Canal headings. Prior to 1999, there was a separate diversion from the Rio Grande at the Riverside Canal heading. In 1999, the American Canal Extension ("ACE") was completed so that all diversions at American Dam could be delivered through a concrete-lined channel to the Franklin Canal and Riverside Canal headings. Until 1938, there was another diversion from the Rio Grande further downstream that supplied the Tornillo Canal. Reconfiguration of the river alignment in the Fabens area and adjacent irrigation infrastructure as part of the Rio Grande Rectification Project eliminated the river diversion for the Tornillo Canal, and since that time the supply for the Tornillo Canal has been derived from water tailing out of the Franklin Canal and Riverside Canal. Periodically, water has been diverted at times from drains to supply water to the Tornillo Canal.

Deliveries of treaty water to Mexico are made at the International Dam located downstream of the American Dam. Following completion of the American Dam in the 1930s, all of the Rio Grande flow has typically been diverted into the American Canal, except for the water that is left in the river to meet the delivery obligation to Mexico at the Acequia Madre. Prior to construction of the ACE, Project water that was destined for the Riverside Canal was diverted into the American Canal and then released back to the Rio Grande downstream of the International Dam through the Leon Street Wasteway or the Ascarate Wasteway where it flowed down the river channel to the Riverside Dam.

The HCCRD is located in Hudspeth County and receives its supply as waste and irrigation return flows from the Project. The Project is not supposed to be operated to intentionally or directly deliver water to the HCCRD.

2.4 Rio Grande Project Operating Procedures

Project lands are distributed along the Rio Grande in the relatively narrow Rincon, Mesilla, and El Paso Valleys. The first Project diversion occurs at Percha Dam approximately two miles below the Caballo Reservoir outlet and the last river diversion is at the International Dam approximately 110 miles downstream. As described above, other Project diversions from the river existed further downstream at Riverside Dam until 1999 and at the Tornillo Canal until 1938.

Due to the long and narrow configuration of the Project lands along with Rio Grande, irrigation return flows to the river from each canal service area as well as any other inflows are available as part of the supply for downstream Project diversions. This can result in efficient Project operation with full reuse of most or all of the irrigation return flows and other flows except those that accrue to the drains or river below the last Project diversion point. Originally, reuse of return flows within the Project occurred downstream of American Dam by means of major diversions from the Rio Grande at the canal headings for Riverside Canal and Tornillo Canal. When these canal headings were removed in 1938 (Tornillo Canal) and the 1999 (Riverside Canal) the opportunity to reuse return flows within EPCWID become more limited. However, reuse of return flows was still possible by diversion and use of drain flows for irrigation of the lower portions of the EPCWID service area. This use of drain flows within EPCWID is reflected in the Project records in many years from 1945 - 1982 (USBR, 1992 and NMSU, 2004). Additional details and discussion of the use of drain water is provided in both the Barroll Report (2019) and the MMA Report (2019).

The normal annual Project release of 790,000 AF described in the Compact appears to be largely based on an analysis in the RGJI that showed that the total supply diverted at the Project canal headings was comprised of varying amounts of storage releases, returns flows and seepage, and a small amount of tributary inflows. The RGJI describes a required annual storage release of 773,000 AF. This figure appears to have been increased to 790,000 AF during the Compact negotiations.

Historical descriptions of the day-to-day Project operations reinforce how the drain flows, wasteway flows, and other river gains or losses are considered in determining the reservoir releases necessary to meet orders for Project water. The following description from the 1936 Project History report is typical:

> *Water releases at the reservoir are changed twice a week to meet the irrigation requirements. The amount to be released is determined by advance orders to ditchriders by water users. These orders are summed for the different divisions and an allowance made for drain and waste return to arrive at the amount to be released. Under normal conditions this can be done very accurately with a small waste below the project limits. (Reclamation, 1936)*

More detailed descriptions of how the reservoir releases were determined are contained in certain versions of the annual Project History reports. A particularly detailed description is provided in the 1943 Project History report (Reclamation, 1943). It describes how the amount of flow needed in the Rio Grande at El Paso is computed by first tabulating the water orders for users in the El Paso Valley and Juarez with allowances for drain returns, waste returns and transmission losses. This figure is then used as a starting point for computations that systematically proceed upstream adding diversion demands and transmission losses and subtracting returns to arrive at the reservoir release that, when combined with the available return flows, is sufficient to meet the Project water demands.

While there have been changes in water allocation procedures through the years (e.g., the D1/D2 operation and the 2008 OA), the process for determining reservoir releases is similar today as it was at the time of the Compact. This is reflected in the following statement contained in the September 16, 2019 Supplemental Disclosure of Dr. Ian Ferguson:

> *Under the Operating Agreement, Reclamation releases Project water from Caballo Dam in accordance with water orders from EBID, EPCWID, and the United States section of the International Boundary and Water Commission ("US-IBWC") on behalf of Mexico. Water orders for Mexico are determined by the Mexican Section of IBWC ("MX-IBWC") and provided to Reclamation by US-IBWC. Water orders for EBID and EPCWID are determined and provided by each district, respectively. Water orders are limited by the allocation balance remaining on each entity's respective Project water account. The quantity of water released from Caballo Dam to satisfy Project water orders is determined by EBID and EPCWID, in consultation with Reclamation, based on the total amount of water ordered and anticipated gains and losses to the Rio Grande between Caballo Dam and Project diversion points. Project diversion dams and canal headings are subsequently operated to execute diversions and deliveries in accordance with water orders placed by EBID, EPCWID, and by US-IBWC for delivery to Mexico.*

The foregoing descriptions show how the amount of irrigation return flows and other flows entering the river are carefully considered in determining how much water to release from Project storage. For a particular aggregate demand, the more return flows that are entering the river, the less water that needs to be released from storage to meet that demand.

The term "diversion ratio" is used in characterizing the relative amount of reservoir release that is needed to meet downstream water demands. The diversion ratio may be computed as the sum of the river heading diversions divided by the reservoir release[1]. The lower the diversion ratio, the higher the reservoir release needs to be to meet downstream water demands. On an annual basis, the diversion ratio can range from 0.6 or less in dry years to over 1.0 in full supply years. The diversion ratio also varies throughout the year depending on river conditions. It is typically low at the beginning of the season when drain flows are low and river seepage losses are high. Drain flows and

[1] In the accounting under the 2008 Operating Agreement, the diversion ratio is computed as the sum of charged diversions divided by the reservoir release.

river seepage fluctuate through the irrigation season in response to surface water irrigation and pumping and this impacts the diversion ratio throughout the year.

2.5 Rio Grande Project Water Allocation

The allocation of Project water to Project water users has consistently been based on equal delivery of water per acre until the 2008 OA, as discussed below.

2.5.1 Equal Allotment Per Acre (Inception - 1978)

Reclamation operated all Project facilities through 1978 including the canals and laterals that delivered water to the Project water users. During this time Reclamation attempted to make available to all Project water users an equal amount of water per acre irrigated. There were no significant shortages during the first several decades of the Project operation and Reclamation did not impose any full-season Project water allotments until 1951 when the first significant drought following the completion of Elephant Butte Reservoir in 1915 occurred. Prior to 1951, there were often years when the releases from Project storage exceeded the normal annual release of 790,000 AF described in the Compact.

2.5.2 D1/D2 Allocation Procedure (1979 - 2007)

When the Project water users completed payments under their repayment contracts, Reclamation contracted with EBID (1979) and EPCWID (1980) to take over operation of the canal facilities and deliveries to the water users under each canal. This necessitated accounting for Project deliveries at canal headings rather than at the farm headgates. After this accounting adjustment, there still was equal delivery of water per acre to the Project water users, however, the districts became responsible for these deliveries rather than Reclamation.

To facilitate the delivery change to canal headings, Reclamation analyzed records of historical Project operations from 1951 - 1978 and developed relationships between Project releases and Project diversions and deliveries based on linear regression. The D1 Curve defined the relationship between Project releases and the sum of deliveries to U.S. farms and deliveries to Mexico at the head of the Acequia Madre. The D2 Curve defined the relationship between Project releases and the sum of diversions at all U.S. canal headings and at the Acequia Madre heading.

From 1979 - 2005, the D1 Curve was used to compute the allocation to Mexico based on the usable water available in Project storage and the D2 Curve was used to compute the diversion allocation to EBID and EPCWID. The districts were responsible for distributing water from their canal headings to the water users in their respective service areas.

An accounting system was established by Reclamation to track diversions by each district against their annual allocations. In general, the districts are charged against their allocations for the water they divert and use, but receive credits for certain operations. These credits are described in detail in the Barroll Report (2019).

2.5.3 2008 Operating Agreement (2006 - Present)

Reclamation, EBID, and EPCWID entered into an Operating Agreement for the Rio Grande Project on March 10, 2008 ("2008 OA"). Under the 2008 OA, the annual allocation to Mexico and EPCWID continued to be computed using the D1/D2 Procedure, while the allocation to EBID was modified to be based on the diversion ratio. In years when the diversion ratio is low, the EBID allocation is lower than the D1/D2 allocation that it previously received. In years when the diversion ratio is high, EBID could potentially receive an allocation greater than a D1/D2 allocation, although this has not happened since 2008 OA has been in effect. The revised allocation procedure, referred to as the D3 Procedure, was implemented informally beginning in 2006.

The other significant change in the 2008 OA was that each district was allowed to carry over any unused allocation that remained at the end of the year to add to the allocation it received in the subsequent year. Prior to the 2008 OA, the Project was operated on an annual basis and any unused allocation at the end of the year became part of the supply that was reallocated in the next year 57%/43% to EBID and EPCWID after determining the Mexico allocation under the D1 curve.

3.0 LOWER RIO GRANDE HYDROLOGIC DATA

Surface water data in the Lower Rio Grande have been collected by various agencies since the late 1880s. SWE compiled much of the available data into the Rio Grande Project Surface Water Dataset ("SWDataSet"). The SWDataSet is a compilation of flow and reservoir storage data that are used in various analyses and models by New Mexico representatives and consultants. The purpose of the SWDataSet is to provide a central data repository to ensure data integrity and consistency in the data that are used in the various analyses and models developed on behalf of New Mexico for this case. As more data become available through discovery or other means, these additional data will be added to the SWDataSet collection. The SWDataSet spreadsheet, original data, and metadata are being disclosed along with this report.

Most of the data in the SWDataSet fall into the following data categories:

- Streamflows
- Reservoir storage
- Diversions
- Drain flows
- Wasteway flows
- Municipal flows
- Metered ground water pumping

A list of all the flow data compiled in the SWDataSet is shown in **Table 3-1**. The measurement sites are listed by flow data type and location. The available period of record is also provided in the table. The earliest flow data are from 1889 and all available flow data have been compiled through 2017. All measurements sites with location information are shown in **Figure 3-1** through **Figure 3-5**.

3.1 SWDataSet Description

3.1.1 Organization of SWDataSet

The flow data have been imported into a single Excel spreadsheet and are organized by type, including river flows, canal flows, wasteway flows, drain flows, municipal flows, reservoir data, and metered irrigation pumping data.

3.1.2 Data Sources

The following is a summary of the major data sources used in the SWDataSet. A list of the data sources is provided in **Table 3-2.**

- EBID
- EPCWID
- Environmental Protection Agency ("EPA")
- IBWC
- RGCC
- Reclamation
- United States Geological Survey ("USGS")

3.1.3 Time-step

Most of the data in the SWDataSet are monthly data consistent with the monthly stress periods or time-steps used in the modeling and other analyses. Certain of the data that originated as daily data were aggregated and converted to monthly volumes, and these aggregation operations are contained in separate worksheets in the data backup folders.

Annual totals and monthly averages are generally provided below the monthly data. In cases where there are only annual data available, these values are shown in the annual total section and noted in the comments under the period of record. As needed for input into modeling or analysis, these annual data were converted to monthly volumes.

3.1.4 Period of Record

The SWDataSet includes all available flow data for the measurement sites from the earliest record available through 2017. The earliest compiled river flow records are for the Rio Grande at El Paso which date back to 1889. The earliest canal diversion records are for the Leasburg Canal which date back to 1908.

For certain data, there are missing months or years within the period of record. These data gaps are shown in two data matrices provided in the SWDataSet - one showing the monthly data availability and the other showing annual data availability. The monthly and annual data availability matrices are included in **Appendix 3A**.

3.1.5 Data Column Heading

The heading of the column for each measurement site contains the following information:

- District
  - EPCWID, EBID, HCCRD, and JID.
- Region
  - The region refers to the irrigation basin or main canal system (Rincon, Leasburg, Mesilla (NM), Mesilla (TX), El Paso, Hudspeth, and Mexico).
- Location
  - The location information is sourced to a worksheet (“Loc_info”). The location information is an export from an ArcGIS shapefile and in decimal degrees (1983 datum).
- Units
  - Data are in units of monthly AF and are typically rounded to the nearest AF.
- Site Code or other codes/gages numbers
  - The site code is from NMOSE.
    - The site code is based on the basin, type of gage, and miles downstream from Elephant Butte Dam. For example, the site code Westside Canal is 4C95.8A, the “4” is for the Mesilla basin below Leasburg, the “C” is for canal, the “95.8” is the miles downstream of Elephant Butte Dam, and the “A” is needed since there are three canal diversions from the Mesilla Dam (note that Eastside Canal is “B” and Del Rio Lateral is “C”).
  - The other site codes include USGS gage numbers, Reclamation 2008 Operating agreement codes, and EPA National Pollutant Discharge Elimination System (“NPDES”) permit numbers.

- Period of record
  - The period of record contains the year of the earliest record to the year of the latest record. Missing data are documented in the "Data_List" worksheet and are shown in the data matrices. As described above, some the records may be annual only and are noted in a comment.
  - Any estimated data are also noted in a comment.
- Name of measurement site/structure.

3.1.6 Backup Data Folders

The SWDataSet contains a series of backup folders that include the original data and metadata. The backup folders are named based on a source code (i.e., LRG.Doc.SWXXX). Each monthly data entry has a corresponding source code that references the source of the data/backup folder. The source code for each monthly data entry is located in the same worksheet as the monthly data in a parallel table labeled "Source Files." The table of source codes is located to the right of the data table. A summary of the backup data folders and various data sources is provided in **Table 3-2**.

Certain records in the SWDataSet are sourced to LRG.Doc.SW025. The source LRG.Doc.SW025 refers to a compilation of monthly data and not the original source data. Therefore, when data are sourced to the LRG.Doc.SW025, there is an additional source column adjacent to the LRG.Doc.SW025 column that lists the original source. An example of this is shown in the table below.

		DATA	SOURCE FILES	
District:		EBID	EBID	
Region:		Rincon	Rincon	
Location Lat (dd):		32.869	32.86912627	32.86912627
Location Long (dd):		-107.305	-107.305247	-107.305247
Units:		(af)	(af)	(af)
BOR 2008 OA Code:		R2	R2	R2
Site Code:		2C29.5A	2C29.5A	2C29.5A
Extent of Record:		1918-2017	1918-2017	1918-2017
Year	Month	Arrey Canal	Data Source - Arrey Canal	SW25 Source - Arrey Canal
1938	1	0	LRG.Doc.SW025	LRG.Doc.SW016
1938	2	1,698	LRG.Doc.SW025	LRG.Doc.SW016
1938	3	7,234	LRG.Doc.SW025	LRG.Doc.SW007
1938	4	12,294	LRG.Doc.SW025	LRG.Doc.SW007

In the above example, the data can be found in both source folders (SW025 and SW016 or SW007), but the original data are in the SW016 or SW007 folders.

3.1.7 Metadata

Metadata documentation for each data source is contained in the backup data folders in a Word document. The metadata documents native units, conversion factors, data quality, period of record, contacts for the data, compilation notes, links to online data, etc.

3.1.8 Conversion Units

The following conversion factors wereused to convert the measurement units of certain data in the SWDataSet:

- 1 cubic meter per second = 35.31467 cubic feet per second
- 1 cubic foot per second = 1.98345 acre-feet per day
- 1 million gallons = 3.0689 acre-feet

3.1.9 Gage Location Information

Reasonable efforts have been made to compile the geographic coordinates of all measurement sites. Location data include confirmed gage locations and approximate gage locations. Confirmed gage locations are those in which the publishing entity (USGS, EBID, IBWC, etc.) provides coordinates, there are ArcGIS shapefiles associated with the measurement site, or the site has been field verified using a Global Positioning System ("GPS") device. Approximate locations include sites in which the location of the feature (i.e., wasteway) is generally known, but the exact location of the gage is unknown. Schematic diagrams from Reclamation and IBWC and high-resolution imagery from Google Earth were used to approximate gage locations. The source of the location information is described in the "Loc_info" worksheet in the SWDataSet.

3.1.10 Quality Assurance and Quality Control ("QA/QC")

The general QA/QC process of data entry into the SWDataSet is double-checking the data after they are entered into a spreadsheet. For example, after data are copied in, the data are totaled and checked against the totals of the corresponding data in the original source files. Details of the QA/QC process for each data source are included in the metadata.

3.1.11 Data Summaries

For each type of data, there are data summary tabs that include a table generator and a generator for a several summary charts. The summary table and charts show monthly and annual data from 1889 or 1903 through 2017. Example summary tables and charts for each data type is provided in **Appendix 3B.**

Worksheets "ToFarmBudget" and "ToRiverWare" were added to the SWDataSet to facilitate export of certain data for use in modeling.

3.2 Missing Data

Certain of the missing surface water data were estimated to provide complete datasets for modeling or other analyses. Procedures were developed to estimate missing data based on averages, correlations, and other statistical approaches involving comparison to other measured data such as Rio Grande flow data. Municipal wastewater discharges were largely estimated using correlations of annual wastewater discharge and total municipal pumping. Details for how the missing data were estimated are in shown in **Table 3-3**.

The SWDataSet has two worksheet tabs for certain data types that have missing data that were estimated. One worksheet tab contains the raw data and is indicated with an "X" (i.e, "CanalsX"). The other worksheet contains estimates of the missing data and is named without the "X" (i.e., "Canals"). In the worksheets with missing data estimates, the estimated data are noted with a comment in the "Period of Record," and a note in the data source referencing the backup folder with the missing data calculations.

3.2.1 Rincon and Mesilla Basin Data Gaps

The datasets for the Rincon and Mesilla basins are mostly complete. Estimates of wastewater treatment plant ("WWTP") discharges prior to the late 1990s were made and are summarized in **Table 3-3**.

Missing months of data within a year were estimated using an average for that month from the prior and subsequent year. For years with no data, the WWTP was estimated using an average annual percentage of pumping. Ground water pumping from municipalities contributing to the WWTPs were obtained from SSPA. The annual estimated WWTP discharge was distributed evenly into each month (divided by 12). There are two exceptions to this method described below.

For El Paso Electric, a wastewater discharge of 53% was used based on a report from NREL (2004). This reported percentage is comparable to the average percentage computed from the records.

The Village of Hatch receives water supplies from outside of the Lower Rio Grande area for which records are not available. For this town, a relationship between WWTP discharge and population was developed to estimate the WWTP discharge back in time.

3.2.2 Hueco Basin Data Gaps

NMOSE/ISC staff, MMA, and SWE coordinated to identify missing data needed for the Hueco Model back to 1903 when the simulation period commences. A majority of the missing data that needed to be estimated for the Hueco Model was for Mexico from 1903 - 1939. A summary of the missing data for the Hueco Model area and data estimation techniques are summarized in **Table 3-3**.

For Ciudad Juarez, there are no data available for sewage/WWTP production. Estimates made by IBWC (1989) were used for 1950 - 1984. For the rest of the years, the sewage/WWTP production was estimated as 49 percent of the total Ciudad pumping based on an average derived from the IBWC estimates.

For EPW, discharge from the Northwest WWTP, Socorro WWTP, and Bustamante WWTP were estimated back in time. Northwest WWTP estimates from 1987 to August 2002 were based on data used in the Upper Rio Grande Water Operations Model ("URGWOM") model and these data were provided by the NMOSE.

There are EPA discharge data for Socorro WWTP available from 1989 - 1993. The annual Socorro WWTP discharge decreased from 28,000 AF in 1990 to 500 AF in 1993 (zero by 1994). The Bustamante WWTP discharge first began in 1991 and the first record of Bustamante WWTP discharge is 31,000 AF in 1995. It was assumed that the Bustamante WWTP increased from 1991 - 1993 as the Socorro WWTP discharge decreased. To estimate the annual total Socorro/Bustamante WWTP discharge, the unit waste flows from Bustamante WWTP (gallons per day per capita) were multiplied by the percentage of the total City of El Paso population served by the Bustamante WWTP (Brown and Caldwell, 1997). The City of El Paso population was obtained from the El Paso County website (El Paso County, 2016).

The Socorro WWTP had several treatment ponds known as the Socorro Ponds located south of the current location of Bustamante WWTP. Based on appearance of these ponds in a 1967 aerial photo, it was assumed that the Socorro WWTP began operating in 1967. The Socorro WWTP discharge was estimated from 1967 - 1988. From 1991 - 1994, the Bustamante WWTP discharge was estimated as the total Socorro/Bustamante WWTP minus the reported Socorro WWTP discharge.

There are no data for the JID diversions downstream of Acequia Madre. However, there are estimates from various sources from USNRC (1938), Carreno (1957), and IBWC (1989) for 1930 - 1936, 1938 - 1947, and 1950 - 1984, respectively. The IBWC estimates of lower river diversions by JID were based on analysis of gaged river flows. This procedure was used to estimate diversions before 1984 in the years that estimates from others were not available. The lower river gages were discontinued in 1984, and no estimates of lower river JID diversions were made after that time.

3.3 Urban Deep Percolation

Urban deep percolation represents the ground water returns from municipal water use and includes systems losses and deep percolation from lawn irrigation. No records of urban deep percolation volumes were available and therefore values were estimated as described below.

System losses represent leakage from municipal water conveyance systems. Estimates of total system losses for Las Cruces and El Paso are published in various reports. Based on these reports, the system loss to ground water was estimated as the lower end of the reported range of the total system loss, which may include measurement and billing errors. The system loss for EPW was estimated as 7% of the total water use (EPW, 2014 and EPW, 2019). For Las Cruces and all other municipalities, as system loss of 10% was assumed (Shoemaker, 2008).

Lawn irrigation deep percolation was estimated as a percentage of the computed outdoor use of municipal water. The outdoor use was computed as the total monthly water use (total diversion less system loss) minus the monthly indoor use which was estimated as the average monthly water use during December through February. Monthly lawn irrigation deep percolation was computed as 15% of the total monthly outdoor use. This assumes an average irrigation efficiency of 80% (Barta, 2004 and Rogers, 1997) and a spray loss of 5% (Kincaid, 1987).

Urban deep percolation was computed for the following municipal areas:

- Mesilla Basin
  - Las Cruces
  - Santa Teresa
  - Anthony
  - Mesquite
  - Berino
  - Garfield
  - Radium Springs
- El Paso Valley
  - El Paso

The total monthly municipal water use was based on reported total pumping and use of Project water by EPW. Pumping data for the municipal users in the Rincon and Mesilla basins were provided by SSPA and pumping data for EPW were provided by MMA.

Surface water use data were obtained from the SWDataSet. The resulting urban deep percolation volumes are summarized in Section 5.9.

4.0 RIO GRANDE PROJECT ACCOUNTING DATA

4.1 Introduction

Project accounting is comprised of flow data to track the delivery of water to Project lands and to Mexico. The Project accounting data includes the following three types of data.

- Water Distribution Reports
- Project Water Allocation
- Accounting Records

The accounting dataset is comprised of two Excel spreadsheets. The Project Water Allocation and Accounting Reports data are in one spreadsheet (2019-10-25 Draft RGP Accounting Data – Confidential.xlsx) and the Water Distribution Report data are in the other spreadsheet (2019-10-25 Draft WDR Data – Confidential.xlsx). The following sections describe and summarize the different types of Project accounting data.

4.2 Water Distribution Reports (1918 - 2011)

The Water Distribution Reports ("WDRs") are part of the Rio Grande Project Histories and date back to 1918. The Rio Grande Project Histories are annual published reports from Reclamation that are available from 1912 - 1988. These documents include information on the operation and maintenance of the Project and contain data on crop, irrigation, weather, surface flows, operational costs, etc.

From 1918 - 1978[2], the WDRs report the monthly deliveries of Project water to the farms by unit or major canal system. The units include Rincon, Leasburg, Mesilla, and El Paso (a.k.a. Yselta). There are also total Rio Grande Project WDRs which are a sum of the data for individual units. After the Project operations were transferred to the districts in 1979, the WDRs are reported by district (EBID and EPCWID) and there are records for HCCRD as well. A summary of the available and compiled WDR data is shown in **Figure 4-1**. Examples of the WDRs are shown in **Appendix 4A**.

[2] For the first couple of years, only the river headgate diversions and irrigated acreages were reported.

The following is a list of the WDR data types:

- Irrigated acres,
- River headgate (“RHG”) or canal heading diversions,
- Canal loss,
- Canal waste,
- El Paso Valley carriage,
- Non-agriculture diversions, and
- Farm headgate (“FHG”) deliveries.

The RHG diversions or canal heading diversions are measured flows for the major canals. Most of the canals divert from the river, but some canal headings are off other canals. These include the Franklin Canal that diverts from the American Canal, the Riverside Canal that diverts from the ACE (after 1999), and the Mesilla Texas diversions that divert from the Eastside and Westside Canals.

The WDRs include the reported total FHG deliveries to Project water users. Between the canal heading diversion and the farm headgates, a portion of the water seeps into the ground water or is consumed by vegetation in and around the canal (“Canal Loss”). Water is also spilled through various wasteways and returned to the river (“Canal Waste” or “Operational Spill”). To improve the conveyance of water downstream, some water is carried through EBID canals to the El Paso Valley (“El Paso Valley Carriage”). The non-agricultural diversions by EPW in the El Paso Valley are also reported.

The calculations for the reported canal heading diversions and Canal Waste in the WDRs for the El Paso Valley vary from year-to-year. Some of the El Paso Valley WDRs have notes indicating how these values were calculated, and these have been compiled and are shown in **Appendix 4B.**

4.2.1 FHG Deliveries (1920 - 2016)

FHG delivery records reported by unit are available from 1920 - 1978 and include Rincon, Leasburg, Mesilla, and El Paso Valley. Since 1979, the FHG deliveries are reported by district. Some EBID records from 1991 - 2010 are reported separately for the Rincon and Mesilla Valleys (including Leasburg). In 2011, there is a separate WDR for the Mesilla Valley only.

In addition to the WDR data, there are annual total EBID FHG deliveries available for 2011 - 2016 reported by the EBID. These records were compiled into the accounting dataset in the WDR spreadsheet.

Within the WDR accounting dataset, the FHG deliveries were disaggregated into units as necessary to have a continuous record of deliveries by unit over time. This was done by pro-rating the monthly district total values using the reported RHG diversions for each unit. For example, the Rincon FHG delivery was computed as the total EBID FHG delivery multiplied by the Rincon diversions (Arrey Canal plus Percha Lateral) divided by the total EBID diversions (Rincon, Leasburg, Mesilla Eastside NM, and Mesilla Westside NM). The diversions to each unit were obtained from the SWDataSet.

Prior to 1979, the total FHG deliveries for the Mesilla Unit were disaggregated into Mesilla Eastside and Mesilla Westside using the canal diversions for the Eastside Canal and Westside Canal. Then, the computed Mesilla Eastside and Mesilla Westside FHG deliveries were further disaggregated into New Mexico and Texas portions using reported irrigated area data.

After 1979, the total district-wide FHG deliveries for EBID and EPCWID were distributed by unit based on reported monthly diversions.

The compiled FHG deliveries by unit and by district from 1938 - 2016 are shown in **Table 4-1.** The values in black are from the records and the values in blue are computed and include the disaggregated values and the totals by district.

The FHG deliveries from the records were used as input into the CFB Models described in Section 6. Some additional adjustments and estimates of missing data were made to the records as needed and as described in that section.

4.3 Allocation Data (1951 - Present)

Prior to the development of the D1/D2 allocation procedures in 1979, Reclamation operated the Project to make available for delivery an equal amount to the farm headgates of all Project lands (Reclamation, 2015). The allocation of Project water beginning in 1951 was reported in the Rio Grande Project Histories as an allotment in AF per acre. An initial allotment was made in the beginning of the irrigation season. This allotment was occasionally increased over the runoff season (May - July) based on the amount of runoff accrued in the Project storage. During the 1940s, with ample available Project storage, there were no full season allotments reported in the Project Histories. The initial and final Project allotments from 1951 - 1978 are summarized in **Table 4-2** based on a summary table prepared by Reclamation (2012).

The D1/D2 allocation procedures started in 1979, and the annual allocations were computed as annual diversion volumes for EBID and EPCWID. Distribution of water from the canal headings to the farms was handled by the districts (Reclamation, 2015). Initial and final allocations to the districts are shown in **Table 4-3**. The values from 1979 - 2018 were obtained from Reclamation and district accounting and allocation reports provided by Dr. Peggy Barroll**.** There are some missing allocation data for EBID (1979 - 1983) and EPCWID (1980 - 1982). Also, except for 1984 - 1985, there are no data for the Mexico allocation from 1979 - 2002. Annual allocations for these years were estimated by Dr. Barroll. Examples of the allocation records are shown in **Appendix 4C**.

As described above, the 1940s were wet years with plentiful reservoir supply and the first full-season Project water allotment did not occur until 1951. Therefore, 1940 - 1950 were assumed to be full supply years[3]. From 1951 - 1978, there were a mix of full supply and less than full supply years. Full supply years were assumed to be years with final allotments to the farms of 3.0 AF/acre or more (Reclamation, 1985). From 1979 - 2005, full supply years were assumed to be years with Mexico being allocated 60,000 AF or diverting roughly 60,000 AF or more. After 2005, full supply years were assumed to be years with an annual allocation to EPCWID (not including carryover) of at least 360,000 AF. The 360,000 AF figure was determined in consultation with Dr. Barroll based on review of deliveries and allocations during full supply years from 1984 - 2005.

4.4 Accounting Records (1979 - present)

Accounting records for EBID and EPCWID from 1979 - 2018 have been compiled into the Accounting Dataset. The accounting records track the allocation, diversion charges, credits, and allocation balance for each district. The first available accounting records are reported as irrigation season totals. Monthly accounting records are available beginning in the mid-1980s. The accounting records are in a mostly consistent format throughout the D1/D2 allocation time period (1979 - 2005). Credits to EPCWID were added after the construction of the ACE, and the accounting reports changed after the 2008 OA to reflect changes in the allocation procedures. Below is a list of the type of data in the accounting records:

[3] The term "full supply" as used herein is synonymous with "full allotment" or "full allocation."

- Allocation of Project water,
- Delivery charges,
- Credits, and
- Allocation balance/carryover.

Project water is delivered to the districts at canal headings in New Mexico and Texas. Texas lands in the southern Mesilla basin receive Project water that has been diverted by EBID at canal headings in New Mexico. Project water is delivered to the following structures, listed generally in upstream to downstream order. Maps of the accounting points for EBID and EPCWID are shown in **Figure 4-2** and **Figure 4-3.**

Examples of the accounting reports are provided in **Appendix 4D**.

New Mexico Delivery Points	**Texas Delivery Points**
• Arrey Canal	• La Union West Canal
• Percha Canal	• La Union East Canal
• Leasburg Canal	• Three Saints Lateral
• Westside Canal	• Robertson- Umbenhauer WTP
• Eastside Canal	• Franklin Canal
• Del Rio Lateral	• Jonathan Rogers WTP
• California Lateral	• Riverside Canal
• Various river pumps	

Delivery charges to EBID include the total diversions to EBID at the canal headings listed above minus deliveries to Texas in the Mesilla basin. Credits to EBID include credits for bypass water diverted at Arrey Canal or Leasburg Canal, and credit for flood waters diverted. In addition, there is an adjustment to the EBID delivery charges for diversions that are less than 95 percent of orders. EBID is charged the maximum of 95 percent of its order or the actual diversions.

Delivery charges to EPCWID include the total diversions to EPCWID at the canal headings listed in the above table. In recent years, EPCWID has also been charged for diversions to others including Tigua Pueblo, IBWC, and Yselta del Sur. The largest credits to EPCWID consist of water discharged though the Ascarate Wasteway prior to completion of the ACE in 1999, Haskell WWTP effluent discharges to the ACE, and a credit to the district for unordered and unused water. Since 2003, EPCWID has also received an ACE Conservation Credit that is added to EPCWID's total allocation and not included in the delivery charge.

For both EBID and EPCWID, if one district is ordering water and the other is not, the delivery charge to the district ordering water is equal to the total Caballo Dam release.

Figure 4-4 shows the total allocations to each district, JID, and the total delivery charges to each district from 1979 - 2018. Since 1979, EBID tended to take delivery of most of its allocation. Since 1979, EPCWID took delivery of less than its full allocation in most years. The total EPCWID annual deliveries have decreased since 2005.

5.0 HISTORICAL WATER SUPPLY AND WATER USES

5.1 Introduction

The Rio Grande, like many rivers of the southwestern United States, is characterized by wide swings in annual flow, owing largely to the significant variability in the annual snowpack accumulation and runoff from the headwaters in southern Colorado and northern New Mexico from which most of the Rio Grande flow is derived. Irrigation development in the San Luis Valley of Colorado and later the Middle Rio Grande of New Mexico have long affected the flow of the Rio Grande at San Marcial that is the source of most of the water for the Project. Regulation of upstream water uses in Colorado and New Mexico to meet the annual delivery obligations of Colorado (at the State line) and New Mexico (at San Marcial until 1949 and at Elephant Butte Reservoir thereafter) also have affected the flow available to Lower Rio Grande water users.

Construction of Elephant Butte Reservoir in 1915 and Caballo Reservoir in 1938 were instrumental in regulating the variable supply from upstream for delivery of a more dependable irrigation supply to Project water users. The Project water supply is described in the RGJI as comprised of storage releases, irrigation returns, and, to a minor degree, sporadic tributary inflows.

The average annual demand for irrigation water for the Project and for delivery to Mexico was estimated in the RGJI based on diversion records for the period from 1930 - 1936 and estimates of reuse of return flows and reservoir evaporation losses as follows:

Table 95 – Required Annual diversion demand upon Rio Grande at San Marcial for Rio Grande project and Mexican treaty obligation (USNRC, 1938)

Item	*Annual Demand (acre-feet)*
Net diversions for Rio Grande Project irrigated acreages of 145,000	*600,000*
Rio Grande Project wastes	*65,000*
Riverbed losses above Tornillo Heading	*64,000*
Salinity control in area under Tornillo Canal	*7,000*
Fulfillment of Mexican Treaty obligation	*37,000*
Total reservoir releases	*773,000*
Reservoir evaporation	*120,000*
Reservoir seepage	*60,000*
Total demand on San Marcial	*953,000*

The total release requirement of 773,000 AF/y was increased slightly during the Compact negotiations to the normal annual release of 790,000 AF/y described in the Compact.

The RGJI also included analysis of the flow available at San Marcial. Based on analysis of historical gage records from 1890 - 1935, corrected to account for upstream development that had occurred by the mid-1930s, the average annual flow available at San Marcial for downstream use was estimated at 1,031,000 AF/y. Records of water availability and water use since the mid-1930s indicate that the average available supply has been less than what was estimated in the RGJI and the use of water has been slightly more than what was estimated.

This section summarizes various historical records of water supply and water uses from before the Compact to the present.

5.2 Rio Grande Flows

Rio Grande flow records for the period of available record were compiled for gages between San Marcial and El Paso as follows:

- San Marcial (1890-2017),
- Elephant Butte Reservoir Outlet (1915-2017),
- Caballo Reservoir Outlet (1922-2017, Rio Grande above Percha Dam used for 1922-1937), and
- El Paso (Courchesne) (1895-2017).

Since completion of Caballo Reservoir in 1938, releases from Project storage have been measured below the Caballo Reservoir outlet. Prior to that time Project releases were measured below Elephant Butte Reservoir. From 1922 - 1937 there was a Rio Grande gage upstream of Percha Dam, the first Project diversion located approximately two miles downstream of the Caballo Reservoir outlet. Comparison of the annual releases from Elephant Butte Reservoir to the annual flows in the Rio Grande above Percha Dam during the period of concurrent record shows there was an average annual gain of about 20,000 AF in the 29-mile reach between the Elephant Butte Reservoir outlet and Percha Dam. Therefore, the records for the Rio Grande above Percha Dam are a better representation of the flow available at the upstream end of the Project prior to the time that Caballo Reservoir was constructed.

The upper graph in **Figure 5-1** plots the annual Rio Grande flows at San Marcial since 1890 as well as the 10-year average flow. Annual San Marcial flows averaged approximately 890,000 AF/y during the period of record. The 10-year average line clearly shows the cyclical nature of the flows in the Lower Rio Grande basin during the last almost 130 years. By decade, the flows were above average through the 1940s, below average from the 1950s through the 1970s, above average in the 1980s and 1990s, and below average thereafter.

The middle chart in **Figure 5-1** compares the annual San Marcial flows to the Project releases below Caballo Reservoir since 1922 (Rio Grande at Percha Dam flows used before 1938). The regulating and dampening effect of Project storage is seen by comparing the two lines in this chart.

Another illustration of the cyclical nature of the Rio Grande flows is presented in the lower chart in **Figure 5-1** that depicts the cumulative departure from average for the San Marcial gage and the Caballo Reservoir releases during the period from 1922 - 2017. The cumulative departure line for the San Marcial gage flows generally increases through

1945, then decreases until 1978, then increases again until 1999, and decreases thereafter. The cumulative departure line for the Caballo Reservoir releases follows a similar pattern, except it is dampened and shifted forward in time by 3-5 years reflecting the storage regulation of the reservoir inflows.

Table 5-1 provides a comparison of the average annual San Marcial inflows and Caballo Reservoir releases for various historical periods and against the comparable planning estimates presented in the RGJI. These comparisons show that the San Marcial flows have been substantially less than were estimated in the RGJI. During the generally wet period until 1950, actual reservoir releases were greater than the estimated releases needed to supply the Project. This was due in part to the Project irrigated area that grew to about 160,000 acres by the early 1950s and well in excess of the 145,000 acres analyzed in the RGJI. The early 1950s also marked the end of the prolonged wet period that had existed for several decades and, as a result, reservoir releases were less than projected in the RGJI due to the drier conditions.

The upper chart in **Figure 5-2** compares the annual Caballo Reservoir releases and El Paso gage flows from 1920 - 2017. The decreases in flow from Caballo Reservoir to El Paso generally reflect the consumptive use of surface water and ground water for irrigation and non-irrigation uses as well as the consumptive use by native vegetation.

The net Rio Grande depletion between the Caballo Reservoir release and El Paso gage, computed as the difference between the lines in the upper chart is plotted as the blue bars in the lower chart in **Figure 5-2**. The 10-year average depletion, plotted as a black line, shows the annual depletions remained relatively steady around 250,000 AF until the wet period of the early 1980s when the average annual depletions increased to over 300,000 AF during the 1990s. With the commencement of the recent dry period in the early 2000s, the average annual depletions have declined back down to around 250,000 AF. **Table 5-1** includes a summary of the average annual Caballo to El Paso depletions for various historical periods.

Figure 5-3 summarizes the annual Rio Grande flows at the Ft. Quitman gage that is located downstream of the HCCRD. Until the mid-1940s, the annual flows often exceeded 200,000 AF. In the following three decades, which were characterized by drier conditions and more careful Project operation to minimize waste, the Ft. Quitman flows averaged less than 40,000 AF. A return of wetter conditions and less efficient Project operation resulted in a significant increase in Ft. Quitman flows that persisted through 2010. Additional discussion of the Project waste is provided in Section 5.6.

5.3 Irrigated Area

The authorized irrigated area for the Project is described in the 1938 contract between EBID and EPCWID and consists of 90,640 acres in New Mexico (57%) and 69,010 acres in Texas (43%). The actual irrigated area in the Project varied through time as new lands were brought into irrigation during the early years of the Project and as lands were taken out of production due to urbanization. In addition, the actual irrigated area fluctuated from year to year as a result of planting and fallowing decisions by farmers in response to forecast water supplies.

The preparers of the RGJI assumed that not all irrigable acres would be irrigated in any one year because of fallowing and other decisions, and they estimated the water requirements for the Project based on a total combined actual irrigated area of 145,000 acres.

The reported annual Project irrigated areas for EBID, EPCWID, and the combined total are plotted in the upper chart in **Figure 5-4** for 1920 - 2017. The Project irrigated area increased rapidly to approximately 140,000 acres in the mid-1920s at which time it leveled out for about 10 years. The irrigated area slowly increased through the 1940s and reached a peak of approximately 160,000 acres in the early 1950s. This is about 15,000 acres greater than the acreage figure used in the RGJI for estimating the average annual reservoir release of 773,000 AF/y.

Since the peak in the early 1950s, the irrigated area steadily declined to the current (2017) value of approximately 105,000 acres. This represents a decline of 55,000 acres or 34% from the peak. The irrigated area in EBID has decreased by 23,000 acres (25%) from a peak of about 93,000 acres to the current 70,000 acres. The decrease in irrigated area in EPCWID has been greater at 32,000 acres (48%), declining from 67,000 acres to 35,000 acres.

As shown in the lower chart in **Figure 5-4**, the reported irrigated area in the HCCRD also increased rapidly during the 1920s reaching almost 15,000 acres in 1930. After declining to about 11,000 acres in 1938, it rose to a peak of 18,000 acres in the early 1950s. As a consequence of the severe drought that affected the Project in the mid-1950s, the irrigated area in the HCCRD, which relies on waste from the Project for its supply, declined precipitously to about 4,000 acres in the late 1950s. Since then, the irrigated area has fluctuated up and down and peaked again in the late 1980s at 17,000 acres, and then declined to the current (2017) 8,000 acres.

The reported irrigated area for the JID is also plotted in the lower chart in **Figure 5-4**. The area increased from about 19,000 acres in 1920 to about 58,000 acres in the mid-1930s and then declined to about 24,000 acres in the mid-1950s. Since then, the JID irrigated area has fluctuated between about 30,000 acres and 45,000 acres, and currently stands at about 32,000 acres (2017).

The decline in irrigated area in the Project and in the JID has been due in part to urbanization, mostly in and around Las Cruces, El Paso, and Juarez. It appears that the fluctuation in the HCCRD irrigated area may have been due to the variability in the water supply for the area.

EPW has reportedly contracted for use of the Project water associated with some of the EPCWID lands that have gone out of production, and this reportedly is the basis for the deliveries of Project water they began receiving in the mid-1940s.

5.4 Diversions

Annual irrigation season (Mar - Oct) diversions at or near the canal headings are plotted in **Figure 5-5** for EBID and EPCWID and **Figure 5-6** for HCCRD and JID during the period from 1920 - 2017. EBID diversions include diversions at the Arrey Canal in the Rincon basin, and the Leasburg Canal, Westside Canal, and Eastside Canal in the Mesilla basin. The Westside Canal and Eastside Canal deliver water to EBID lands in New Mexico and to EPCWID lands in Texas, and the diversions for these canals were pro-rated to EBID and EPCWID based on reported annual irrigated area in each district.

EBID diversions were highest during the wet period that lasted until about 1950. Diversions fluctuated during the 1950s - 1970s as the Project supply cycled through dry and wet periods. Diversions generally increased during the full supply years of the 1980s and 1990s with the 10-year average diversions returning to the level that occurred in the 1940s. Since 2002, diversions have declined dramatically as a result of the drought and enactment of the 2008 OA that has substantially reduced Project water allocations to EBID.

EPCWID diversions include diversions at the Franklin Canal, Riverside Canal (starting in 1928), Tornillo Canal (until 1937), the EPCWID portions of the Westside Canal and Eastside Canal in the Mesilla basin, and EPW diversions. The EPCWID diversions increased rapidly through the 1920s as additional lands were brought into irrigation. Similar to EBID, the EPCWID diversions were at a high level throughout the wet period of the 1930s and 1940s. Diversions plummeted during the early and mid-1950s and then varied up and down through the wet and dry years of the 1960s and 1970s. Diversions during the full supply years of the 1980s and 1990s almost reached the pre-1950 levels with increasing amounts of water delivered to EPW (orange bars in **Figure 5-5**). Commencement of the drought in

2002 resulted in a decline in EPCWID diversions, but because of the 2008 OA diversions did not decline as much as in EBID.

Irrigation season canal heading diversions for the HCCRD are plotted in the upper chart in **Figure 5-6** and include measured or estimated flows in the Tornillo Canal at Alamo Alto, the Hudspeth Feeder Canal, and the Tornillo Drain. Because the HCCRD supply is derived entirely of EPCWID waste and return flows, the HCCRD diversions generally follow the pattern of the EPCWID supply. HCCRD diversions were high in the 1930s and 1940s, and even higher in the 1980s and 1990s. Flows were more variable in the 1950s, 1960s, 1970s and after 2002.

Irrigation season diversions to the JID are plotted in the lower chart in **Figure 5-6**. These include reported diversions at the International Dam to the Acequia Madre and reported and estimated diversions from the Rio Grande downstream of International Dam until 1984. Completion of the American Dam in 1938 allowed the United States to better regulate deliveries to Mexico under the 1906 Treaty. After that time, the United States could divert all flow in the Rio Grande except for the amount being passed a short distance downstream to Mexico for diversion into the Acequia Madre. Diversions into the American Canal could then be delivered to the Franklin Canal heading or returned to the river downstream of the International Dam for delivery to the Riverside Canal heading. Before construction of the American Dam, delivery of flows to the Riverside Canal and the Tornillo Canal had to be delivered in the river past the Acequia Madre and there was no physical way to keep Mexico from diverting in excess of its treaty allotment. This accounts for the large diversions by Mexico until 1938. Since that time, JID diversions have fluctuated in concert with the diversions by the U.S. districts. Reported annual diversions often exceeded the 1906 Treaty limit of 60,000 AF because of the unregulated diversions from the river downstream of the International Dam.

Computed irrigation season canal heading diversions for irrigation in <u>AF per acre</u> are shown in **Figure 5-7** for EBID and EPCWID and in **Figure 5-8** for HCCRD and JID. These figures are based on the actual reported irrigated area in each district. Because of the generally declining acreages in both EBID and EPCWID average per acre diversions for both districts have increased since 1950s. This is especially the case for EPCWID which saw its 10-year average per acre diversions increase from about 3 AF/ac in the early 1960s to about 7 AF/ac in the 1990s. Per acre diversion have declined in recent years due to the prolonged drought.

Average per acre diversions for the HCCRD also increased markedly from about 3 AF/ac in the 1960s to about 8 AF/ac in the 1990s. In the JID, per acre diversions have remained relatively steady since completion of the American Canal in 1938. The per acre diversions are relatively low compared to EBID, EPCWID, and HCCRD because JID has significant additional supply from sewage/WWTP returns and drain flows that are not included in the per acre diversions shown in **Figure 5-8**.

Irrigation season canal heading diversions per <u>authorized acre</u> for EBID and EPCWID are summarized in **Figure 5-9**. The EPCWID diversions include diversions by EPW for municipal use. The authorized Project acres total 90,640 acres in EBID and 69,010 (EBID 1938). The per authorized acre diversions in EBID increased from approximately 4 AF/y in the 1960s to over 5 AF/y in the 1990s before declining in recent years due to the effects of drought and the 2008 OA. Similarly, the per authorized acre diversions in EPCWID increased from about 3 AF/y in the 1960s to about 5 AF/y in the 1990s before declining in recent years. The per authorized acre diversions in EPCWID are generally lower than in EBID because there has been more urbanization in EPCWID resulting in less overall water demand.

5.5 Farm Headgate Deliveries of Surface Water

Similar charts to the canal heading diversion charts were prepared to summarize the reported and estimated FHG deliveries of surface water. Summaries of the annual FHG delivery volumes are shown in **Figure 5-10** for EBID and EPCWID and **Figure 5-11** for HCCRD and JID. The FHG delivery volumes vary widely depending on the Project supply.

EBID FHG deliveries during full supply years of the 1980s and 1990s are slightly greater than during the full supply years of the 1960s and 1970s. EBID FHG deliveries have declined sharply since 2002 due to effects of drought and the 2008 OA.

FHG deliveries for EPCWID are shown as stacked bars for irrigation deliveries (red) and EPW deliveries (yellow). There are 10-year average lines in the EPCWID chart for the irrigation deliveries only and the total deliveries. The EPCWID FHG deliveries during full supply increased from approximately 150,000 AF during the 1960s - 1980s to over 200,000 AF in many years during the 1990s and 2000s.

FHG deliveries to HHCRD varied widely from 1940 to the present but increased from an average of 20,000 AF/y - 30,000 AF/y during the 1960s and 1970s to approximately 50,000 AF/y in the 1990s and early 2000s.

There are no records of FHG deliveries for JID and the values in **Figure 5-11** were estimated based on total diversions minus an estimated total canal loss. The estimated JID FHG deliveries have increased through time due to reported increases in WWTP discharges to the canal system and lining of the JID canals and laterals.

Computed irrigation season farm headgate diversions for irrigation in AF per acre are shown in **Figure 5-12** for EBID and EPCWID and in **Figure 5-13** for HCCRD and JID. These figures are based on the actual reported irrigated area in each district. Because of the generally declining acreages in both EBID and EPCWID average per acre FHG deliveries for both districts have remained steady or slightly increased since the 1950s. Per acre FHG deliveries have declined in recent years due to the prolonged drought. The declines are greater in EBID due to effects of the 2008 OA. Per acre farm deliveries in HCCRD increased from an average of 2 AF/ac in the 1960s to an average of 3.5 AF/ac in the 1990s and 2000s. In JID, FHG deliveries increased from an average of 1 AF/ac in the 1960s almost 2 AF/ac in recent years.

5.6 Farm Headgate Deliveries of Surface Water Plus Pumping

Charts summarizing FHG deliveries of surface water plus supplemental ground water pumping are shown in **Figure 5-15** through **Figure 5-18**. These charts are identical to the charts in **Figure 5-10** through **Figure 5-13** except that the estimated supplemental ground water pumping was added to the FHG deliveries to compute the total applied water. The estimated supplemental ground water pumping was computed as part of the CFB Model analyses that are described in Section 6.

The stabilizing effect of the supplemental pumping is obvious in the total applied volumes for EBID and EPCWID summarized in **Figure 5-15**. The applied water volumes for HCCRD in **Figure 5-16** are more variable due to the large variations in surface water supply and large variations in irrigated area. The total applied water volumes for JID increase substantially through the 1950s and 1960s due to the development of supplemental ground water supplies and increased supply from Ciudad Juarez sewage/WWTP returns.

The computed annual total applied water per actual irrigated acre shown in **Figure 5-17** are relatively stable for EBID and EPCIWD throughout the study period with the averages fluctuating between approximately 3 AF/ac and 3.5 AF/ac in both districts.

The annual total applied water for HCCRD shown in **Figure 5-18** has more variability than the EBID and EPCWID values, but the 10-year average also fluctuates in the range of 3 to 3.5 AF/ac. The JID total applied water values also shown in **Figure 5-18** increased from approximately 2 AF/ac in the early 1950s to an average that varies between 3 and 3.5 AF/ac from about 1970 to the present.

The annual total applied water for EBID and EPCWID are shown per authorized acre in **Figure 5-19**. The EBID amounts varied above and below 3 AF/ac throughout the study period. The EPCIWD amounts were slightly less averaging about 2.5 AF/ac. The lower average for EPCWID is likely due to greater urbanization in the EPCWID service area and resulting in lower irrigation water demands.

5.7 Waste and Deliveries to HCCRD

Historical data were reviewed to assess how Project operational waste has changed over time. Operational waste is a generally unavoidable part of operating a large irrigation Project. In order to operate without waste, it would be necessary to release the water from storage in the amounts and with the timing that, when combined with the gains and losses between the reservoir outlet and the delivery points, would result in delivery of exactly what was ordered. Such operational perfection is generally not achievable due to the time it takes for releases to reach the farms, the day-to-day variations in gains and losses between the Caballo Reservoir outlet and the delivery points, changes in water orders after releases have been made, and variations in efforts to control and manage the Project supply. Operational waste appears as discharges from canals back to the river or drains through wasteways, and as water tailing out the end of the canals.

Operational waste is not lost to the Project if it can be diverted downstream and used within the Project. Indeed, this is what happens with much of the waste from the EBID canals that returns to the river and is part of the supply that is diverted and used in the EPCWID or the JID. The operational waste that is lost to the Project is the waste that leaves the Project area below the Tornillo Division of the EPCWID.

Reported annual volumes of operational waste for EBID are plotted in **Figure 5-20** along with annual canal heading diversions. The annual EBID operational waste was relatively consistent and trending downward from the 1940s through the 1970s. The operational waste spiked upward during a few years in the late-1980s and early-1990s before declining to the lower levels in the mid-1990s and thereafter. Note that portions of the reported EBID operational waste may have been intentional because water that was destined for downstream delivery below El Paso was reportedly sometimes delivered through EBID canals and wasted back to the river downstream because the conveyance efficiency of the canals was often better than the river during dry conditions.

Figure 5-21 shows the annual waste and FHG deliveries as a percentage of annual canal diversions. The operational waste fluctuated above and below 10% through the mid-1960s and then declined to around 5% from the mid-1960s through 2001 except during the wet periods in the mid-1980s and mid-1990s. As described above, much of the EBID operational waste would have been diverted and used in the EPCWID and therefore was not lost to the Project.

Similar charts for reported operational waste in the El Paso Valley portion of the EPCWID are provided in **Figure 5-22** and **Figure 5-23**. The reported annual waste volumes in **Figure 5-22** exhibit a somewhat similar pattern to the EBID waste volumes in that the annual volumes were relatively high in the 1930s and 1940s and then lower through the 1970s.

However, beginning in the 1980s, the reported El Paso Valley waste increased substantially over what it was prior to that time, and not just during a few years in the 1980s and 1990s like it did in EBID. It is noteworthy that that increase in waste generally coincided with the EPCWID taking over the water distribution within the district from Reclamation.

Records of operational waste for the El Paso Valley are not available after 2002, so the annual waste volumes after 2002 were estimated based on a linear regression with the reported total annual canal flow to HCCRD (Tornillo Canal at Alamo Alto + Hudspeth Feeder Canal) that is also plotted in **Figure 5-22** and seems to generally follow the pattern of the reported El Paso Valley waste prior to 2002.

Figure 5-23 shows the annual El Paso Valley waste as a percentage of total El Paso Valley diversions (computed as Franklin Canal diversions minus Ascarate Wasteway flows [before completion of the ACE in 2000] plus Riverside Canal diversions plus EPW diversions). When Reclamation tightened up Project operations in the early 1950s, the waste declined from over 20% of diversions to generally less than 10% of diversions where it remained through the late-1970s. Then, inexplicably, the waste increased to an average of approximately 25% of diversions where it remained until the recent drought.

Assuming 10% represents a reasonable upper limit for El Paso Valley operational waste, **Figure 5-24** was prepared to summarize the annual waste volumes that exceeded this threshold. As shown in the table embedded in **Figure 5-24**, the annual El Paso Valley operational waste since 1980 during non-spill years averaged 51,200 AF, and annual operational waste in excess of 10% averaged 28,000 AF. Assuming this operational waste represents water that could have been saved, EBID and EPCWID would have shared in this savings 57%/43%. EBID’s share of the savings would have averaged approximately 16,000 AF/y and this represents a reasonable approximation of the impact that the increase in El Paso Valley waste had on EBID during the period from 1980 - 2017.

5.8 Irrigation Pumping

Since 2009, all wells in the New Mexico part of the LRG basin have been required to be metered by order of the New Mexico State Engineer (with the exception of single-family domestic wells and small stock wells). Many non-irrigation wells were metered long before 2009 under State Engineer permit conditions. All metered ground water uses are reported annually in the LRG Water Master Reports. The total annual metered irrigation pumping volumes in the Rincon basin and Mesilla basin in New Mexico from 2009 - 2018 are shown in **Figure 5-25**. Since 2016, the irrigation pumping has also been reported by subarea (Rincon, Mesilla North/Leasburg, and Mesilla South) and outlying areas. The stacked bars in **Figure 5-25** depict the annual irrigation pumping by subarea starting in 2016.

5.9 Non-Irrigation Water Uses and Return Flows

Water used for non-irrigation purposes in the LRG Area includes domestic, municipal, commercial, and industrial ("DCMI") uses. Most of the non-irrigation water uses are supplied by in-basin ground water pumping with the exception of EPW use of Project water, and ground water imported by Las Cruces from the Jornada basin.

A portion of the non-irrigation water use returns to the Rio Grande, canals, and drains through WWTP discharges and to the ground water system through urban deep percolation. These return flows were tabulated and estimated as described in Section 3.

Summaries of the combined annual non-irrigation water uses and measured and estimated return flows in New Mexico, Texas, and Mexico are shown in **Figure 5-26** through **Figure 5-28**. Annual pumping and return flows have averaged the following volumes during the past five years:

Average Annual Non-Irrigation Pumping and Return Flows
LRG Study Area
2013-2017
(acre-feet)

Region	Pumping	WWTP Discharges	Urban Deep Percolation	Total Returns
New Mexico	36,500	12,900	4,100	16,900
Texas	86,700	52,100*	11,900	64,000
Mexico	150,900	71,400	0	71,400

* NW WWTP (7,100 AF/y), Haskell WWTP (15,500 AF/y), and Bustamante WWTP (29,500 AF/y)

6.0 LOWER RIO GRANDE CANAL AND FARM BUDGET MODELS

Canal and Farm Budget Models ("CFB Models") were prepared to simulate historical irrigation water use in the major irrigation units in New Mexico, Texas, and Mexico between Elephant Butte Reservoir and Ft. Quitman. The models employ typical water balance calculations based on the simple formula:

- Inflows - Outflows = Change in Storage.

The CFB Models simulate use of surface water and ground water to meet the irrigation requirements for the crops that were historically grown in the study areas. The models simulate delivery of water from the canal headings to the farms including conveyance losses to seepage, incidental consumptive losses, wasteway flows, and carriage water operations. Simulated deliveries of surface water to the farms are used to meet crop irrigation water requirements limited by reasonable maximum farm irrigation efficiencies, and the deliveries that are not consumed return as deep percolation or surface runoff. A soil moisture reservoir is simulated in the root zone of the crop to carry over excess surface water applications from one stress period to the next. After development of irrigation wells in the late-1940s and early 1950s, unmet crop water demands are assumed to be met by ground water pumping.

The CFB Models were developed to assess the historical use of surface water and ground water in the LRG Area, and specifically to compute:

- Crop-weighted consumptive use ("CU") of applied water for the irrigation units in the LRG Area;
- FHG deliveries for periods when records were not available;
- Supplemental pumping for all irrigation units, and the primary (ground water only) pumping in New Mexico; and,
- Annual inputs for the Hueco Model simulation of period from 1903 - 1939).

In addition, the CFB Models were used to verify the canal and farm budget simulation process that was implemented in the RiverWare Model.

6.1 Simulated Irrigation Units

Separate CFB Models were developed for distinct irrigation units within the four irrigation districts in the LRG Area (EBID, EPCWID, HCCRD, and JID) based on the geography and availability of input data (e.g., diversion data, irrigated area data, cropping data, etc.). The following tables lists the separate CFB Models that were prepared, and the geographic area for each model is mapped in **Figure 6-1**.

Identification of CFB Models by Irrigation Unit

Irrigation Unit	District	Location
Rincon	EBID	Rincon Valley in Sierra and Dona Ana Counties, New Mexico
Leasburg	EBID	Leasburg Canal service area in the Mesilla Valley in Dona Ana County, New Mexico
Mesilla Westside (NM)	EBID	Westside Mesilla Canal service area in the Mesilla Valley in Dona Ana County, New Mexico

JID Unit 3	JID	Southern portion of the JID Irrigation District in Chihuahua, Mexico

6.2 Study Period

The primary CFB Models simulate historical irrigation operations using available historical data from 1938 - 2017 using a monthly time-step. CFB Model simulations for the irrigation units in the El Paso Valley area of the EPCIWD, HCCRD, and JID were also prepared for the period from 1903 - 1937 using an annual time-step to compute certain data that were used in the Hueco Model developed by MMA.

6.3 CFB Model Simulation Processes

The equations used in the CFB Models for lands with supplemental ground water are shown on **Table 6-1** and a schematic flow diagram of the computations is shown in **Figure 6-2**. In each time-step, the irrigation demand volume is computed based on the weighted crop irrigation requirement ("CIR") multiplied by irrigated area. Water supplies are simulated to meet the monthly irrigation demand in the following order:

1. Farm headgate deliveries of surface water,
2. Soil moisture carryover from the prior month, and
3. Ground water pumping.

The surface water available to the crop is computed as FHG delivery multiplied by the estimated maximum farm irrigation efficiency ("MFE").

If the available surface water is not sufficient to meet the irrigation demand, stored soil moisture carried over from the prior time-step is used next to meet any unmet irrigation demand. The simulated capacity of the soil moisture reservoir for each irrigation unit is based on the management allowable depletion ("MAD") portion of water holding capacity of the crop root zone.

Ground water pumping is computed as the unmet irrigation demand that remains after simulating the use of surface water and stored soil moisture, and is computed as the unmet CIR demand divided by the MFE and limited by the available ground water pumping capacity. The available ground water pumping capacity is specified by (a) the pumping season, (b) the pumping development, (c) the pumping capacity, and (d) the portion of the unmet demand met by pumping.

If the available surface water supply exceeds the crop irrigation demand, the excess surface water supply is stored in the available capacity in the soil moisture reservoir. Water stored in the soil moisture is available for crop water consumption in subsequent months. If the water available for soil moisture carryover plus the beginning of month soil moisture exceeds the soil moisture reservoir capacity, then the excess supply adds to the on-farm losses.

On-farm losses are computed as the total water delivery to farm (surface water and ground water pumping) multiplied by the on-farm irrigation inefficiency (100% minus MFE) plus the portion of the delivery that exceeds the CIR and the excess soil moisture reservoir capacity. The on-farm losses are divided between surface runoff and deep percolation. Surface runoff is computed as the on-farm loss multiplied by a user-specified surface runoff percentage. Deep percolation is computed as the total on-farm loss minus the surface runoff.

Lands irrigated solely by ground water ("primary ground water lands") have been identified within or near the EBID area and are simulated in the EBID CFB Models. There currently is no simulation of primary ground water lands in the Texas and Mexico CFB Models because there is no available information on lands that may be irrigated solely by ground water in these areas.

The simulation of primary ground water lands in the EBID CFB Models is similar to the CFB Models of the areas with supplemental pumping except there is no simulation of a soil moisture reservoir. Ground water is pumped to meet the weighted irrigation water demand limited by the available pumping capacity as described above. The well development for primary ground water lands is implicit in the specified annual primary ground water acres. The primary ground water pumping is computed as the consumptive use of primary ground water pumping divided by the specified MFE. The total on-farm loss is computed as the primary ground water pumping minus the crop consumptive use. The on-farm losses are split between surface runoff and deep percolation as described above.

The annual CFB Models for the irrigation units in the Hueco Model area for 1903 - 1937 employ the same logic as the monthly CFB Models except they use an annual time-step.

Descriptions of the input data that were used in preparing the monthly CFB Models for the 1938 - 2017 study period are provided below. The input data for the annual CFB Models for the Hueco Model area from 1903 - 1937 are described in **Appendix 6A**.

6.4 CFB Model Inputs

The following is a list of the input data and input parameters that are required for the monthly CFB Models:

- Monthly surface water diversions (AF)
- Irrigated area (acres)
    - Lands that receive both surface water and ground water ("supplemental acres")
    - Lands that receive only ground water ("primary acres")
- Monthly crop irrigation requirement (feet)
- Excess effective precipitation (feet)
- Farm headgate deliveries (AF)
- Conveyance loss, wasteway flows, and carriage water percentages (% of diversions)
- Maximum farm irrigation efficiency (percent)
- Surface runoff percent (% of total on-farm loss)

- Available soil moisture reservoir capacity within the crop root zone of the irrigated crops (feet)
- Supplemental ground water pumping capacity (pumping coverage %, maximum pumping rate, % unmet demand met by pumping, pumping season)
- Primary ground water pumping capacity (maximum pumping rate [gpm], % unmet demand met by pumping, pumping season)

Detailed descriptions of the input data and parameters used in the monthly CFB Models are provided below.

6.4.1 Surface Water Supplies

Monthly surface water diversions for the CFB Models were obtained from the SWDataSet described in Section 3. The following table summarizes the surface water diversions from 1938 - 2017 simulated in each CFB Model.

Surface Water Diversions for Monthly CFB Models

Irrigation Unit	Surface Water Diversions (1938 - 2017)
Rincon	Arrey Canal (1938 - 2017) + Percha Lateral (1953 - 2017)
Leasburg	Leasburg Canal (1938 - 2017) + California Extension (1986 - 2017) + Pumped from River (1985 - 2017)
Mesilla Westside (NM)	Westside Canal (1938 - 2017); pro-rated to NM Mesilla lands and TX Mesilla lands based on irrigated area
Mesilla Westside (TX)	
Mesilla Eastside (NM)	Eastside Canal (1938 - 2017) + Del Rio Lateral (1955 - 2017); pro-rated to NM Mesilla lands and TX Mesilla lands based on irrigated area
Mesilla Eastside (TX)	
El Paso Valley	Franklin Canal (1938 - 2017) – Ascarate Wasteway (1938 - 1999) + Riverside Canal (1938 - 2017) + Bustamante WWTP outfall to Riverside Canal (1991 - 2017 in Feb - Nov) + 50% x Socorro WWTP (1967 - 1993 in Feb - Nov) + Drain Water Diverted at Fabens (1945 - 1982)
HCCRD	1938 - 4/1947: Hudspeth Canal (Tornillo End) + Tornillo Drain 5/1947 - 2017: Tornillo Canal (at Alamo Alto) + Tornillo Drain + Hudspeth Feeder Canal
JID Unit 1	2/3 x Acequia Madre (1938 - 2017)
JID Unit 2	1/3 x Acequia Madre (1938 - 2017) + 3/4 x Ciudad Juarez Sewage (1938 - 2017 in Feb - Nov) + 1/2 x River Diversions (1938 - 1984)
JID Unit 3	1/4 x Ciudad Juarez Sewage (1938 - 2017 in Feb - Nov) + 1/2 x River Diversions

There is evidence of reuse of drain water for irrigation in El Paso Valley, HCCRD, and JID (IBWC, 1989; USBR, 1992; NMSU, 2004). There are some limited records of these drain returns to canals in the El Paso Valley from 1945 - 1982 and these are used in the CFB Model for that area (Reclamation, 1992 and NMSU, 2004). There are no records of drain flow use in HCCRD and JID and no drain flow use is simulated for these areas in the CFB Models.

Monthly diversions records for the primary surface water sources used in the Rincon, Leasburg, and Mesilla units are complete for the 1938 - 2017 study period. The diversion data for several small diversion facilities that were developed after 1938 (Percha Lateral, California Extension, Del Rio Lateral, and Pumped from River) are also complete.

Monthly diversion records for the surface water sources used in the El Paso Valley, HCCRD, and JID units are largely complete for the 1938 - 2017 period, but include some estimates as described in Section 3. Additional details regarding the irrigation water supplies for the El Paso Valley, HCCRD, and JID are provided below.

El Paso Valley Surface Water Supplies

A simplified schematic diagram of the El Paso Valley diversion works is shown in **Figure 6-3**. There are two main canals, Franklin Canal and Riverside Canal, that supply the El Paso Valley. All water for the El Paso Valley is diverted at American Dam into the American Canal that conveys water to the Franklin Canal heading. Water is diverted from the American Canal upstream of the Franklin Canal heading to supply EPW's Robertson/Umbenhauer Water Treatment Plant ("WTP"), and a portion of American Canal flow can be wasted back to the Rio Grande through the Leon Street Wasteway. Until 1999, water was returned from the Franklin Canal to the Rio Grande through the Ascarate Wasteway. The discharges from the Leon Street and Ascarate Wasteways were conveyed down the Rio Grande for diversion at Riverside Dam into the Riverside Canal.

The Riverside Dam failed in the late 1980s and a coffer dam was used to continue diverting water into the Riverside Canal until the completion of the ACE in 1999. The ACE extended the American Canal south past the Franklin Canal heading to the Riverside Canal heading. EPW diverts from the Riverside Canal to supply the Jonathan Rogers WTP that was constructed in 1993. The measuring structure of the Riverside Canal is reportedly located downstream of the intake for Jonathan Rogers WTP.

EPW currently has two WWTPs in the El Paso Valley - the Haskell WWTP constructed in 1923 and the Bustamante WWTP constructed in 1991. Prior to the completion of the ACE, the Haskell WWTP discharged to the river upstream of Riverside Dam. Since 1999, the Haskell WWTP has discharged either to the river or to the ACE. Haskell WWTP discharges are included in the measured diversions for the Riverside Canal. The Bustamante WWTP typically discharges into the Riverside Canal downstream of the Riverside Canal heading, and while these discharges are not included in the measured Riverside Canal diversions, they are available for irrigation use by EPCWID farmers. The Bustamante WWTP can also discharge to the Rio Grande or to the Rio Bosque Wetlands Park through the Riverside Drain.

Prior to construction of the Bustamante WWTP, the Socorro WWTP treated wastewater in the area, and reportedly discharged to the Socorro Ponds and canals located downstream of the Bustamante WWTP. There are limited discharge records for the Socorro WWTP and most of the monthly discharges were estimated as described in Section 3. While there is little information available regarding the Socorro WWTP operations, it appears that water was discharged to the ponds and canals in the vicinity, but the outfall locations and portion of discharges to the canals is unknown. Given the absence of information, it was assumed 50% of the Socorro WWTP discharges were discharged to canals and available for irrigation of EPCWID farms in the El Paso Valley. Simulated irrigation use of WWTP discharges in the EPCWID was limited to the months of February - November.

HCCRD Surface Water Supplies

HCCRD primarily receives its water as waste and return flows from EPCWID at the El Paso-Hudspeth County Line. The HCCRD diversion works are shown in **Figure 6-4**. From 1938 to April 1947, water was conveyed to HCCRD through the Hudspeth Canal (Tornillo End) and the Tornillo Drain. In May 1947, the Hudspeth County Regulating Reservoir No. 1 was completed at the El Paso-Hudspeth County Line, and the HCCRD inflow system was reconfigured and thereafter, the surface water supply available to HCCRD is represented by the measured flows in the Tornillo Canal at Alamo Alto, the Hudspeth Feeder Canal, and the Tornillo Drain.

JID Surface Water Supplies

The surface water supplies used in the JID vary among the three JID irrigation units (Units 1, 2 and 3). The following is a summary of how the reported and estimated JID surface water supplies were distributed among the three JID units:

JID Surface Water Supplies (% Source)

Source	Unit 1	Unit 2	Unit 3
Acequia Madre	67%	33%	0%
Sewage/WWTP Flow	0%	75%	25%
River Diversions	0%	50%	50%

Unit 1 is allocated two-thirds of the Acequia Madre diversion and Unit 2 is allocated the remaining one-third (IBWC, 1989). Based on location, the Juarez sewage/WWTP discharges are available to Units 2 and 3, and it was assumed that the Unit 2 receives 75% and Unit 3 receives the remaining 25%. There are two diversions from the Rio Grande downstream of the Acequia Madre heading at the International Dam. One is located near the El Paso-Hudspeth County Line and can supply water to Unit 2 and the other is located near the Alamo Arroyo in Hudspeth County and can supply water to Unit 3. The total river diversions were assumed split equally between Unit 2 and Unit 3.

The diversion records of Acequia Madre are mostly complete during the 1938-2017 study period, and missing records were estimated as described in Section 3. The estimates of JID river diversions downstream of the Acequia Madre, and Juarez sewage/WWTP discharges described in Section 3 were used.

6.4.2 Irrigated Area

The CFB Models require input of annual values for the irrigated area that receives surface water and supplemental ground water (supplemental acres), and the irrigated area that receives only ground water (primary acres).

The annual irrigated areas values used in the monthly CFB Models for 1938 - 2017 were provided by David's Engineering ("DE") for each irrigation unit, with the exception of the Mexico irrigated area from 1938 - 1949 which are from Carreno (1957). The following is a summary of the irrigated area data from 1938 - 2017.

Irrigated Area Data for CFB Models

District	**Supplemental Acres 1938 - 2017**	**Primary Acres 1938 - 2017**
EBID	1938 - 1975: Reclamation reports 1976 - 2017: Intera Normalized Difference Vegetation Index ("NDVI") analysis	New Mexico Hydrographic Survey
EPCWID		There are no data on primary ground water acres in EPCWID, HCCRD, and JID and therefore the primary ground water acres were set to zero.
HCCRD	1938 - 1975: Reclamation reports and Intera NDVI analysis 1976 - 2017: Intera NDVI analysis	
JID	1938 - 1949: Carreno (1957) 1950 - 1975: IBWC (1989) 1976 - 2017: Intera NDVI analysis	

6.4.3 Crop Irrigation Requirements

The CFB Models require the monthly crop-weighted CIR in feet (AF/ac) for each irrigation unit (including during the winter months). The CIR is the total crop evapotranspiration less effective precipitation. Monthly crop-weighted CIR values for each irrigation unit were developed by DE (2019). Separate CIR values were provided for the primary ground water lands in the EBID irrigation units based on determination that these areas had slightly different cropping patterns than the lands with surface water and supplemental ground water.

The crop-weighted CIR values provided by DE were adjusted downward in the CFB Models from 1938 - 1970 at the direction of DE. The crop weighted CIR values were reduced by 5% from 1938 - 1953, followed by a linear reduction in the adjustment each year until it reached 0% in 1970.

6.4.4 Excess Effective Precipitation

Excess effective precipitation is the monthly effective precipitation in excess of the monthly crop evapotranspiration that is available for storage in the soil moisture reservoir. The monthly excess effective precipitation was computed by DE for each irrigation unit as the effective precipitation minus surface runoff minus CIR (DE, 2019). The monthly excess effective precipitation was added to the soil moisture reservoir in the CFB Models.

6.4.5 Farm Headgate Deliveries

Monthly records of FHG deliveries are published by Reclamation in the WDRs. These records were disaggregated as necessary to the irrigation units simulated in the CFB Models as described in Section 4.2. There were limited adjustments made to the reported FHG deliveries when the reported values were greater than the reported RHG diversions or when the reported canal loss was negative. For example, in 2010 there are several months that the reported El Paso Valley RHG diversion is less than the reported El Paso Valley FHG deliveries. In months such as these, the FHG delivery was computed as the minimum of the reported FHG delivery or the RHG diversion minus the estimated canal loss, and the waste was set to zero.

When FHG delivery records were not available, they were estimated as the monthly surface water diversions minus the reported or estimated monthly canal loss, waste, and carriage water. Descriptions of the methods used to make these estimates are provided in the following section. Annual summaries of the reported and estimated FHG deliveries that were used in the CFB Models are provided in **Table 6-2**.

6.4.6 Canal Loss, Operational Waste, and Carriage Water

The CFB Models simulate the losses and bypasses (carriage deliveries) that historically occurred in delivering water from the canal headings to the farms. There are records of monthly conveyances losses and carriage deliveries published by Reclamation in the WDRs for EBID and EPCWID. The following is a summary of the different types of losses and carriage water that are contained in the WDRs.

- Canal Loss – Canal diversions lost to seepage and incidental consumptive use.
- Waste / Operational Spills – Canal diversions returned to the river via wasteways.
- El Paso Valley Carriage – Canal diversions conveyed to El Paso Valley in the EBID canals instead of the river to reduce transit losses.
- To Eastside Canal – Leasburg Canal diversions delivered to Eastside Canal.

Monthly average canal loss and waste percentages were computed from the 1951 - 1978 WDR records for EBID and EPCWID from as a percentage of the monthly canal heading diversions for the months of March - October. Seasonal average loss percentages were computed for the winter months (November - February). These monthly and seasonal percentages were used to compute the canal loss and waste when records were not available. While there reportedly has been some canal lining in EPCWID during recent decades, there were no adjustments made to the percentages for estimated canal loss in recent years.

There are no records of El Paso Valley Carriage after 1978, and it was assumed there was no El Paso Valley carriage thereafter.

There are no records of Leasburg diversions delivered to the Eastside Canal after 1978, however it was assumed these operations continued and the To Eastside Canal flow was estimated as 1.5% of the total Leasburg diversion.

The canal loss for HCCRD was based on reported values when available and estimated as 50% of diversions when records were not available based on the historical data. There are no records of waste for HCCRD and it was assumed to be zero.

There are no data for the JID waste and canal loss, and the waste was assumed to be zero. JID canal losses were estimated as 40% of diversions before canal lining that reportedly began in 1970. This is based on the approximate average of conveyance losses in the El Paso Valley.

Based on reports regarding JID operations obtained and translated by MMA, significant canal lining occurred in the JID between about 1970 and 1987. MMA provided information on lengths and widths of the primary and secondary JID canals that were lined between 1970 and 1987. Assuming that fully unlined canals would lose 40% of diversions and fully lined canals would lose 5% of diversions, weighted average annual conveyance losses were estimated based on the proportion of the total canal area in each unit that was lined. The resulting adjusted canal losses ranged from 40% in 1970 to 33% for Unit 1, 20% for Unit 2, and 21% for Unit 3 in 1987.

6.4.7 Incidental Canal Loss and Canal Seepage

The incidental canal loss is the portion of the total canal loss that is lost to evaporation and evapotranspiration from vegetation along the canals. The incidental canal loss was computed as 6% of the total reported or estimated canal loss (LRGGWMCC, 2005). The canal seepage is computed as the total canal loss minus the incidental canal loss.

6.4.8 Maximum Farm Irrigation Efficiency

The CFB Models require input of an MFE that limits the percentage of the farm water supply (FHG deliveries surface water plus ground water pumping) that is available for crop consumptive use. The MFE functions as an upper limit on the portion of the applied water that is either consumed within the current time-step or stored in the soil moisture reservoir for later use.

The MFE values used in the CFB Models were provided by DE and were developed based on the estimated achievable unit-wide average efficiencies that would occur under water short conditions given the soil types, field configurations and slopes, irrigation practices, and assuming a reasonably high level of management. The MFE values provided by DE started at 65% for 1938-1950 and transitioned upward to 75% for 1984-2017. The same time varying MFE values were used for all CFB Models.

6.4.9 On-Farm Surface Runoff

The simulated on-farm losses were split between deep percolation and surface runoff.

DE provided annual surface runoff percentages that decrease through time due to improved irrigation and water management practices, laser land leveling, and increased use of border irrigation. The surface runoff percentages provided by DE varied from approximately 6% of the on-farm loss for 1938-1950 to approximately 1% of the on-farm loss for 1984-2017. The same time-varying surface runoff percentages were used in all CFB Models.

6.4.10 Soil Moisture Reservoir

The CFB Models simulate a soil moisture reservoir that can be used to store excess irrigation water in the current month for carryover and use in subsequent month(s). The simulated soil moisture reservoir is limited to the soil moisture reservoir capacity within the crop root zone. The following equation was used to compute the capacity of the soil moisture reservoir

SM Cap = AWC x Root Depth x MAD% x Irr Area

where

SM Cap =	Soil Moisture Reservoir Capacity in (AF)
AWC =	Weighted available soil moisture holding capacity of the soils (field capacity minus wilting point) in inches/foot of soil depth. (feet/feet)
Root Depth =	Crop weighted average maximum rooting depth (feet)
MAD%=	Crop-weighted MAD that defines the portion of the AWC in which irrigated fields are maintained to avoid significant moisture stress to the crop (%)
Irr Area =	Irrigated area (acres)

All of the soil moisture reservoir input parameters were provided by DE. A value of 1.74 inches per foot was specified as the AWC for all irrigation units. Separate crop weighted average Root Depth and MAD values were provided for EBID, EPCWID, HCCRD, and JID.

6.4.11 Supplemental Pumping

Supplemental ground water pumping was computed in the CFB Model based on all or a specified percentage of the unmet crop demand on the supplemental acres after consideration of the available surface water supplies as follows:

SupplCU = min (UnmetCIR x %SupplCIR, SupplMax x %PumpDevelop) x Pump Season Flag

where

SupplCU =	CU of supplemental ground water (AF)
UnmetCIR =	Unmet CIR after surface water supplies (AF)
%SupplCIR =	% of unmet CIR met by pumping (%)
%PumpDevelop =	% irrigated area with wells (%)
SupplMax =	Maximum monthly supplemental pumping rate (AF/month)
PumpFlag =	Start and end month flag for pumping

The UnmetCIR is computed as the total CIR minus the CIR met from surface water deliveries in the current month and the available soil moisture carryover from prior the month.

The %SupplCIR provides the ability to limit pumping to less than the amount needed to meet the full unmet demand, after applying the surface water supply. The % Suppl CIR is currently assumed to be 100%

The %PumpDevelop describes the portion of the study area served by wells. Well development proceeded rapidly during the early 1950s into the mid-1950s in response to the multi-year drought that resulted in the first significant water shortages in the history of the Project. The specified pumping development is based on a well development timeline developed by Dr. Barroll (NMOSE 2015) for New Mexico and Texas. MMA provided information on well development in JID. For all units except JID Unit 1, the %PumpDevelop is specified to increase linearly from 0% in 1947 to 100% in 1955. For JID Unit 1, the %PumpDevelop is specified to increase linearly from 0% in 1939 to 100% 1954.

The SupplMax is the upper limit on the maximum available well pumping capacity in AF/month that would limit pumping in peak demand months. There were no SupplMax limits imposed in the CFB Models.

The PumpFlag specifies the months in which pumping is allowed to occur to meet unmet irrigation demands. The pumping season in all CFB Models was set as February - November.

6.4.12 Primary Pumping

Primary ground pumping occurs on irrigated lands that have no access to surface water. The irrigated area data for the primary ground water lands are available for New Mexico based on Hydrographic Survey information, and these data were provided by DE and used in the CFB Models of irrigation units in New Mexico.

There are placeholders for primary ground water acres in the Texas and Mexico CFB Models, but no information is presently available to specify the primary ground water acres in these areas.

The primary ground water pumping is computed in the CFB Models based on the crop irrigation demand on the primary acres as follows:

PrimaryCU = min (PrimaryCIR x %PrimaryCIR, PrimMax)

where

PrimaryCU = CU of primary ground water (AF)

PrimaryCIR =CIR on primary acres (AF)

%PrimaryCIR = % of CIR that can be met by pumping

PrimMax = Maximum monthly primary pumping rate (AF/month)

The PrimaryCIR is the weighted average CIR for the crops grown on the lands irrigated solely by ground water. DE developed different cropping patterns from the primary acres compared to the supplemental acres, and therefore the weight average CIR is different between the primary and supplemental lands. There is no soil moisture simulated on the primary acres because it is assumed that pumping occurs to meet the crop CIR and not to carryover additional water in the soil moisture reservoir for later use.

The %PrimaryCIR can be specified to limit the percent of demand met by pumping on primary ground water lands. This input parameter is set at 100% in the current CFB Models.

The PrimMax parameter can be set to limit primary ground water pumping based on the available pumping capacity of the well. There is no upper limit on the well pumping capacity specified in CFB Models.

There is no pumping development percentage for the primary ground water acres like there is for the supplemental ground water pumping. It is assumed sufficient pumping capacity exists to irrigate the specified primary ground water acres.

6.5 Simulation of Historical Irrigation Operations

6.5.1 EBID CFB Models

There are four EBID CFB Models, including the Rincon, Leasburg, Mesilla East (EBID), and Mesilla West (EBID). The Rincon CFB Model simulates all lands irrigated in the Rincon basin. The Leasburg CFB Model simulates lands irrigated in the northern portion of the Mesilla basin from the Leasburg Canal. A portion of the Leasburg Canal diversions are conveyed to the Mesilla East CFB Model. Mesilla East (EBID) Model simulates lands in the southern portion of the Mesilla basin under the Eastside Canal, and the Mesilla West (EBID) Model simulates lands under the Eastside Canal. The surface water supplies for the Eastside Canal and Westside Canal are distributed between EBID and EPCWID proportionally based on irrigated acreage. The boundaries of the CFB Models for EBID are illustrated in **Figure 6-1**.

6.5.2 EPCWID CFB Models

There are three EPCWID CFB Models, including Mesilla East (EPCWID), Mesilla West (EPCWID), and El Paso Valley. As described above, the surface water supplies for the Eastside Canal and Westside Canal are distributed proportionally between EBID and EPCWID based on irrigated area. The lands in the El Paso Valley Model consist of all areas served by the Franklin, Riverside, and Tornillo Canals simulated as a single unit. This is reasonable because the Project is reported operated to make available water on an equal per acre basis. The boundaries of the CFB Models for EPCWID are shown in **Figures 6-1.**

6.5.3 HCCRD CFB Models

There is little information available on the historical operation of HCCRD, and the area is simulated with a single CFB Model assuming that the HCCRD operates to equalize the supply made available to all district lands. The boundaries of the HCCRD CFB Model are shown in **Figure 6-1.**

Based on review of aerial photographs, it was determined that HCCRD Regulating Reservoir No. 1 and HCCRD Regulating Reservoir No. 2 (aka Clayton Reservoir) were constructed in 1947, and HCCRD Regulating Reservoir No. 3 (aka McKinney Reservoir) was constructed in 1996. The HCCRD CFB Model includes the capability to simulate the operation of the three HCCRD reservoirs as a single reservoir to regulate the sometimes erratic HCCRD supply.

There is little data on the HCCRD reservoirs and operations. The composite reservoir capacity was set at 2,600 AF (estimated capacity for HCCRD Reservoir Nos. 1 and 2) until

1995 and was increased by 1,000 AF (estimated capacity for HCCRD Reservoir No. 3) to 3,600 AF in 1996. Reservoir evaporation is computed in the HCCRD CFB Model as the net monthly evaporation provided by DE multiplied by the surface area of the reservoirs. The surface area was assumed to be 257 acres from 1947 - 1955 and 541 acres from 1996 - 2019 based on delineation of the reservoir surface areas from aerial photos. The simulated operation of the HCCRD reservoirs was disabled in the runs of the CFB Model that are provided with this report. This was determined to have less than 5% impact on the simulated historical HCCRD pumping.

6.5.4 JID CFB Models

The surface water supplies and other information for the JID CFB Models are based on limited information that is available for the JID operation. There are three CFB Models for JID that simulate the operations in JID Units 1, 2, and 3. The boundaries of the JID CFB Models are shown in **Figure 6-1**.

The JID surface water supplies were distributed to the JID irrigation units as described above in Section 6.5.1. It is assumed that all JID irrigation units supplement the available surface supplies with ground water pumping. It is suspected based on review of aerial images that drain water is used for irrigation in Unit 2 and Unit 3, but such use is not simulated in the CFB Models, except to the extent that the drain flows are present in the simulated River Diversions.

6.6 Results

The Excel spreadsheet for the CFB Models contains numerous tables and charts to present monthly and annual results. District-wide summaries of the CFB Model results are provided in **Appendix 6B** and include the following tables and charts:

- Monthly charts of on-farm CU (1938 - 2017),
- Annual charts of farm deliveries, CU, losses, irrigated acres, and loss and efficiency percentages (1938 - 2017),
- Annual and average monthly charts of pumping and deep percolation (1938 - 2017),
- Average monthly tables of the inflows, outflows, and changes in storage (1938 - 2017), and
- Annual tables of the inflows, outflows, and changes in storage (1938 - 2017).

Annual tables and charts summarizing the simulated 1903 - 1937 results for the annual CFB Models developed to provide inputs to the Hueco Model are also available in the CFB Model spreadsheet.

Among the results provided in the CFB Model spreadsheet are the computed supplemental pumping and primary pumping (EBID only) volumes. Records of annual ground water pumping are available for EBID from 2009 - 2017. Comparisons of computed vs. actual annual ground water pumping for the EBID CFB Models are shown in **Figure 6-5**. In general, there is good agreement between the computed and actual pumping from 2009 - 2017.

The results from the CFB Models are referenced in Section 12 in the responses to the M&A expert report.

7.0 NEED FOR MODELING ANALYSIS OF CLAIMS AND COUNTERCLAIMS

The Rio Grande between Elephant Butte Reservoir and Fort Quitman is a highly developed working river system that is the life blood to the region in sustaining local economies and natural ecosystems. The historical time-series data in Section 5 show there have been changes and/or fluctuations in Rio Grande flows and Project diversions and deliveries prior to and since the Rio Compact was entered in 1938. The Rio Grande flow and water supply available for use is affected by numerous natural and man-caused factors including the following:

- Precipitation runoff,
- Water surface evaporation,
- Evapotranspiration of native vegetation,
- Project operations,
- Irrigation operations,
- Municipal water supply operations,
- Ground water pumping, and
- Surface and ground water interaction.

The claims and counterclaims filed in the pending lawsuit assert that certain actions such as pumping and changes in Project operating procedures have impacted Rio Grande flows and deliveries of Project water. Due to the complex interactions between the above factors and surface and ground water flows, it is not possible to reliably quantify and differentiate the effect of a certain action (e.g., pumping) on a certain outcome (e.g. changes in El Paso flow) using historical data alone. The mere presence of a correlation between two quantities does not mean there is a cause-and-effect relationship between them. The correlation may be spurious, or there may be multiple factors causing a change in some quantity.

Texas has claimed that changes in the Rio Grande flow at El Paso are due to the development of upstream ground water pumping. The double-mass curve analysis presented in the Texas expert report by Robert J. Brandes is based on an alleged cause and effect relationship evidenced by a correlation.

While pumping has certainly impacted Rio Grande flows, there are likely other factors that have contributed to the changes in flow including the following:

- Reduction in inflows to Project storage,
- Changes in irrigated area and crop selection,
- Changes in irrigation practices,
- Increases in downstream pumping, and
- Changes in Project operations.

While changes in the flow of the Rio Grande at El Paso may be of historical interest, flow changes at any single river gage are irrelevant to this case, to the Compact, and to the operation of the Project. Of more relevance are changes in the deliveries of Project water for beneficial use.

For complex water systems like the Lower Rio Grande, it is necessary to develop simulation model(s) to better understand and quantify the interrelationships among natural and man-influenced processes, and to isolate and compute the effects of actions relevant to the claims and counterclaims in this case. The reliability of predictions from a simulation model is enhanced if (a) the model is reasonably calibrated over a representative historical period, and (b) the simulated processes reflect reasonable and appropriate dynamic responses to simulated changes to historical conditions.

The modeling requirements in this case are more complex than in a typical ground water modeling project that might, for example, involve determining the amount, timing, and location of impacts on ground water levels and surface water flows resulting from ground water pumping. In typical ground water pumping evaluations, the objective in constructing the model is to reasonably simulate the relevant physical process so that the model produces reasonable estimates of stream depletions and changes in ground water levels given the simulated pumping volumes. Model calibration in this instance would be focused on adjusting aquifer characteristics, boundary conditions, and other physical parameters so that the simulated historical conditions (e.g., water levels and streamflows) reasonably match historical values.

The Lower Rio Grande system is more complicated because of the need to simulate the operations of the Project and the LRG irrigation systems. The Project facilities and irrigation systems are operated and managed to respond to changes in the available water supply, and this introduces a human element that needs to be incorporated in the model processes. Not only do the physical processes need to reasonably respond to changes in inflows and modeled stresses, but so do the Project operations. For example, simulating a reduction in pumping within the Project area would be expected to cause the following responses:

- Reduced on-farm consumptive use, deep percolation, and surface runoff from pumping.
- Increased ground water levels and drain flows.
- Increased riparian evapotranspiration due to shallower ground water levels.
- Increased ground water flow to the Rio Grande and/or reduced Rio Grande flows to the ground water system.
- The above responses would generally increase Rio Grande flows which in turn would affect Project operations depending on the Project supply at the time.
  - During full supply periods, the increased river flows would prompt reductions in reservoir releases to deliver the same amounts to Project water users. This in turn would accumulate additional water in storage that would be carried forward and used in subsequent non-full supply periods.
  - During non-full supply periods, the additional flow in the river and additional water carried over in reservoir storage would increase the supply available for delivery to New Mexico, Texas, and Mexico water users.
- Increased deliveries for irrigation would increase surface water consumptive use, deep percolation, and surface runoff. If pumping in only certain areas was reduced or turned off, then the changes in surface water supplies to other areas would result in corresponding changes in pumping to meet unmet demands in those areas.
- Increased reservoir storage would increase reservoir evaporation and increase reservoir spills.
- During the non-irrigation season, much of the additional river flow would exit from the downstream end of the system unconsumed.

The foregoing list of expected responses to simulated changes in pumping are the same types of responses that historically occurred when the surface water supplies and pumping varied between historical wet and dry periods.

7.1 Required Model Features

In order to fully evaluate the claims and counterclaims in this case, a robust model of the hydrologic and water use systems between San Marcial and Fort Quitman is needed. The model should generally simulate the following features:

- Inflows
- Reservoir operations

- River routing
- Irrigation operations and pumping
- Non-irrigation operations and pumping
- Non-beneficial ET
- Ground water flow
- Ground water/surface water interaction

The model features listed above should not be simulated based on fixed inputs that cannot change in alternative scenarios. A model based on fixed inputs rather than dynamic processes has little or no ability to dynamically respond to changes in the modeled stresses. For example, if reservoir releases and canal diversions are fixed at historical levels in simulation of alternative scenarios (e.g., reduced pumping), then the model has no functionality to adjust to changes in river flow, and most or all of the changes in river flow will unreasonably accumulate as changes in Rio Grande outflows from the study area.

The manner of dynamic simulation of model processes depends on whether the processes are physically-based or management-based as described below. **Table 7-1** contains a list of the required simulation processes, including whether they are physical or management processes.

7.2 Physical Processes

Physical processes move water based on physical relationships or mass balance calculations that are not dependent on human decisions or management. For example, reservoir evaporation is a physical process that depends on evaporation rates and reservoir surface area. It may be dynamically simulated in a model using a time-series input of evaporation rates and reservoir surface area computed based on the simulated reservoir storage contents and the surface area-volume relationship for the reservoir. Another example of a physical process is river seepage computed based on the simulated head difference between the river surface and the connected ground water system, and the conductance of the riverbed materials through which the seepage travels. In the foregoing examples, there obviously are human decisions that affect the reservoir contents or river flows, but the physical processes involved in evaporating water from the reservoir surface or seeping water from a river are independent of those human decisions.

Physical processes may be calibrated by adjusting input parameters in the simulation equations within reasonable bounds to match simulated values to observed values. In the calibration process, reservoir releases, diversions, and FHG deliveries are set at historical values and the model parameters are adjusted to match streamflows, drain flows, and ground water levels.

7.3 Management Processes

Project and irrigation operations involve management decisions that need to be translated into rule-based simulation processes appropriate for the spatial and temporal scales of the model. For example, rules can be developed to simulate farm headgate demands as a function of irrigated area and crop irrigation requirements. Farm headgate deliveries can then be simulated as the lesser of the demand or the available supply. Such rules allow the model simulation to dynamically adjust farm headgate deliveries in alternative scenarios in response to changes in the available water supply.

Simulation of management processes can also be adjusted to reasonably match simulated and observed values. The process of adjusting the simulated management processes is described in this report as "tuning" to distinguish it from "calibrating" the physical processes. In the tuning process, the simulation rules are adjusted to reasonably match historical reservoir operations, canal diversions, farm headgate deliveries, and other historical data.

8.0 OVERVIEW AND ASSESSMENT OF INTEGRATED LRG MODEL

8.1 Introduction

Three simulation models were developed and integrated for use in assessing certain of the claims and counterclaims in this case. These models consist of a RiverWare Model of the surface water and alluvial ground water systems from San Marcial to Ft. Quitman ("RiverWare Model"), a MODFLOW ground water model of Rincon and Mesilla Valleys located between the Caballo Reservoir outlet and the Rio Grande at El Paso gage, and another MODFLOW ground water model of the El Paso Valley and Juarez Valley located between the El Paso gage and Ft. Quitman. Together, the three models are referred to as the "Integrated LRG Model" or "ILRG Model." A map showing the spatial domains of the three models is provided **Figure 8-1**.

The RiverWare Model is the principal vehicle for computing the impacts of pumping and the effects of operational changes on the surface water system. The ground water models play a supporting role in computing certain inputs to the RiverWare Model including canal seepage, evapotranspiration of native/riparian vegetation, and flux between the shallow Rio Grande alluvial aquifer and the Upper Santa Fe Group and/or Middle Santa Fe Group.

The ILRG Model simulates irrigation and non-irrigation water uses over a study period that extends from January 1940 to December 2017 using monthly stress periods. Integration of the three models occurs through passing of certain information between the RiverWare Model and the ground water models as they are run iteratively until closure.

This section provides on overview of the three models, their suitability for assessing claims and counterclaims in this case, and development of post-processing tools for summarizing and assessing alternative model scenarios. Details regarding the development, calibration, and operation of the three models are provided in the reports of other New Mexico experts.

8.2 RiverWare Model

The RiverWare Model was developed by Hydros Consulting ("Hydros") in Boulder, Colorado. The model simulates the operations of EBID and EPCWID that comprise the Project, the HCCRD system located south of the EPCWID in Hudspeth County, and the JID system located west of Rio Grande in Mexico. A simplified schematic diagram of the flow linkages in the RiverWare Model is shown in **Figure 8-2**.

RiverWare is a full-featured customizable river system modeling package that is well-suited for modeling a river system like the Rio Grande between San Marcial and Fort Quitman. The modeling software is equipped with a rich menu of functions to simulate various flow process and can be customized to simulate other flow processes through development of scripted rule sets.

The RiverWare Model performs the following water budget calculations during each monthly stress period to simulate Project and other irrigation operations within the study area.

- Reservoir Budget,
- River Budget,
- Canal and Farm Budget, and
- Shallow Ground Water Budget.

Schematic diagrams of the RiverWare water budgets are shown in **Figure 8-3** through **Figure 8-7**.

8.2.1 Reservoir Budget

The Reservoir Budget in the RiverWare Model simulates operation of Project storage in Elephant Butte Reservoir and Caballo Reservoir. Inflows to the reservoirs consist of historical Rio Grande at San Marcial gage flows, precipitation, and unmeasured gains/losses derived from water balance analysis of historical reservoir operations data. Releases from storage are simulated to meet Project water demands, a small pre-Project diversion, and to spill water when the reservoir is full.

The simulated usable water in Project storage available for allocation is computed each month from February through July as the usable water in storage plus the reservoir releases to date. The usable Project supply is allocated to EBID, EPCWID, and Mexico in the Historical Base Run using three sets of allocation rules. D1/D2 Rules are used to simulate historical operations from 1948 - 2005. While the D1/D2 Rules did not actually go into operation until 1980, they were judged to reasonably simulate the equal allocation per acre procedure that functioned before that time. The D3+Carryover Rules from the 2008 OA are used to simulate allocation of Project water from 2008 - 2017. The D3 Rules without carryover accounting are used in 2006 and 2007.

During the wet period from 1940 - 1947 when Reclamation did not set any annual Project water allotments, historical records show that the Project water users generally called for and were delivered whatever water they needed and sometimes more. Therefore, the

RiverWare rules during the 1940 - 1947 period were developed to generally match historical operations without the restriction of an annual allocation.

Storage releases to Mexico are made on a set monthly schedule for delivery to the International Dam and diversion into the Acequia Madre. Storage releases to EBID and EPCWID are made based on rules that deliver water to meet the demands of EBID and the combined irrigation and EPW demand of EPCWID, as limited by the computed annual allocations. Water available to HCCRD is comprised of simulated waste and return flows from EPCWID.

8.2.2 River Budget

The River Budget in the RiverWare Model simulates the routing of flows down the Rio Grande. Inflows consist of reservoir releases, drain and wasteway flows, wastewater treatment plant discharges, and on-farm surface runoff. Outflows include canal diversions, river evaporation, and flow past Ft. Quitman. Seepage between the river and alluvial aquifer is computed based on the difference in head between the river water surface and the simulated ground water level and is calibrated using specified riverbed conductance values.

8.2.3 Farm Budget

Irrigation operations within EBID, EPCWID, HCCRD, and JID are simulated in RiverWare Model using a farm budget simulation algorithm similar to one used in the CFB Models described in Section 6. The farm budget calculations in the RiverWare Model are performed using monthly stress periods for the following geographic areas.

Geographic Units for RiverWare Model Farm Budget Calculations[4]

EBID	EPCWID	HCCRD	JID
Rincon	Mesilla Eastside	Unit 1	Unit 1
Leasburg	Mesilla Westside	Unit 2	Unit 2
Mesilla Eastside	El Paso Valley	Unit 3	Unit 3
Mesilla Westside			

[4] Calculations for the above geographic units are disaggregated to a sub-area level in Riverware to spatially distribute the pumping, and irrigation return flows along the Rio Grande.

Simulated deliveries to the various major canal headings on the Rio Grande are conveyed to farms after being reduced by wasteway discharges back to the river and by canal and lateral conveyance losses. The conveyance loss includes a seepage component computed by the ground water models. The total conveyance loss is computed in the RiverWare Model as the seepage loss from the ground water models divided by 0.94 reflecting an assumed incidental consumptive conveyance loss of 6%.

The monthly crop water demands for each unit are computed as the irrigated area multiplied by the crop-weighted average CIR. The CIR for each crop is computed outside of the RiverWare Model as the potential evapotranspiration ("PET") less the effective precipitation.

The water supply available to meet the crop water demand is computed in the RiverWare Model as the farm headgate delivery multiplied by a specified MFE that increases through time. Available supply in excess of the crop demand may be stored in the root zone of the crop for subsequent use. Until 1948, if the simulated monthly available water supply, including the soil moisture carryover from the prior month, was insufficient to meet the crop water demand, then a shortage was computed. Significant use of ground water for irrigation commenced in 1948 and was fully implemented by 1955, and shortages in crop water demand were assumed alleviated in part by ground water pumping beginning in 1948 and in full by 1955 and beyond.

On-farm losses and excess farm deliveries become surface runoff to the Rio Grande and deep percolation to the alluvial aquifer. Additional irrigation return flows include wasteway discharges to drains or to the river and canal seepage accruals to the alluvial aquifer.

8.2.4 Ground Water Budget

The RiverWare Model includes a ground water object under each water user object that functions like a large cell in a MODFLOW ground water model. Inflows to the ground water object include canal seepage computed in the ground water models, flow between the alluvial aquifer and other aquifers in the ground water model (inflows or outflows to the ground water object), and on-farm deep percolation losses computed in the Farm Budget. Outflows from the ground water object include alluvial ground water pumping and riparian ET computed in the ground water models. Other inflows/outflows are computed based on head differences between the ground water object and surrounding objects including river seepage, drain flows, and lateral flows to other ground water objects.

8.3 New Mexico Rincon-Mesilla Ground Water Model

The New Mexico Rincon-Mesilla Ground Water Model ("NMR-M Model") was developed by SSPA using the USGS MODFLOW software to simulate ground water use in the Rincon Valley and Mesilla Valley between the Caballo Reservoir outlet and the Rio Grande at El Paso. The modelled area includes all of the EBID service area in New Mexico and the Mesilla Valley portion of the EPCWID service area in Texas. The model simulates ground water flow in the Rio Grande alluvium and the deeper and more laterally extensive aquifers of the Upper, Middle, and Lower Santa Fe Groups. Lying over the upper model layers is a surface flow network constructed using the MODFLOW SFR Package that simulates head dependent interaction between the ground water system and the Rio Grande and the Project canals, laterals, and drains. Most of the irrigation pumping is simulated in the alluvial aquifer and most of the non-irrigation pumping is simulated in the aquifers of the Santa Fe Group.

Water budget diagrams illustrating the simulation processes of the NMR-M Model are shown in **Figure 8-8**. Specified time-series inputs to the NMR-M Model are pumping from non-alluvial wells and mountain front recharge. Other inputs to the NMR-M Model are passed from the RiverWare Model and consist of reservoir releases, canal diversions, farm headgate deliveries, wasteway flows, deep percolation, and pumping from the alluvial aquifer for irrigation. Data passed from NMR-M Model to the RiverWare Model include canal seepage, riparian ET, non-irrigation pumping from the alluvial aquifer, flow between alluvial aquifer and Santa Fe Group.

Simulated monthly farm headgate deliveries are removed from NMR-M Model and the corresponding deep percolation and surface runoff from the RiverWare Model are added to the NMR-M Model. The difference between the removed farm headgate deliveries and the added irrigation return flows represents the on-farm consumptive use of applied water in the RiverWare Model.

8.4 Hueco Ground Water Model

The Hueco Model was developed by MMA using USGS MODFLOW software to simulate ground water use in the alluvial aquifer and the Santa Fe Group aquifers of the Hueco Bolson that underlie the El Paso Valley from the Rio Grande at El Paso gage to near Ft. Quitman. The modeled area includes a large portion of El Paso County in Texas including the City of El Paso, Hudspeth County, and the Juarez Valley, including Ciudad Juarez.

The model simulates Irrigation and ground water pumping of EPCWID in the El Paso Valley, the HCRRD, and the JID. Non-irrigation pumping is simulated for EPW, which serves the City of El Paso, other significant M&I water users in the El Paso area, and the water and sanitation utility for Ciudad Juarez, Junta Municipal de Aqua y Saneamiento ("JMAS"). Like the NMR-M Model, surface water features and their interaction with the underlying ground water system are simulating using the MODFLOW SFR Package.

The ground water model water budget diagrams in **Figure 8-8** also apply to the Hueco Model. Specified inflows and information passed between the RiverWare Model and the Hueco Model are the same as for the NMR-M Model.

8.5 Integration of LRG Models

A manual iteration procedure is used to execute runs of the ILRG Model, and a diagram illustrating the procedure is shown in **Figure 8-9**. The major simulation processes are shown on the right side of the diagram in blue for the RiverWare Model and the left side in brown for the ground water models. Information passed between the models is listed in the center with the information passed from the RiverWare Model to the ground water models shown in blue and the information passed from the RiverWare Model to the ground water models shown in brown.

An illustration of the model execution process is provided at the bottom of **Figure 8-9**. The procedure for making an iterated model run starts by running the RiverWare Model with an initial time-series of input data from the ground water model from a prior run. After running the RiverWare Model, the required RiverWare Model outputs are passed to the two ground water models and they are both run. Required outputs from the ground water model are then passed to the RiverWare Model and it is executed again. This iterative process is repeated until the differences in the simulated flows from one iteration to the next is relatively small. Closure typically occurs within several iterations.

8.6 Calibration of LRG Models

As described previously, calibration of the LRG Models is specific to adjustment of the simulation of the physical processes in the model. The models were calibrated by simulating the historical study period using historical data for the following model inputs:

- Reservoir releases,
- River diversions,
- Farm headgate deliveries,
- EPW deliveries,
- Non-irrigation pumping, and
- Non-irrigation return flows.

Selected model input parameters were varied during the calibration process to improve matching of the following simulated outputs to the historical observed values:

- River flows,
- Drain flows,
- Ground water levels in the alluvial aquifer, and
- Ground water levels in the Santa Fe Group (ground water models).

A diagram illustrating the calibration process for the RiverWare Model is shown in **Figure 8-10**. The fixed historical time series inputs are shown in black, the values computed in the RiverWare Model are shown in blue, the values computed in the ground water models and passed to the RiverWare Model are shown in green, and the calibration targets are shown in red.

Summaries of the RiverWare Model calibration results for the Rio Grande at El Paso and the Rio Grande at Ft. Quitman are provided in **Figure 8-11** and **Figure 8-12**, respectively. Each figure contains three charts and several calibration statistics at the bottom of the page.

El Paso Gage

The measured and modeled monthly flows for the Rio Grande at El Paso gage are plotted in the upper graph in **Figure 8-11**. All model error[5] or imperfections in simulating consumptive use, return flows, well pumping depletions, drain flows, and other processes upstream of the El Paso gage accumulate as differences between the modeled and measured flows at the gage. Visual comparison of the two lines in the upper chart indicates generally excellent agreement between the modeled and measured streamflows. The other charts in **Figure 8-11** compare the modeled and measured annual flows (lower left) and the modeled vs. measured flows in a scatter plot (lower right). The mean monthly flow during the calibration run was 31,698 AF compared to a mean measured flow of 31,191 AF. The mean residual or mean error is +506 AF or approximately +1.6% of the measured mean monthly flow. Depictions of modeled and measured flows at El Paso gage were evaluated for model calibration purposes only, and contrary to Texas's position in this case, the El Paso gage is not a Compact delivery point.

Ft. Quitman Gage

The measured and modeled flows at the Rio Grande at Ft. Quitman gage at the downstream end of the ILRG Model are plotted in **Figure 8-12**. Comparison of the measured and modeled flows in the upper chart shows the model performs well in matching the trends and fluctuations in flows, but also shows accumulation of some additional model error in simulating conditions downstream of the El Paso gage in the El Paso Valley and Juarez Valley. This is due in part to the general lack of data regarding water use and water distribution in these areas. The mean monthly modeled flow during the calibration run was 11,030 AF compared to a mean measured flow of 10,345 AF. The mean residual or mean error is +685 AF or approximately +6.6% of the measured mean monthly flow.

8.7 Tuning of LRG Models

After calibrating the physical processes in the RiverWare Model, the historical time series data for reservoir releases, diversions, and farm headgate deliveries were replaced with rules to simulate major management processes of the Project operations and water uses. Tuning of the RiverWare Model refers to adjustment of the rules for these management processes to reasonably match historical operations, specifically the following:

---

[5] In modeling parlance, "error" refers to differences between simulated values and observed values. It does not mean or imply a mistake in the model.

- Allocations,
- Reservoir releases,
- River diversions,
- Wasteway flows,
- Farm headgate deliveries, and
- River flows.

A diagram illustrating the tuning process for the RiverWare Model is shown in **Figure 8-13**. The diagram is the same as the calibration diagram in **Figure 8-12** except the tuning targets are highlighted in yellow.

Simulation of Project operations with rules rather than using historical data results in some decline in the agreement between modeled and historical streamflows because of the challenge in developing fixed rules to simulate operations that may include to varying degrees uncertain and ad hoc decision processes. Some decline in agreement between simulated and observed flows is an unavoidable consequence associated with development of a model that appropriately responds to simulated changes in historical conditions.

Further, the errors that are present in the tuned model simulation of historical conditions (i.e., in the historical operations run) are also largely present in alternative simulations using the tuned model (e.g., in no-pumping runs). Therefore, when differences are computed between the output of two runs of the tuned models (e.g., simulated streamflows or farm deliveries), these errors tend to cancel each other out, resulting in changes in outputs that reasonably represent the effects of changes in the simulated model inputs.

Figure 8-14 through **Figure 8-18** provide comparisons of various model outputs from the tuned ILRG Model simulation of historical operations during 1940 - 2017 against the results from the calibration run in which reservoir releases, diversions, and farm headgate deliveries were set at historical values. As described further in Section 9, the tuned model simulation of historical conditions is designated as the Historical Base Run against which simulations of alternative scenarios were compared. Consistent with this, the tuned model results are identified as the Historical Base Run (black line) and compared to the Calibration Run (orange line). The following is a list of the comparisons between the Historical Base Run and the Calibration Run shown in **Figure 8-14** through **Figure 8-18.**

- **Figure 8-14** – Annual Summary of Project Storage and Rio Grande Flows
- **Figure 8-15** – Annual Summary of Irrigation Operations – EBID
- **Figure 8-16** – Annual Summary of Irrigation Operations – EPCWID
- **Figure 8-17** – Annual Summary of Irrigation Operations – HCCRD
- **Figure 8-18** – Annual Summary of Irrigation Operations – JID

The graphical comparisons in the above figures show that the simulated values in Historical Base Run of the tuned ILRG Model reasonably matches the values from the historical Calibration Run. Of particular note is how well the simulated irrigation pumping in the Historical Base Run matches the magnitude and trends in the simulated pumping in the Calibration Run. Differences in the simulated pumping reflect the accumulated differences in all simulated processes that occur between the Project storage and farm headgate deliveries of surface water. Given this, the general agreement between the simulated pumping in the Historical Base Run and the Calibration Run is considered excellent.

The matches between the simulated reservoir storage contents, Caballo Reservoir releases, El Paso flows and Ft. Quitman flows in the Historical Operations Run and the Calibration Run are also excellent.

Additional discussion of the results of the Historical Base Run is found in Section 9 below.

8.8 Model Output and Post-Processing of Results

Post-processing spreadsheets were prepared to summarize output from the ILRG Model. The purpose of the spreadsheets is to help illustrate and explain the model results and to help verify the models are correctly functioning. Post-processing spreadsheets were developed to summarize the following model results:

- Calibration and tuning results,
- Water budgets and balances,
- River point flow diagrams and flow maps, and
- Changes in modeled outputs for alternative scenarios.

Tables and charts from the post-processing spreadsheets are presented in the foregoing subsections on model calibration (Section 8.6) and model tuning (Section 8.7), in Section 9 in the discussion of the Historical Base Run, and in Section 10 in the discussion of the model runs that were made in support of New Mexico's counterclaims.

8.9 Suitability of ILRG Model for Assessment of Claims and Counterclaims

The ILRG Model was successfully calibrated and tuned over a 78-year study period comprised of a wide variety of hydrologic conditions ranging from the wet periods of the 1940s, 1980s, and 1990s with little or no pumping, to the dry periods of the 1950s and 2010s with substantial pumping. The calibration and tuning results demonstrate that the model reasonably simulates surface and ground water use between Elephant Butte Reservoir and Ft. Quitman as well as the physical interaction between the surface and ground water systems.

In addition, the ILRG Model complies with the objectives described in Section 7 for developing calibrated rule-based models that are capable of reasonably simulating appropriate responses to simulated changes in historical input data and/or operating conditions. This includes dynamic simulation of the substantive real-world processes of allocating Project supplies to the U.S. districts and Mexico, releasing those allocations to meet the Project water demands and the 1906 Treaty obligation to Mexico in combination with the simulated downstream return flows to the river from irrigation and non-irrigation uses.

It is my opinion that the ILRG Model is the best available scientific tool for evaluating the effects of hydrological and institutional changes within the LRG Area on surface water supplies, streamflows, and ground water storage in the Rio Grande basin between Elephant Butte Reservoir and Ft. Quitman.

9.0 HISTORICAL BASE RUN OF INTEGRATED LRG MODEL

9.1 Introduction

The ILRG Model was used to simulate historical conditions over the 1940 - 2017 study period for purposes of calibrating and tuning the model as described above. In addition, the tuned version of the model was used to develop the Historical Base Run that was compared to the results of alternative scenarios that were also simulated with the tuned version of the ILRG Model. This section of the report provides an overview of the operational specifications for the Historical Base Run as well as summaries of the simulated results.

9.2 Key Operational Specifications for Historical Base Run

The following is a summary of the key specifications and rules for simulating Project operations and irrigation and non-irrigation water uses in the Historical Base Run of the ILRG Model:

- Project Water Allocation – The D1/D2 allocation procedure developed by Reclamation and implemented starting in 1979 is used to allocate Project water from 1940 - 2005. While the D1/D2 Procedure was not officially implemented until 1979, it was determined to reasonably approximate the somewhat ad-hoc equal allocation per acre procedure that existed prior to 1979. Annual full supply allocations prior to 1979 were estimated based on maximum allocations reported during that time. The D3 allocation procedure without carryover is simulated in 2006 and 2007. The D3+Carryover allocation procedure is simulated starting in 2008 through the end of the study period. While certain details of the 2008 OA allocation procedure were modified from time to time after 2008, the allocation procedure simulated in the ILRG Model is consistent with the 2017 version of the 2008 OA allocation worksheet.
- Project Accounting – The Project accounting includes tracking the Project diversions to EBID, EPCWID, and JID. Reservoir releases are made from the Project storage to deliver water to the districts and the diversions are limited to the Project water allocations. The EBID diversion charges include Arrey Canal, Leasburg Canal, Eastside Canal, and Westside Canal flows to New Mexico. The EPCWID diversion charges include Eastside Canal and Westside Canal flows to Texas, Franklin Canal minus Ascarate Wasteway (pre-1999), Riverside Canal, and EPW diversions of Project water. Credits against diversion charges are simulated for the ACE credit and the Haskell WWTP credit.

- FHG Demands – Irrigation demands at the farm headgate are computed based on historical irrigated area, historical monthly crop-weighted average CIR values, and specified maximum farm irrigation efficiency values that increase through time.
- Conveyance Losses – Canal conveyance losses are computed in the SFR packages of the NMR-M Model and the Hueco Model. An incidental loss of 6% is added to the computed conveyance loss to represent consumptive use by evaporation and vegetation along the canals and laterals.
- Canal Diversion Demands – Diversion demands at the canal headings are computed as the FHG demands divided by the conveyance efficiency (1.0 minus the conveyance loss factor) multiplied by factors developed during the model tuning to match historical diversions.
- Irrigation Pumping – Irrigation pumping coverage is specified to increase linearly from 0% in 1947 to 100% in 1955 and remain at that level for the rest of the study period. Upon reaching full coverage in 1955, it is conservatively assumed that irrigation pumping meets 100% of the unmet irrigation demand after Project water deliveries to Project lands. Pumping on the simulated non-Project lands in EBID that are served only by wells is also conservatively assumed to meet 100% of the simulated irrigation demand.
- Non-irrigation Pumping and Return Flows – Municipal pumping, wastewater treatment plant return flows, and urban deep percolation are based on historical records and estimates. Domestic pumping is set at historical estimated levels.

9.3 Historical Base Run Results

The Historical Base Run simulates historical Project operations and water uses between Elephant Butte Reservoir and Ft. Quitman from 1940 - 2017. The simulated Project operations and water uses generally track the historical records that are summarized in Section 5. However, simulation of the Historical Base Run provides additional information and insight on the hydrologic and water use processes for which comprehensive measurements and records are not available. For example, the model results show estimated historical ground water pumping that was needed to meet the unmet irrigation demands after Project water deliveries, and the various components that contribute to the gains and losses of selected river reaches. The following are selected results and observations from review of the Historical Base Run.

9.3.1 Reservoir Operations

Figure 9-1 summarizes the simulated annual inflows, outflows, and end-of-year storage contents of Elephant Butte Reservoir, Caballo Reservoir, and the two reservoirs combined. Inflows are represented as stacked positive bars and include Rio Grande inflows, local inflows, and precipitation. Outflows are shown as stacked negative bars and consist of releases, evaporation, and storage adjustments (for periodic adjustments to the reservoir stage-capacity table due to siltation). The end-of-year storage contents is plotted as a black line in the figures and the annual changes in the end-of-year storage correspond to differences between the total reservoir inflows and outflows.

Review of the combined reservoir storage chart shows how the reservoir inflows varied through times affecting the reservoir contents and the reservoir releases. Two years of high inflows in the early 1940s caused the reservoirs to spill in 1942. This followed by a mix of average and below average inflows during the 1940s that resulted in a decline in the simulated reservoir contents. This was followed by six out of seven years with very low inflow that resulted in five consecutive years from 1953 - 1957 with reservoir releases of less than 500,000 AF. Inflow conditions improved in late 1950s resulting in some increases in reservoir contents and Project supply. The 1960s and 1970s were characterized by inflows typically ranging between 400,000 AF and 1,000,000 AF, and reservoir releases fluctuated accordingly between full and partial. The late 1970s ushered in prolonged period of above normal inflows and full water supply conditions for the Project that lasted until the early 2000s when drought again returned to the Rio Grande basin and Project deliveries plummeted. Since that time, Project storage has remained low and reservoir releases have been less than average.

The simulated annual allocations and charges to EBID and EPCWID during the 1940 - 2017 study period are summarized in **Figure 9-2.** These reflect allocations under the D1/D2 Procedure until 2005, the D3 Procedure without carryover in 2006 and 2007, and the D3 + Carryover Procedure thereafter. The full supply conditions during the 1940s and 1980s and 1990s are reflected in the full allocations to the districts during these years. The fluctuations in allocations during the 1950s - 1970s are also evident.

When the recent extended drought commenced in the early 2000s, the allocations to EBID and EPCWID declined together as provided for under the D1/D2 procedure. This changed when the D3 accounting was implemented with the allocations to EBID generally dropping in comparison to the EPCWID allocations which continued to be determined under the D1/D2 methodology. The carryover accounting under the 2008 OA is evident in the simulated EPCWID allocations during the late 2000s that were greater than any time prior.

9.3.2 EBID Operations

Figure 9-3 summarizes the simulated historical diversions, FHG deliveries, pumping, and conveyance losses for EBID. The simulated EBID diversions and FHG deliveries were greatest during the full supply periods of the 1940s, 1980s, and 1990s. Diversions were low during the multi-year droughts of the mid-1950s and 2010s, and during shorter term dry periods in the 1960s, 1970s, and 2000s. Adoption of the 2008 OA also contributed to the relatively low diversions after 2007.

The simulated pumping was generally inversely proportional to the FHG deliveries with low pumping in full supply years and high pumping in low supply years. Simulated annual pumping during recent dry years has ranged between about 200,000 AF and 300,000 AF, which is similar to the simulated annual pumping during the dry years of the 1950s, 1960s, and 1970s.

9.3.3 EPCWID Operations

Figure 9-4 summarizes the simulated historical diversions, FHG deliveries, pumping, and conveyance losses for EPCWID. Similar to EBID, the EPCWID diversions were high during the full supply years of the 1940, 1980s, and 1990s, and low during the non-full supply years of the 1950s, 1960s, 1970s, and during the recent extended drought that began in the early 2000s. The simulated EPCWID diversions did not decline as much as the EBID diversions after 2007 because the 2008 OA allocates water first to EPCWID at the expense of the allocations to EBID.

The simulated annual pumping by EPCWID was greatest during dry years between 1950 and 1980 reaching as much as 154,000 AF. Because of the reduction in irrigated area and enactment of the 2008 OA, simulated annual irrigation pumping in EPCWID during the recent drought topped out at about 70,000 AF. The modeling shows little unmet irrigation water demand after considering the available surface water supply during the 1980s and 1990s and therefore little simulated supplemental pumping.

9.3.4 Hudspeth Operations

Figure 9-5 summarizes the simulated historical diversions, FHG deliveries, pumping, and conveyance losses for HCCRD. Because HCCRD relies on waste from EPCWID, the pattern of its supply generally mirrors the supply of EPCWID, rising in wet years and falling in dry years. Most of the simulated supplemental pumping to meet unmet demand occurred prior to 1980, with the simulated maximum annual pumping of 32,000 AF in 1954. The simulated surface water supply after 1980 was generally adequate to meet irrigation demands without supplemental pumping.

9.3.5 Juarez Operations

Figure 9-6 summarizes the simulated historical diversions, FHG deliveries, pumping, and conveyance losses for Juarez. Pursuant to the 1906 Treaty, 60,000 AF are delivered to the headgate of the Acequia Madre in full supply years. Deliveries to Juarez are reduced in non-full supply years in proportion to the reduction in deliveries to the districts. The simulated farm headgate deliveries have steadily increased since 1980 due to simulated increases in wastewater discharges to the Acequia Madre and increased use of irrigation return flows. However, because of gradual increases in irrigated area through time, the annual supplemental pumping has generally fluctuated between 50,000 AF and 100,000 AF during most years since ground water use became widespread in the early 1950s.

9.3.6 River Flows

Annual water budget summaries of river inflows and outflows are shown in **Figure 9-7** for Rincon and Mesilla basins upstream of El Paso and in **Figure 9-8** for the El Paso Valley down to Ft. Quitman. The stacked positive bars represent inflows to the river and the stacked negative bars represent outflows from the river. The black line represents the net difference between the sum of the inflow bars and the sum of the outflow bars. The black line also is equal the difference between the Rio Grande inflows entering the top of the reach and the Rio Grande outflows existing the bottom of the reach, which are not shown on the graph.

In the Caballo to El Paso reach, the largest inflows are wastewater and drain returns. The primary outflows are canal diversion. The simulated annual river seepage is positive during the wet periods of the 1940s and 1990s indicating that the river is gaining flow from the ground water system. During most of the remainder of the simulation period the river seepage is negative indicating the river is losing water to the ground water system. Within each year, the river gains and losses vary monthly and seasonally.

In the El Paso to Ft. Quitman reach, the largest inflows are wasteway returns (mostly discharges from the American Canal below International Dam that are rediverted at the Riverside Canal prior to construction of the American Canal Extension in 1999). The next largest inflows are the canal returns at the lower end of the HCCRD. Other relatively minor inflows are drain returns and wastewater treatment plant discharges. The largest outflows are the canal diversions at American Dam and at the Riverside Dam when it was in operation. The other outflow is the net river seepage from the river to the ground water system.

Figure 9-9 summarizes the annual flow at different points between Caballo Reservoir and Ft. Quitman. The difference in reservoir releases between wet years and dry years is evident in the point flow charts. The point flows generally decrease in the downstream direction as water is diverted for irrigation. There is a characteristic increase in flows downstream of the Mesilla Dam that represent the simulated flows of the La Mesa Drain and other drains in the area. River flows are typically depleted to at or near zero below International Dam followed by an increase in flow as water was discharged from American Dam back to the Rio Grande to deliver water for diversion at Riverside Dam until completion of the American Canal Extension in 1999. Some increase in flow at the County Line and at Ft. Quitman is also evident in many years as the river is replenished by irrigation return flows.

A different depiction of the historical river flows is provided in the monthly flow maps **Figure 9-10** that show the simulated monthly average flow in cubic feet per second at various locations between Caballo Reservoir and Ft. Quitman. The flows are color coded in ranges to aid in interpretation ranging from dark blue for flows greater than 500 cfs through lighter shades of blue then green and finally white flow flows less than 10 cfs. The characteristic pattern of flows is for large releases from Caballo during the irrigation season and these flows are gradually depleted to zero at some point downstream, typically at American Dam and/or International Dam. The flows are modestly restored in the downstream reaches down to Ft. Quitman. During the non-irrigation season, there are no simulated releases from Caballo, the simulated flows increase through return flows in varying amounts depending on whether conditions are relatively wet or relatively dry.

10.0 ALTERNATIVE RUNS OF INTEGRATED LRG MODEL

10.1 Introduction

The ILRG Model was used to simulate alternative scenarios in response to certain of the Texas claims and to support certain of the New Mexico counterclaims. All alternative scenarios were simulated with the tuned version of the ILRG Model that was used to produce the Historical Base Run described in Section 9. The simulated alternative scenarios fall into two categories as follows:

- No-Pumping Scenarios – Most of the alternative scenarios involved turning off pumping in certain geographic areas or turning off certain types of pumping.
- Operations Scenarios – Other alternative scenarios involved simulation of changes in certain rules for Project operations or irrigation operations.

A list of the model runs that were performed for this report is provided in **Table 10-1**. The no-pumping scenario runs are described in Section 10.2 and the operations scenario runs are described in Section 10.3.

10.2 No-Pumping Scenarios

The purpose of simulating no-pumping scenarios was to evaluate the effects that pumping in New Mexico, Texas, and Mexico has on Project operations and deliveries of Project water. The no-pumping scenarios were simulated by running the ILRG Model with changes in rules or input data depending on the type of pumping that was turned off. For irrigation pumping, the RiverWare Model rule that computes pumping based on the unmet crop irrigation demand is switched off. Reductions in surface runoff and deep percolation return flows that result from turning off the irrigation pumping are simulated as part of the farm budget algorithm in the RiverWare Model.

As previously described, non-irrigation pumping and the corresponding WWTP returns and urban deep percolation returns are simulated in the ILRG Model based on external input of data to the model. Therefore, turning off non-irrigation pumping requires modifying these model inputs to set the pumping and corresponding return flows to zero.

After modifying the irrigation pumping switch and/or the non-irrigation pumping and return flow input data sets, the ILRG Model is executed using the same iterative procedure involving alternating runs of the RiverWare Model and the ground water models until closure is reached (typically 3 to 4 iterations). Turning off pumping results in increased in ground water levels, increased drain flows, and reduced river seepage. This in turn causes the RiverWare Model to adjust Project water allocations, reservoir releases, canal diversions, and FHG deliveries to adjust to the change in water supply. The simulated changes in water supply and system responses ripple spatially and temporally through the model linkages.

Output data from the alternative scenario run are tabulated and compared to the results from the Historical Base Run or another run to quantify what changed between the runs.

Appendix 10A contains two tables and one figure that compare results from each no-pumping run to the Historical Base Run for the period from 1985 - 2016. This period was selected for summarizing the results of the no-pumping runs because it is the period for which Texas is claiming damages from New Mexico pumping. The following is an explanation the summary tables and figure in **Appendix 10A** for the All Pumping Off run (Run 2) (**Table 10A-2a**, **Table 10-A2b**, and **Figure 10A-2**). These explanations are also applicable to the summary tables and figure for the other no-pumping runs summarized in **Appendix 10A**.

Table 10A-2a tabulates average annual differences in certain model inputs and outputs during the 1985 - 2016 period. The first several rows tabulate the "Change in Pumping Stress" which summarizes the differences in model inputs between the no-pumping run and the Historical Base Run. The change in pumping stress consists of the irrigation pumping and/or net non-irrigation pumping (total non-irrigation pumping minus corresponding WWTP returns and urban deep percolation returns) that are turned off.

The remaining rows in **Table 10A-2a** under "Effects of Change in Pumping Stress" show the simulated effects of the changes in input stresses on the following model outputs:

- Farm Headgate Deliveries (Mar-Oct)
- Farm Headgate Deliveries (Nov-Feb)
- Irrigation Pumping
- Reservoir Evaporation
- Riparian ET
- River Evaporation and Incidental Canal Loss
- Rio Grande at Ft. Quitman Flows

- Changes in Storage (Reservoir, Ground Water, Soil Moisture)
- Sum of the above effects.

The first two columns in **Table 10A-2a** summarize annual averages for the Historical Base Run and the All Pumping Off Run, respectively. The third column presents the annual average differences between the two runs. The last two columns show percentage changes computed in two different ways; the first computes the differences between the model runs as a percentage of the simulated change in stress, and the second computes the percentage change of each quantity from the average in the Historical Base Run. The sum of the annual changes does not equal the total change in the simulated stress because certain of the model outputs are not independent quantities (e.g., pumping and FHG deliveries).

The results summarized in **Table 10A-2a** generally illustrate how the model simulates the real-world response of the Project operation and LRG Area irrigation systems to the changes in water supply that would have resulted if the historical pumping had not occurred. These responses are described in more detail below for certain of the no-pumping runs.

Note that for discussion purposes, the results of the no-pumping runs are described in terms of the effect of turning off pumping and the resulting increases in various simulated quantities (e.g., Project water deliveries, reservoir storage, ground water storage, Rio Grande flows, etc.) However, by changing the algebraic sign, the results can also be interpreted as the effects of pumping on the simulated results.

Table 10A-2b presents the change in each year from 1985 - 2016 for certain of the model outputs that are summarized in **Table 10A-2**. Specifically, the annual outputs summarized in **Table 10A-2** include changes in farm headgate deliveries, reservoir evaporation, riparian ET, river evaporation plus incidental canal loss, Rio Grande flows at El Paso and Ft. Quitman.

Figure 10A-2 contains bar charts showing the simulated change in FHG deliveries to EBID, EPCWID (including deliveries to EPW), and HCCRD. The blue bars illustrate the change in FHG deliveries during March - October and the orange bars show the change in FHG deliveries during November - February.

10.2.1 No New Mexico Pumping Scenario (Run 3)

In response to the analyses of impacts of New Mexico pumping described in the Texas expert reports, the No New Mexico Pumping Scenario was simulated with the ILRG Model to analyze the Project operations that would occur in the absence of New Mexico pumping, including the re-operation of the Project that would occur with the changes in drain flows, and river gains and losses without pumping. The results described in this section show that the simulated effects of New Mexico pumping on deliveries to Texas water users are far less than the impacts computed by the Texas experts.

In the No New Mexico Pumping Scenario, the RiverWare Model rule that simulates irrigation pumping to meet the unmet monthly irrigation demand that remains after the simulated use of surface water and soil moisture is switched off. This results in simulated irrigation shortages in EBID during all years. The magnitude of the shortage varies depending on the Project supply. In wet years with full allocations, the shortages to Project lands are relatively small, while in dry years with low allocations, the shortages are substantial.

The simulated effects of turning off New Mexico pumping in the ILRG Model during the 1985 - 2016 study period are summarized in in **Table 10A-3a**, **Table 10A-3b**, and **Figure 10A-3** in **Appendix 10A**.

The average annual effects of turning off New Mexico pumping on river flows, diversions, storage, and other simulated processes are summarized in **Table 10A-3** for 1985 - 2016 period. The simulated effect of turning off irrigation and non-irrigation pumping in New Mexico results in year-round increases in drain flows, and reductions in river losses and/or increases in river gains. These changes in flow in turn result in changes in reservoir operations and deliveries of Project water depending largely on the simulated allocation of Project water. In full allocation years there is relatively little change in FHG deliveries while in non-full allocation years there are much larger changes. The simulated effects on reservoir operations from pumping include (a) increases in reservoir evaporation, (b) increases in allocations in non-full supply years, and (c) increases in spills.

The increased river flows without New Mexico pumping that would either increase Project water deliveries in the current year or would be carried over in Project storage and allocated and delivered in subsequent years both show up in the simulations as impacts to the Project supply delivered to both New Mexico and Texas. This is reflected in the results in **Table 10A-3a** that show that New Mexico pumping impacts on March - October FHG deliveries average 26,200 AF/y to EBID and 8,200 AF/y to EPCWID.

Without New Mexico pumping, there would be increased reservoir evaporation due to the reduction in reservoir releases necessary to make deliveries to Project water users, increased river and canal evaporation due to the general increase in the surface water supply, and more riparian evapotranspiration due to increased ground water levels. Together, these effects would have averaged 11,600 AF/y during 1985 - 2016, or approximately 8% percent of the net pumping stress. This can be characterized as the salvage effect of New Mexico pumping.

Turning off pumping in New Mexico would also increase the flow of the Rio Grande at Ft. Quitman. The simulated increase in annual Ft. Quitman flows averaged 66,600 AF during the 1985 - 2016 period and is comprised of increased spills from Project storage, increased winter flows, and return flows from the additional Project water deliveries to EPCWID, HCCRD, and JID.

Finally, the ILRG Model shows that if there had been no New Mexico pumping then alluvial ground water storage would have increased by an average of 10,500 AF/y and non-alluvial ground water storage would have increased by an average of 12,100 AF/y over the 1985 - 2016 period.

The annual volumes of impacts from New Mexico pumping that correspond to the averages in **Table 10A-3a** are presented in **Table 10A-3b**. The impacts on seasonal and annual FHG deliveries to EBID, EPCWID, and HCCRD are summarized in **Figure 10A-3**.

Additional comparisons of the model outputs for the Historical Base Run and the No New Mexico Pumping Scenario are provided in **Appendix 10B** for the entire 1940 - 2017 study period to illustrate the ILRG Model responses to turning off New Mexico pumping. Comparisons of annual storage and Rio Grande flows are shown in **Figure 10B-1**. Comparisons of annual diversions, FHG deliveries, pumping, and conveyance losses are presented in **Figure 10B-2** for EBID, **Figure 10B-3** for EPCWID, and **Figure 10B-5** for HCCRD. The results in these figures illustrate that diversions by EBID and EPCWID are not appreciably different with or without pumping in full supply years. The impacts of pumping are concentrated in the non-full supply years with additional diversions and deliveries of water in the no-pumping run to EBID, EPCWID, and HCCRD.

More detailed depictions of the simulated Project storage, river flows, and deliveries or Project water are presented in **Figure 10B-5** through **Figure 10B-17**. These figures compare the simulated monthly volumes from the Historical Base Run (black line) and No New Mexico Pumping Scenario (orange line). In these figures, the differences in Project operations during full supply years and non-full supply years are evident. In addition, the differences in flows during the irrigation and non-irrigation seasons are also evident.

The results of the No New Mexico Pumping Scenario show that the effects of New Mexico pumping on deliveries to Texas water users are much smaller than computed in the analyses performed by the Texas experts. The summary results in **Appendix 10A** and more detailed results in **Appendix 10B** show that the ILRG Model simulates reasonable and appropriate responses that would result from turning off New Mexico pumping that reflect the real-world response of Project operations to changes in water supply.

Additional comparisons of the ILRG Model results for the No New Mexico Pumping run to the results in the Texas expert reports are provided in Section 13 and Section 14.

10.2.2 No Texas Pumping Scenarios (Runs 4, 7, 8)

Several runs were made of the ILRG Model to evaluate the effect of pumping in Texas on Project operation and the surface water supplies of the LRG water users. The results from these simulations show that pumping in Texas also impacts Project operations and deliveries of Project water to EBID and EPCWID, particularly in non-full supply years.

The No Texas Pumping Scenarios were simulated in the same manner as the No New Mexico Pumping Scenario. Turned off in the No Texas Pumping Scenarios were all or a portion of the supplemental irrigation pumping, and all or a portion of the non-irrigation pumping and the associated WWTP and urban deep percolation return flows. The following are specifications and summaries of the results of the No Texas Pumping Scenarios.

All Texas Pumping Off (Run 4) – In this scenario, all supplemental irrigation pumping and non-irrigation pumping in the Texas portion of the Mesilla basin and the El Paso Valley was turned off. In addition, the urban return flows from the non-irrigation pumping were also turned off, including WWTP discharges and urban deep percolation. On average over the period from 1985 - 2016, 20,500 AF/y of irrigation pumping, 88,900 AF/y of non-irrigation pumping, and 45,600 AF/y of urban return flows were turned off. This was a net change in pumping stress of 63,800 AF/y. The results from the All Texas Pumping Off run are summarized in **Table 10A-4a**, **Table 10A-4b**, and **Figure 10A-4** in **Appendix 10A**. If Texas had not pumped ground water, the EBID farm deliveries during 1985 - 2016 would have increased by an average of 5,100 AF/y with a maximum annual increase of 32,500 AF in 2009. Without Texas pumping, EPCWID and Hudspeth diversions and FHG deliveries would increase in some years and decrease in other years. The reason for the decreases is due to the impacts of pumping on surface flows sometimes being less than the changes in irrigation and non-irrigation return flows. On average, the greatest effect of no Texas pumping would be an increase in ground water storage averaging 49,300 AF/y over the 1985 - 2016 period.

- Texas Mesilla Pumping Off (Run 7) – In this run, all supplemental irrigation pumping and non-irrigation pumping in the Texas portion of the Mesilla basin (including EPW's Canutillo wells) was turned off. On average over the period from 1985 - 2016, the net change in pumping stress averaged 13,800 AF/y and was comprised of an average of 2,800 AF/y of irrigation pumping, 24,100 AF/y of non-irrigation pumping less 13,200 AF/y of urban return flows. The results of this run are summarized in **Table 10A-7a**, **Table 10-7b**, and **Figure 10-7** in **Appendix 10A**.

- Texas Non-irrigation Pumping Off (Run 8) – In this run, all Texas non-irrigation pumping and associated urban return flows were turned off. On average over the period from 1985 - 2016, the net change in pumping stress totaled 43,300 AF/y and was comprised of an average of 88,900 AF/y of non-irrigation pumping less 45,600 AF/y of urban return flows. The results of this run are summarized in **Table 10A-8a**, **Table 10A-8b**, and **Figure 10A-8** in **Appendix 10A**.

10.2.3 No Mexico Pumping Scenario (Runs 5)

In this scenario, all supplemental pumping in JID and all municipal pumping and associated WWTP discharges in Ciudad Juarez were turned off. On average over the period from 1985 - 2016, 59,200 AF/y of irrigation pumping, 115,000 AF/y of municipal pumping, and 57,300 AF/y of WWTP discharges were turned off. The results of these runs are summarized in **Table 10A-5a**, **Table 10A-5b**, and **Figure 10A-5** in **Appendix 10A**. The maximum annual impacts of Mexico pumping on FHG deliveries were 3,900 AF to EBID, 3,400 AF to EPCWID, and 9,400 AF to HCCRD. Mexico pumping had an average annual impact on ground water storage of 89,200 AF/y during 1985 - 2016.

10.2.4 No Rincon-Mesilla Pumping Scenario (Runs 6)

A run of the ILRG Model was made to evaluate the effect of turning off all irrigation and non-irrigation pumping in the Rincon basin and Mesilla basin in New Mexico and in the Texas portion of the Mesilla basin. The purpose of this run was to simulate a scenario that was directly comparable to 100% reduced pumping run of Texas Model described in the Hutchison Report. In this scenario, all irrigation pumping and all non-irrigation pumping and urban return flows in the Rincon and Mesilla basins were turned off. This included pumping of the Canutillo wellfield (EPW) and the Conejos-Medanos wellfield (Juarez). On average over the period from 1985 - 2016, 125,800 AF/y of irrigation pumping, 64,900 AF/y of non-irrigation pumping, and 28,100 AF/y of urban return flows were turned off. The results of these runs are summarized in **Table 10A-6a**, **Table 10A-6b**, and **Figure 10-6** in **Appendix 10A**. Without pumping in the Rincon and Mesilla basins, EBID farm deliveries during 1985-2017 would have increased by an average of 30,400 AF/y with the greatest increases being 109,400 AF in 2010. Additional discussion of the No Rincon-Mesilla Pumping scenario is provided in Section 14.

10.3 Operational Scenarios

Three alternative operating scenarios were simulated using the ILRG Model. Two runs were made to evaluate the impacts of the 2008 OA on Project operations. The other run was made to assess the effects on the Project from excess operational waste.

10.3.1 2008 Operating Agreement Scenarios (Runs 11 and 12)

Two runs of the ILRG Model were made to evaluate the effect of the D3+Carryover accounting in the 2008 OA on Project operations and LRG water supplies. In Run 11, the D1/D2 allocation procedure was simulated to allocate Project water during the entire period from 1948 - 2017 period, and in Run 12 the D3+Carryover accounting was simulated during this 70-year period[6]. Otherwise, both runs utilized the same RiverWare Model simulation rules as in the Historical Base Run. Irrigation pumping was simulated based on the unmet irrigation demand and the non-irrigation pumping and associated return flows were set at historical levels.

The simulated effects of the D3+Carryover accounting from the 2008 OA are illustrated by the simulated differences in the ILRG Model outputs computed as the Run 12 minus Run 11 during the 1948 - 2017 period. The differences between these runs are summarized in **Table 10A-12** in **Appendix 10A** and in **Table 10B-12** in **Appendix 10B**. The impact of the simulated impact of the 2008 OA was to reduce EBID farm deliveries by an average of 42,100 AF/y during 1948 - 2017 and increase EPCWID deliveries by an average of 16,100 AF/y during the same period. The annual results summarized in **Table 10B-12** show that the effect of the 2008 OA on EBID FHG deliveries varies significantly depending on the hydrologic state of the basin. The following is a summary of the average annual effect on EBID and EPCWID FHG deliveries in three intervals of the 1948-2017 period.

Average Effect of 2008 Operating Agreement on March - October FHG Deliveries In Wet and Dry Periods

Period	Wet/Dry	EBID	EPCWID
1948 - 1985	Dry	-68,700	13,400
1986 - 2000	Wet	56,900	23,300
2001 - 2017	Dry	-70,000	15,600
1948 - 2017	All Years	-42,100	16,100

In the two historical dry periods with a relatively low diversion ratios (55 years), annual EBID FHG deliveries are substantially reduced by an average of approximately 68,700 AF while in the wet period from 1986-2000 (15 years) with a relatively high diversion ratios, annual EBID FHG deliveries increased by an average 56,900 AF. The effect of the 2008 OA

[6] As described in Section 8.2.1, the RiverWare rules do not simulate annual allocations during the wet period from 1940 – 1947.

on EPCWID is more consistent with increased FHG deliveries in most years with an average annual increase of 16,100 AF.

10.3.2 Reduced Waste Scenario (Run 13)

As discussed in Section 5, beginning with the 1950s drought and continuing through the 1970s, Reclamation was able to operate the Project with operational waste below 10% during most years. In a few years during the wet periods of the mid-1980s and mid-1990s, the EBID waste increased to approximately 20%. The situation in EPCWID was markedly different than in EBID from the 1980s through the 2000s (after EPCWID took over operations) with the operational waste consistently in the range of 20% to 30%.

A run of the ILRG Model was made to evaluate the benefit to the Project from reducing the operational waste. The RiverWare operational rules were modified so that the operational waste was limited to the lesser of the historical amounts or 10% of the simulated diversions. The differences between this run and the Historical Base Run are summarized in **Table 10A-13** in **Appendix 10A** The results show that reducing excess operational waste would have resulted in increases in annual Project water deliveries during 1985 - 2016 averaging 28,600 AF to EBID and 12,700 AF to EPCWID.

11.0 RESPONSE TO BRANDES REPORT

Robert J. Brandes, Ph.D., P.E. prepared a May 31, 2019 expert report on behalf of the State of Texas ("Brandes Report"). The subjects of the Brandes Report generally included the following:

- New Mexico Ground Water Development
- Historical Changes in Rio Grande Flows
- Project Operations
- Effect of Ground Water Pumping on Project Deliveries

SWE was asked by legal counsel for New Mexico to review the Brandes Report to identify information or opinions with which we disagreed, and to prepare expert opinions to respond to these issues. We attempted to identify and respond to all substantive issues in which there appeared to be differences of opinion, however a lack of response to a particular issue should not be interpreted as tacit agreement with Dr. Brandes' opinion(s).

Brandes Opinion 1 – *Extensive ground water development in the Rincon and Mesilla basins of New Mexico that began in the 1950s has depleted drain flows and river flows, and this has altered the Project water budget by reducing flows in the Rio Grande that would reach water users in Texas. (Page 10 paragraph 1).*

Response:

The conceptual discussion of the impacts of pumping on Texas water users in Section 4 implies that New Mexico pumping has caused continuous and unrelenting impacts on Texas water users since the early 1950s. The discussion exaggerates the impacts for the following reasons:

1. Pumping in New Mexico varied substantially since it developed in the early 1950s with higher pumping amounts in low Project supply years and lower pumping amounts in full supply years.
2. In full supply years, Reclamation delivered all water ordered by EPCWID and EBID up to their total allocations. To the extent there were varying Project delivery efficiencies (i.e., diversion ratio), Reclamation could adjust releases from storage to deliver the water that was ordered. Therefore, there would not be shortages of delivered water to EPCWID as a result of New Mexico (or Texas) pumping on Project water deliveries in full supply years.

3. There were full supply years from 1979 through 2002, and Dr. Brandes ignores the full deliveries to Texas during all of these years.
4. Additionally, if ground water pumping caused any reductions in the diversion ratio within the Project areas, this would apply to New Mexico, Texas, and Mexico pumping. Dr. Brandes ignores the impacts of Texas and Mexico pumping on Project operations.
5. Dr. Brandes also ignores that Reclamation operated the Project releases and deliveries, encouraged conjunctive use of ground water by all Project participants to meet the full irrigation demands from 1951 - 1978, and then formalized the needed conjunctive use of surface water and ground water by implementing the D1/D2 allocation procedure in 1980 and operating thereunder until major changes in the operating procedures were initiated in 2006 and then adopted in the 2008 OA. Instead, Dr. Brandes blames all changes in Project water deliveries and Rio Grande flows on New Mexico pumping.
6. The foregoing criticisms apply to all of the analyses of historical river flows, drain flows, and Project water deliveries that are presented in the Brandes Report.

Brandes Opinion 2 – *The estimated annual withdrawals for irrigation in the Rincon and Mesilla basins since 1940 are presented on the bar chart in Figure 4.3. As shown by the bars on the chart in Figure 4.3, annual groundwater withdrawals for irrigation has varied considerably, likely in response to wet/dry conditions, and the annual volume of groundwater pumpage for irrigation was substantial even in the early 1950s, indicating that the groundwater well pumping capacity, and likely the total number of irrigation wells, at that time were significant. The demands for additional supplies of irrigation water during the severe drought of the 1950s and during other dry periods, particularly in the mid-2000s and after 2010, are illustrated by the higher levels of groundwater withdrawals on the chart. (Page 11 paragraph 2).*

Response:

The ground water withdrawals for irrigation in Figure 4.3 in the Brandes Report include a significant amount of pumping in the Texas portion of the Mesilla basin. Since roughly 10% of the total Project irrigated area in the Mesilla basin is in Texas, it is reasonable to assume that roughly 10% of the estimated Mesilla basin irrigation pumping in Figure 4.3 would also be in Texas.

The high pumping in the early 1950s is unrealistic given that significant irrigation well development began in New Mexico in the late 1940s and was not complete until about 1955. The pumping estimates shown in Figure 4.3 indicate that almost all of the pumping capacity developed in a single year, with pumping increased from about 10,000 AF in 1950 to about 200,000 AF in 1951. It is unrealistic to assume that all of the irrigation wells would have been constructed in a single year.

As described in the responses to the M&A Report, the total irrigation water demands are overstated because the crop irrigation water requirements are too high beginning in the mid-1980s. Since the irrigation pumping is estimated based on the unmet irrigation demand, this leads to the irrigation pumping also being overstated.

The estimated irrigation pumping during the full supply years of the 1980s and early 1990s averaging nearly 100,000 AF/y is unrealistically high given the full allocation of surface water during those years.

Brandes Opinion 3 *–The plot in Figure 4.5 shows the total combined groundwater withdrawals for both irrigation and urban uses in the Rincon and Mesilla basins [5]. As indicated, since 1950, the total annual groundwater withdrawals consistently have been above 100,000 AF per year, with peak pumpage in recent dry years in the range of 300,000 to over 400,000 AF. (Page 12 paragraph 2).*

Response:

A substantial portion the annual pumping in Figure 4.5 of the Brandes Report is from irrigation wells in the Texas portion of the Mesilla Valley, from EPW's Canutillo wellfield, and from the Juarez Conejos-Medanos wellfield. Pumping from these non-New Mexico wells contributes to the depletions of Rio Grande flow for which Texas is claiming damages. **Figure 11-1** disaggregates the Texas estimates of the total annual pumping in the Rincon and Mesilla basins between the amounts from wells in New Mexico, Texas, and Mexico.

Brandes Opinion 4 *– A report by an unknown author reportedly prepared in 1982 is cited as evidence of the following impacts from ground water development in the Rincon and Mesilla basins:*

> *This groundwater development has changed the flow regime established prior to 1951 such that a greater release is required from Elephant Butte Reservoir to achieve the same flow at El Paso. This new trend, which was established after the end of the drought of the 1950's, has continued to the present (1982).*
>
> *In conclusion, all four figures used in this analysis show that the effects of the groundwater development below Elephant Butte Dam induced by the drought of the 1950's have significantly affected the amount of water reaching El Paso. The*

new relationship is well defined and has been continuous to the present (1982). (Page 14 paragraph 2 and 4).

Response:

The reliability of conclusions from a 1982 report by an unknown author with unknown affiliation using unsourced data is questionable. Dr. Brandes presents analyses similar to those in his report, and my responses are therefore focused on review of his analyses.

Brandes Opinion 5 *– A 1986 report by Tipton and Kalmbach prepared for the IBWC is described and the following conclusions are cited from the report*

1) Depletions of the Rio Grande upstream of the El Paso Narrows have increased. The annual depletions from 1922 through 1950 averaged 237,000 acre-feet per year, from 1951 through 1984 averaged 260,000 acre-feet per year, and from 1980 through 1984 averaged 305,000 acre-feet per year.

5) The use of wells in the Rincon Valley and Mesilla Basin for supplemental irrigation water and for municipal, industrial, and domestic uses since 1951 is the principal cause for the increased depletion upstream of the El Paso Narrows. (Page 15 paragraph 1 and 2).

Response:

The Rio Grande depletions upstream of the El Paso Narrows were reportedly computed as the annual flow at El Paso minus the releases from Project storage. Based on this calculation, the 1986 report concluded that annual Rio Grande depletions increased by an average of 23,000 AF/y after 1950 based on comparison of average depletions during 1922 - 1950 (237,000 AF/y) to average depletions during 1951 - 1984 (260,000 AF)/y).

The 1986 report does not describe the specific sources for the data that were used in the analyses described in the report. Also, the attachments to the report that are the basis for some of the conclusions in the report were not provided. This makes it difficult to review and assess the validity of the report analyses and conclusions.

The report text indicates that the releases from Project storage were a combination of releases from Elephant Reservoir and releases from Caballo Reservoir. Since Caballo Reservoir began operating in 1938, it is assumed that Elephant Butte Reservoir releases were used before 1938. As described previously in Section 5, on average, there was an average gain of about 20,000 AF/y between the Elephant Butte Reservoir outlet and the approximately location of the Caballo Reservoir outlet between 1930 and 1938. Therefore, depletions computed from Elephant Butte Reservoir releases would be expected to be lower than depletions computed from Caballo Reservoir releases before 1938. Using Elephant Butte Reservoir releases for more than half of the 1922 - 1950 period would have depressed the average computed depletions during this period. Comparison of this figure to average depletions after 1950 that are computed entirely based on Caballo Reservoir releases would result in misleading conclusion about differences in average depletions before and after 1950.

As described in Section 5, average depletions from the Caballo Reservoir outlet (or Percha Dam prior to 1938) to El Paso remained relatively steady from the 1930s through the 1970s at about 250,000 AF, increased to around 300,000 AF during the 1990s, and fell back to around 250,000 during the last decade. Therefore, any conclusions about long term persistent trends in depletions are not supported by the available data.

Brandes Opinion 6 *– A 1997 report by a hydrologic task committee appointed by a New Mexico District Court is described and the following conclusion from the report is cited as evidence that ground water pumping causes depletions to Rio Grande flows.*

> *Well withdrawals in the LRGB have been derived partly from stored groundwater, partly from surface-water depletion and partly from capture of evapotranspiration. The fraction derived from the surface water grows through time. The historical portion of well withdrawal from surface-water depletion is estimated to be between 80 and 90 percent. Specific wells may derive water from appreciable different proportions of each source. (Page 15 paragraph 6).*

Response:

The 1997 report describes a ground water model that was developed and used for analysis of basic effects of ground water pumping.

> *Various pumping scenarios were examined using a ground water model to illustrate basic hydrologic relationships. The ground water modeling results are dependent on a number of simplifying assumptions and do not simulate the historical development within the LRGB.*

The 1997 report indicates that the model was used to simulate the effect of pumping of a hypothetical well at a rate of 500 gallons per minute ("gpm") at various locations in the basin and distances from the river and at various depths to assess the effect that well location had pumping impacts to (a) ground water storage, (b) river flow, and (c) capture of evapotranspiration (of native vegetation). The report concluded that the location and depth of the well had a significant impact on how much the simulated pumping depleted the river.

Support for the reported conclusion that between 80% and 90% of historical well withdrawals come from surface water depletions was not found in the 1997 report. The results of various model runs in Appendix A of the 1997 report show substantially more variability in the amount of pumping that is derived from the stream after 100 years of pumping (42% - 93%).

Details about the ground water model construction were not provided in the 1997 report and it is unclear whether the model was calibrated. The report includes the following caveats regarding the model results:

> *Although the work presented in this report is based on the most recent technical information available, it should not be considered as a definitive description of the hydrogeologic system or its response to stresses.*
>
> *A cautionary note is in order. Model simulations quantify the impacts of pumping in the LRGB, but are affected by the way that a model is constructed. The simulations are also affected by the assumptions made regarding hydrologic relationships. If an accurate quantification of the effects of ground-water withdrawals is desirable, the key hydrogeologic relationships that are assumed in any model should be subjected to scrutiny and verification.*

Based on stated purpose of the 1997 modeling work, the simplified nature of the model runs, and the caveats regarding the model results, the report conclusions should be interpreted as preliminary, approximate, and conceptual. The NMR-M Model is far more sophisticated and evolved than the relatively simple model described in the 1997 Report. There is no point in relying on results from a model developed over 20 years ago when more capable tools, like the NMR-M Model and the ILRG Model, are available today.

Brandes Opinion 7 *– Dr. Brandes summarizes a 2008 presentation by Gary Esslinger, manager of the EBID concerning the 2008 Operating Agreement. Esslinger explained the development of the D1/D2 Curves that were used to allocate Project water from 1979 - 2007, and which continue to be used to allocate water to Texas and Mexico under the 2008 Operating Agreement, allowed groundwater pumping in New Mexico to be grandfathered at the 1951-1978 levels that are embedded in the D1/D2 Curves. (Page 16 paragraph 5)*

Response:

Figure 4.6 in the Brandes Report illustrates the annual reservoir release and diversion data for 1951 - 1978 (red dots) that were used to develop the D2 Curve (red line). The D2 line is the best fit straight line through the 1951 - 1978 data that are generally scattered above and below the line. More recent data are shown in the plot for two periods from 2003 - 2007 (before full implementation of the 2008 OA) and for 2008 - 2017 (after the 2008 OA). The recent data in Figure 4.6 are charged diversions during Project releases from storage as compared to the 1951 - 1978 data used to develop the D2 Curve which are total annual diversions and include diversions outside of the Project release period. As a result, recent data are biased low compared to the 1951-1978 data.

Additionally, as to the 2003 - 2007 data, all years except 2005 are within the scatter range of the D2 Curve data and therefore do not exhibit unusually low deliveries. Lastly, during the 2008 - 2017 period, Texas received annual allocations based on the 2008 OA procedure, and therefore any deviation in Project performance below the D2 line was fully shouldered by New Mexico under the D3 allocation procedure. During the 2008 - 2017 period, Texas was also able to carry over significant amounts of water, resulting in Texas's annual allocation far exceeding its historical 43% share, and forcing more ground water pumping New Mexico, for which Brandes seeks to blame New Mexico.

Brandes Opinion 8 *– Figure 5.2 is a plot of cumulative releases from Caballo Reservoir (or from Elephant Butte before 1938) and cumulative Rio Grande flows at El Paso beginning in 1930 and extending through 2015. As shown, the cumulative curves for both the Caballo releases (red circles) and the El Paso Rio Grande flows (green squares) exhibit steeper segments reflecting higher flow conditions and also flatter segments indicating lower flow conditions. The effects of the high flows during the early 1940s and mid-1980s and the low flows of the early to mid-1950s are readily apparent in the two curves. Lower flow conditions also are indicated beginning around 2010, which is consistent with observed climatic and hydrologic conditions. Overall, the cumulative curve for the Rio Grande flows at El Paso generally shows a somewhat flatter trend after the 1950s, indicating less river water reached El Paso relative to what was released from Caballo. The early 1950s, of course, is when significant groundwater pumping for irrigation began in New Mexico. Flattening of the slope of the cumulative curve for the Rio Grande flows at El Paso beginning in the early 1950s is more likely than not indicative of the effects of lowered groundwater levels and increased losses from the Rio Grande and drainage ways that resulted from the development of significant groundwater pumping in the Rincon and Mesilla basins. (Page 19 paragraph 1).*

Response:

The historical flow of the Rio Grande at the El Paso gage is not relevant to this litigation because (a) it is not a point of compliance for the Compact, and (b) it is not a point of delivery for the Project. The Project was conceived and has been operated to provide equal delivery of water per acre of irrigated land. Until 1979, Reclamation was responsible for making water available for delivery to the users on an equal per acre basis. After the districts took over the internal distribution of water to the Project water users, Reclamation's obligation to deliver water was changed to the major canal headings with the idea that the district would perform the remainder of the water distribution that would continue equal delivery of water per acre. Since 1979, Reclamation has accounted for deliveries to EBID and EPCWID at canal headings and other points upstream and downstream the El Paso gage, but there continues to be no Project accounting at the El Paso gage.

The relative steep slopes of the reservoir releases (red circles) and El Paso flows (green squares) during the 1930s and 1940s reflects the generally above average water supply conditions that resulted in full Project supplies through that period and relatively high releases from storage. There were no annual water allocations set by Reclamation during the 1940s and 1950s and farmers ordered whatever water they thought they needed.

The general flattening of both curves after 1950 reflects the decline in average annual releases that occurred because the average water supply after 1950 was much lower than before 1950, despite the wet periods of the 1980s and 1990s. The following are comparison of the average reservoir releases before and after 1950:

Comparison of Average Annual Storage Releases (acre-feet)

Years	All Years	Excluding Spill Years
1930-1950	829,000	781,000
1951-2017	607,000	575,000

In addition, as shown in Figure 5.1 of the Brandes Report, the Project is generally more efficient in conveying flows released from the reservoir downstream to El Paso at higher flows. The flattening and slight divergence of the cumulative reservoir release and El Paso flow curves in Figure 5.2 after 1950 are consistent with reduced river efficiency that exists at lower flows.

Brandes Opinion 9 *– Dr. Brandes presents a plot of the cumulated annual flows of the Montoya Drain from 1938 - 1995 in Figure 5.3. As shown on the graph, the historical data exhibit a drastic change of slope beginning during the early 1950s and then continuing with a flatter slope through 1995. This flattening of the slope of the historical data compared to the straight-line extension of the pre-1950 data trend (red dashed line) indicates that the flow discharging from the drain was significantly reduced – by an average of approximately 39,000 acre-feet per year from 1951 through 1995. While some of this flow reduction may be attributed to improved irrigation efficiency, it more likely than not was due to the loss of groundwater inflows to the drain that resulted from the lowering of groundwater levels caused by irrigation pumping that began in the early 1950s. (Page 21 paragraph 2).*

Response:

It appears that the Montoya Drain data plotted by Dr. Brandes in Figure 5.3 were taken directly from the USBR reports. Detailed review of these reports showed that Reclamation was inconsistent in how it aggregated and reported the drain data. Beginning in 1934 (except for 1937) the flows of the West Drain and NeMexas Drain are included in the Montoya Drain records. Prior to 1934 and in 1937, these flows are not included in the Montoya Drain records, and the recorded flows for these two drains need to be added to the Montoya Drain records during these years to create a consistent historical record.

The reported flows of the Montoya Drain were much greater during the wet period before 1950 than during comparable wet and low pumping periods after 1950. As described above, projecting conditions during the wet period of 1938-1950 forward for comparison to conditions that existed during the drier period after 1950 may exaggerate the apparent deviation in flows. As to the pumping impacts, it should be noted that most of the Montoya Drain is located in Texas and therefore most of the pumping impacts to Montoya Drain flows are likely from Texas wells.

Further, as recognized by Dr. Brandes, there likely are other factors that contributed to the reduction in drain flows other than irrigation pumping. Dr. Brandes specifically mentions improvements in irrigation efficiency as one cause. Other potential causes are listed in the response to Brandes Opinion 10 below.

Brandes Opinion 10 *– A double-mass plot of the cumulative annual Rio Grande at El Paso flow versus the cumulative annual releases from Caballo Reservoir from 1930 - 2017 is presented in Figure 5.4 of the Brandes Report. The deviation of the historical flows curve after 1950 (blue triangles) from the extension of the curve before the 1950s (dashed red line) averages 78,667 acre-feet per year, which is equivalent to a total reduction in the flow of the Rio Grande at El Paso of about 5,000,000 acre-feet for the period from 1951 through 2017, excluding the flood years of 1986-1987 and 1995. Based on this demonstration, it is more likely than not that groundwater pumping in New Mexico within the Rincon and Mesilla basins that began in the early 1950s and continues today played a major role in reducing flows in the Rio Grande at El Paso from what they were prior to the 1950s without groundwater pumping for the same annual quantities of water released from Caballo Reservoir. In essence, the extension of the 1930-1950 curve represents the "no compact violation" condition.*

In essence, the extension of the 1930-1950 cumulative flow curve beyond 1950 to 2017 on the plot in Figure 5.4 (red dashed line) can be considered to represent the cumulative flows of the Rio Grande at El Paso that would have occurred if substantial groundwater pumping had not developed in the Rincon and Mesilla basins. (Page 22 paragraph 2).

Response:

Dr. Brandes initially observes that ground water pumping in New Mexico played a major role in reducing flows in the Rio Grande at El Paso. However, he goes much further in later statements without additional evidence to conclude that extension of the 1930 - 1950 cumulative flow line represents the "no compact violation" condition and that any post-1950 deviations from the 1930 - 1950 projection were caused by pumping in the Rincon and Mesilla basins.

As previously described, Dr. Brandes used reservoir releases for Elephant Butte Reservoir prior to 1938, and this affects the 1930 - 1950 projection line. If Dr. Brandes had instead used the Rio Grande at Percha Dam flow for 1930-1938, the average deviation between the 1930-1950 projection line and the cumulative Rio Grande at El Paso flow would be less than 78,667 AF/y.

Further, it is unreasonable to attribute all deviations from the 1930 - 1950 projection line to New Mexico pumping. There are many other factors that may have contributed to the change in the slope of the double-mass curve in Figure 5.4, including the following:

- Pumping in Texas Mesilla – Well pumping in the Texas portion of the Mesilla basin including Irrigation well pumping, municipal well pumping by EPW at the Canutillo wellfield, and other non-irrigation pumping.
- Pumping in El Paso Valley and Juarez Valley – Well pumping in the El Paso Valley and the Juarez Valley that depleted deliveries of Project water and caused additional water to have to be released from Project storage to deliver water to EPCWID farms.
- Reduction in Reservoir Releases – Generally lower reservoir releases after 1950 coupled with the reduced Project delivery efficiency that exists at lower flows as shown in Figure 5.1 of the Brandes Report.
- Reduction in Diversions and FHG Deliveries – Reductions in surface water diversions and farm headgate deliveries as a result of the reduced reservoir releases that occurred after 1950.
- Increased Project Operating Efficiency – Increases in Project operating efficiency (enactment of annual water allotments, reduced waste, etc.) that occurred after the first Project water shortages in the early 1950s.
- Increased On-Farm Irrigation Efficiency – Increases in on-farm irrigation efficiency resulting from land-leveling, lateral lining, increased use of level basin irrigation, soil moisture monitoring, education, and other factors that led to reduced irrigation return flows.
- Reduced Irrigated Area – Reduction in irrigated area in New Mexico and especially in Texas that led to reduced water demands. Increasingly, the EPCWID did not take delivery of its full annual allocation.
- Changes in Crops – Changes to crops that consume more water and return less water to the stream.
- Implementation of 2008 OA – Implementation of the 2008 OA accounting starting in 2006 that reduced the overall delivery efficiency of the Project through reduced deliveries to EBID and reduced drain flow returns to the Rio Grande.

It is also important to note that the cumulative Rio Grande at El Paso flows plotted in Figure 5.4 of the Brandes Report are year-round flows, including flows during the winter period that are not considered a part of the Project water supply. Review of the Brandes analysis indicates that an average of about 16,000 AF/y of the deviation in El Paso flows from the pre-1950 line is represented by changes in flows during the non-irrigation season. Since there are no Project releases during the non-irrigation season, changes in flows during that time are not considered Project water. Further, since the flows at El Paso during the winter are reportedly comprised primarily of poor-quality drain flows, they are less usable for irrigation than Project supplies during the irrigation season.

For the reasons listed above, it is improper to conclude that pumping in New Mexico was the sole cause of reduced flows in the Rio Grande at El Paso after 1950. While the double-mass curve analysis presented as Figure 5.4 in the Brandes Report does show there was a reduction in flow relative to the releases from Project storage, it provides no information or evidence for what caused the reduction in flow.

In addition, as described above, changes in flow at the El Paso gage are irrelevant to this case, to the Compact, and to the Project operations. What is relevant is that the Project has always operated as a unit, and prior to the 2008 OA, operated to allocate and deliver equal amounts of water to each farm acre based on the D1/D2 procedure, which allowed for conjunctive use of ground water to meet irrigation demands (Lopez, 2019) In order to understand whether pumping anywhere within the Project area has impacted the historical Project deliveries, it is necessary to develop and apply a robust simulation model of the entire Project. As described previously, the simulation model must be capable of simulating the full dynamic response of the Project operations to changes in supply. The simple double-mass curve analyses presented in the Brandes Report are not useful for determining the impact of New Mexico pumping on Texas water deliveries.

Brandes Opinion 11 *– The corresponding annual river flows in the absence of groundwater pumping after 1950 (no compact violation condition) can be estimated by calculating the incremental annual increases in the extended cumulative flow curve (red dashed line). These estimated annual flows of the Rio Grande at El Paso without the effects of groundwater pumping for the 1951-2017 period are plotted on the bar chart in Figure 5.5 along with the corresponding historical annual flows. As expected, the annual flows without the effects of groundwater pumping are higher than the actual historical annual flows which were influenced by groundwater pumping. (Page 23 paragraph 2).*

Response:

Figure 5.5 in the Brandes Report is presented as evidence for the annual effects of ground water pumping on Rio Grande at El Paso flows. The differences between the historical flows and the flows without the effects of ground water pumping in Figure 5.5 of the Brandes Report are plotted in **Figure 11-2.** The green shading in the chart indicates whether there was a full allocation of Project water in each year. The estimates of substantial impacts on El Paso flows during every non-spill year of the study period except 1988 do not make sense given how the Project operates. In full allocation years, it is reasonable to assume that the Project water users took delivery of all of the Project water they were allocated or needed. Therefore, assuming there would be more water in the river without pumping, Reclamation would reduce reservoir releases so that the same amount of water would be delivered to the Project water users in full allocation years, including EPCWID. As a result, in full allocation years without pumping, there should be little if any additional flow at El Paso compared to the historical condition, except for some additional flows during the winter resulting from the increase in drain flows that would occur without pumping.

Because the year-in and year-out effects of pumping shown in Figure 5.5 of the Brandes Report are not consistent with the expected response of the Project to changes in supply, the annual differences in the bars in Figure 5.5 are not reliable indicators of the impact of pumping in the Rincon basin and Mesilla basin on El Paso flows.

Brandes Opinion 12 – *The counterpart to the analysis of the change in the Rio Grande flows at El Paso caused by the development of groundwater pumping in the Rincon and Mesilla basins is a similar analysis of streamflow depletions. For purposes of this analysis, streamflow depletions are defined as the difference between the annual releases from Caballo Reservoir and the corresponding annual flows in the Rio Grande at El Paso. Streamflow depletions in this case are the result of diversions from the river into the main canals for irrigation in the Rincon and Mesilla basins, river channel losses due to evaporation and seepage, and evapotranspiration by vegetation along the river, offset by arroyo inflows to the Rio Grande between Caballo Reservoir and El Paso and discharges into the Rio Grande from irrigation drains and canal wasteways. Figure 5.6 presents the double-mass graph of these cumulative streamflow depletions for the 1930 through 2017 period. Here again, the distinct change in slope after groundwater pumping began in the early 1950s and the increasing deviation of the historical data after the 1950s (brown diamonds) from the projection of the pre-1950 historical data (green dashed line) are indicative of the expected effects of groundwater pumping on streamflow depletions. (Page 23 paragraph 3).*

Response:

The results shown in Figure 5.6 of the Brandes Report are skewed due to the use of Elephant Butte Reservoir releases before 1938. This affects the slope of the green line and inflates the differences between the projected 1930 - 1950 line and the cumulative depletions after 1950.

As described in Section 5, the average annual depletions between Caballo Reservoir and El Paso are about the same today as they were in the late-1930s at approximately 250,000 AF/y.

The criticisms of the double-mass curve analysis of El Paso flows described above also apply to the double-mass curve analysis of Rio Grande depletions in Figure 5.6 of the Brandes Report. The double-mass curve can show there was a change in depletions relative to reservoir releases, but does not inform as to the causes for any changes in depletions. Dr. Brandes provided no evidence to support an opinion that all increases in depletions after 1950 are due to pumping. A robust model capable of dynamic response to changes in flow is necessary to compute the portion of the changes in depletions to Rio Grande flow above El Paso caused by pumping in New Mexico and Texas.

Brandes Opinion 13 *– The various graphical illustrations presented in this section all exhibit the common theme that hydrologic conditions along the Rio Grande in the Rincon and Mesilla basins changed noticeably beginning after the 1950s. While this coincides with the onset of the severe drought of the 1950s that affected much of the southwestern United States, it also is when significant groundwater pumping began to develop and accelerate along the Rio Grande in the Rincon and Mesilla basins to provide a supplemental water supply for irrigation in New Mexico. Based on the significant changes that occurred in the observed Rio Grande flows, streamflow depletions, and drain discharges that began with the substantial increase in groundwater pumping, there is strong empirical evidence that groundwater pumping was a primary cause of these changes, which, in turn, lead to reductions in the availability of surface water supplies from the Rio Grande for Project users in Texas. (Page 24 paragraph 3).*

Response:

While I agree with Dr. Brandes that the graphical illustrations presented in Section 5 show that there were changes in drain flows, Rio Grande flows, and streamflow depletions after 1950 relative to releases from Project storage, his quantification of these changes is affected by his use of Elephant Butte Reservoir releases before 1938 in developing the 1930 - 1950 projection lines in the various figures.

In addition, for the many reasons described above, I also disagree that the empirical evidence presented by Dr. Brandes shows that the post-1950 changes are due solely to New Mexico pumping. A robust model capable of simulating the dynamic response of the Project to changes in historical conditions is necessary to assess the effects of New Mexico pumping, Texas pumping, or other operations on El Paso flows and deliveries to Project water users.

***Brandes Opinion 14** – A fundamental premise of Rio Grande Project operations is that the annual supply of water available for Project users each year is determined by the volume of water either in storage or anticipated to be in storage in Elephant Butte and Caballo Reservoirs, and changes in downstream water demands or streamflow depletions do not affect the amount of the available supply. (Page 30 paragraph 5).*

Response:

It is incorrect to state that the available Project supply is solely determined by the volume of water either in or projected to be in Project storage each year. Review of the RGJI report and the record of the deliberations of the engineer representatives of Colorado, New Mexico, and Texas indicates they were very aware of the many factors that cause variations in Project water supply. The amount of water in storage at the beginning of the season and the reservoir inflows during the irrigation season are obviously important in determining the available water supply. However, the drain flows and other return flows from irrigation downstream of the reservoirs contribute substantially to the Project supply and therefore are of significant importance to the Project operation.

The amount of water that is actually released from storage and delivered for use also depends on the demands of the Project water users. In some years, the districts request delivery of most or all of their allocation and in other years they request less. As shown in **Figure 4-5**, EBID has historically requested delivery of most or all of its allocation more often than has EPCWID.

In summary, Project releases are affected by (a) the amount of water available in storage at the beginning of the irrigation season, (b) the inflows to storage during the irrigation season, (c) the gains and losses between the Caballo outlet and the downstream delivery points, and (d) the demands of the Project water users.

The effects on Project operations resulting from variations in downstream operations is evident in comparisons of historical canal heading diversions to historical reservoir releases and historical Project supplies. **Figure 11-3** contains scatter plots of the canal heading diversions versus reservoir releases during the typical March – October irrigation season. Separate graphs are presented for the canal heading diversions of EBID, EPCWID, JID, and the total. Each plot shows a range of diversions for similar reservoir releases. This is consistent with the descriptions of Project operations in the RGJI (NRC 1938), Project histories (Reclamation, 1992), operating manuals, and other information (Reclamation, undated) that indicate reservoir releases are set to deliver the amounts ordered by the Project water uses in combination with the drain flows and other gains and losses between the reservoir and the delivery points. For example, the graph of total Project diversions in the lower right of **Figure 11-3** shows that for approximately the same reservoir release, the annual diversions varied by 200,000 AF or more. Conversely, for approximately the same annual diversion, the annual reservoir releases varied by 150,000 AF to 200,000 AF.

Similar charts are presented in **Figure 11-4** showing the same irrigation season diversions plotted against the total available Project supply computed as the end of February Project storage plus the March - July reservoir inflows. There is even more scatter in the data in the graphs in **Figure 11-3** than in the graphs in **Figure 11-4**.

Another set of charts is presented in **Figure 11-5** to illustrate the year-to-year variability in Project operations. The upper left chart plots the irrigation season diversion ratio vs. the irrigation season releases and the upper right chart plots the diversion ratio vs. the annual available Project supply (end of February storage plus March-July inflows). There is substantial variability in the diversion ratio for similar annual reservoir releases and for similar annual Project supply. The diversion ratio will be higher when there are more drain flows and other return flows available to help meet diversion demands, and the diversion ratio will be lower when the return flows are lower and more reservoir water has to be released to meet demands.

Finally, the lower left chart in **Figure 11-5** shows the irrigation season reservoir releases versus the annual available Project supply. This chart shows substantial variation in annual reservoir releases for the same annual available Project supply. This variability reflects the wide range of downstream conditions that affect how much reservoir water is needed to be released to meet Project water demands.

Brandes Opinion 15 – *It is significant to note, however, that the operation of Elephant Butte and Caballo Reservoirs and the annual allocation of Project water and the associated releases from Caballo do not appear to have noticeably changed as a result of the groundwater pumping. The graph in Figure 6.4 presents a plot of annual reservoir releases from Caballo Reservoir versus the corresponding maximum combined storage in Caballo and Elephant Butte Reservoirs prior to and during the irrigation season. The storage data on this plot are limited to years when the total storage was less than 1,500,000 acre-feet because with storage amounts greater than this, annual releases have been somewhat erratic due to high river flows and releases of flood water. Data plotted on the graph are segregated into two time periods; one for 1940-1955 before the effects of groundwater pumping had fully evolved and the other for 1956-2014 after significant groundwater development had occurred. (Page 38 paragraph 4).*

Response:

The combined maximum storage in Figure 6.4 of the Brandes Report is not an accurate measure of the available annual Project water supply. Dr. Brandes computed the maximum storage separately for Elephant Butte Reservoir and Caballo Reservoir for each year based on the historical maximum end-of-month storage in each reservoir in each month from December - July. The maximum amounts for each reservoir were added together to determine the annual values plotted on the x-axis in Figure 6.4.

One problem with the Brandes methodology is that the maximum monthly storage values for each reservoir may come from different months within the December - July period, and in this instance the sum of those maximum values will exceed the maximum combined end-of-month reservoir storage for that year.

A larger problem is that the maximum monthly reservoir contents is not an accurate representation of the available supply because it does not reflect the reservoir releases before the maximum storage month, nor does it reflect the reservoir inflows after the maximum month. A better indication of the available Project supply is the end-of-February storage contents plus the sum of the reservoir inflows during March - July. These totals have appeared in prior Reclamation summaries of the Project water supply (Reclamation, 2012). This preferred indication of Project supply was used in the graphs in **Figure 11-4** and **Figure 11-5**.

Notwithstanding the inaccurate measure of Project supply plotted on the x-axis, the data plotted in Figure 6.4 of the Brandes Report do not show what Dr. Brandes claims they show. First, he states that the 1940 - 1955 data points shown as blue dots represent conditions before the effects of pumping had fully evolved. This is contrary to analyses presented in other portions of Dr. Brandes report where he describes the effects of pumping that began substantially affecting flows in 1951. Second, for similar maximum storage contents, the data in Figure 6.4 show releases from Caballo that range approximately between 100,000 AF to 200,000 AF. The reason for variations in the annual releases for similar reservoir contents is the annual variation in conditions downstream of the reservoir. This is similar to the scatter shown in the data in **Figure 11-3** through **Figure 11-5** and explained in more detail in the accompanying narrative.

Brandes Opinion 16 – *Notwithstanding the process embedded in the Operating Agreement for attempting to mitigate for the effects of groundwater pumping in New Mexico on deliveries to Texas, the fact remains that groundwater pumping along the Rio Grande in the Rincon and Mesilla basins of New Mexico is not limited and continues at significant levels, adversely affecting flows in the river and diversions for Project water users in Texas. This is evident by the data presented on the graphs in Figures 4.7, 5.4 and*

5.6 where the post-2007 data exhibit little change from conditions prior to adoption of the Agreement. (Page 38 paragraph 3).

Response:

The 2008 OA continued to allocate water to Texas and Mexico based on the D1 and D2 Curves and therefore these two entities generally receive the same allocation of water for a given amount of water in Project storage that they received under the original D1/D2 allocation procedure. To the extent that Project does not perform at the level implicit in the D1 and D2 Curves, the entire amount of the underperformance is born by a reduced allocation to New Mexico water users.

As described above, the D1 and D2 Curves implicitly grandfathered in the effects of pumping during 1951 - 1979 by New Mexico, Texas, and Mexico on Project performance and Project deliveries. To the extent that the annual flow at El Paso has declined further relative to releases from the Project storage since the 2008 OA was enacted, this may be caused in part by EPCWID taking less delivery of its allocation since the agreement was enacted. Prior to 2008 under the D1/D2 accounting in years that EPCWID had an allocation of more than 350,000 AF, the Project water deliveries to EPCWID averaged about 319,000 AF/y. Since 2008 under the 2008 OA EPCWID has taken delivery of an average of 288,000 AF/y in years with an annual allocation exceeding 350,000 AF, or about 30,000 AF/y less than before the 2008 OA was enacted.

Further, the bargain of the 2008 OA was that the percentage of surface water allocated to EPCWID would be increased, the percentage of surface water allocated to EBID would be decreased, and individual carryover accounts would be created in Elephant Butte Reservoir; and in exchange, EBID could pump additional ground water to make up for the reduction in its surface water deliveries. This forced reliance on ground water for EBID under the 2008 OA, would have reduced non-irrigation season return flows that reached the El Paso gage, and this would have contributed to further deviations in the double-mass curve lines after 2008. This impact of the 2008 OA was ignored by Dr. Brandes.

Brandes Opinion 17 – *The graph in Figure 7.2 presents an application of [the double-mass curve methodology] to the New Mexico deliveries to farms data for the 1938-2016 period. As shown, the curve represented by the historical data on this graph exhibits the same break in slope around the early 1950s as the curve for the Rio Grande flows at El Paso shown in Figure 5.4. Again, this supports the conclusion that groundwater pumping in the Rincon and Mesilla basins for irrigation of farms in New Mexico, which began to develop during the early 1950s, more likely than not impacted the deliveries of Project water to farms in New Mexico. The total reduction in farm deliveries for the 1951-2016 period is* *about 2,100,000 acre-feet, which translates to an average annual reduction of 33,547 acre-feet. (Page 41 paragraph 4).*

Response:

As for the other double-mass curves in the Brandes Report, the projection of the 1930 - 1950 line in the Figure 7.2 is skewed by the use of Elephant Butte Reservoir releases during 1930 - 1937. As described above, there are likely many other reasons that annual Project deliveries decreased relative to Project releases after 1950, and these would have also affected deliveries to New Mexico farms. To the extent that ground water pumping did affect deliveries to New Mexico farms, this obviously means that New Mexico pumping does not somehow only affect El Paso flows. In fact, because New Mexico nominally was allocated 57 percent of the Project supply (until 2008) and tended to use more of its allocation than did Texas, any changes in Project performance, regardless of the cause, would generally tend to impact deliveries to New Mexico users more than deliveries to Texas water users.

In addition to the change in slope of the New Mexico deliveries in Figure 7.2 in the early 1950s, there is another break in slope around the time that the 2008 OA went into effect. This would be consistent with the significant reduction in Project water allocations to New Mexico that resulted from the provision of the 2008 OA that causes New Mexico to bear the effect of any and all negative deviations of Project performance from the performance that is implicit in the D1 and D2 Curves.

A robust model capable of simulating the dynamic response of the Project to changes in historical conditions is necessary to assess the effects of New Mexico pumping, Texas pumping, or other operations on deliveries to New Mexico farms.

Brandes Opinion 18 *– The estimated annual values of the New Mexico farm deliveries without the reductions caused by groundwater pumping can be determined by calculating the annual incremental increases in the 1951-2016 extension of the 1938-1950 data curve (red dashed line). These values are plotted on the bar chart in Figure 7.3 along with the corresponding historical deliveries to farms in New Mexico for the 1951-2016 period. (Page 43 paragraph 1).*

Response:

Figure 7.3 in the Brandes Report compares the historical annual deliveries to New Mexico farms to the estimated annual deliveries without the effects of pumping derived from the double-mass curves presented in Figure 7.2. The estimates of substantial impacts on deliveries to New Mexico farms in all years of the study period do not make sense given how the Project operates. In full allocation years, it is reasonable to assume that the Project water users took delivery of all of the Project water they were allocated or needed. Therefore, assuming there would be more water in the river without pumping, Reclamation would reduce reservoir releases so that similar amounts of water would be delivered to the Project water users in full allocation years, including EBID. Because the year-in and year-out effects of pumping shown in Figure 7.3 of the Brandes Report are not consistent with the expected response of the Project to changes in supply, the annual differences in the bars in Figure 7.3 are not reliable indicators of the impact of pumping in the Rincon basin and Mesilla basin on deliveries to EBID farms.

Brandes Opinion 19 *– Estimates of the total annual deliveries to Texas in the El Paso Valley have been derived by subtracting from the irrigation-season Rio Grande flow at El Paso the amount of water diverted into the Acequia Madre for Mexico and adding the annual quantities of the City of El Paso's Canutillo well field pumping. These annual values are plotted on the bar chart in Figure 7.4 along with the corresponding annual deliveries to Texas farms in the Mesilla basin as developed by Montgomery. (Page 43 paragraph 2).*

Response:

The estimates of annual Texas deliveries in Figure 7.4 of the Brandes report are not reasonable estimates of deliveries to water users in Texas. The estimates of annual Texas deliveries generally represent the flow at El Paso adjusted to include Canutillo wellfield pumping and exclude Acequia Madre diversions. As such, these estimates overstate Texas deliveries because they are not reduced for the substantial conveyance losses between the El Paso gage and the Texas farm headgates and the EPW diversion points.

Brandes Opinion 20 *– The double-mass analysis approach has been applied to the historical total Project water deliveries to Texas to assess apparent changes in historical delivery patterns relative to releases from Caballo Reservoir. As shown in Figure 7.5, the curve represented by the historical data on the graph exhibits the same downward change in slope during the early 1950s as depicted on the double-mass graph for deliveries to farms in New Mexico in Figure 7.2. Again, more likely than not this is indicative of the effects of groundwater pumping that began about this same time in the Rincon and Mesilla basins for irrigation of farms in New Mexico. The deviation of the curve represented by the Texas total historical deliveries data (green squares) after 1950 from the extension of the 1938-1950 data curve out to 2016 (red dashed line) demonstrates that there was less water delivered to Texas relative to the releases from Caballo Reservoir. The total reduction in the total deliveries for the 1951-2016 period is about 2,400,000 acre-feet, which translates to an average annual reduction in deliveries of 39,689 acre-feet per year. Whether these reductions in deliveries to Texas are directly attributable to the effects of groundwater pumping in the Rincon and Mesilla basins of*

New Mexico may not be clearly established with this demonstration; however, the trend of reduced deliveries after groundwater pumping began in the late 1950s certainly is consistent with the reductions in the Rio Grande flows at El Paso. Based on these trends, one would conclude more likely than not that groundwater pumping in the Rincon and Mesilla basins played a major role in adversely affecting deliveries of Project water to Texas. (Page 45 paragraph 2).

Response:

The alleged reduction in Texas deliveries of 39,689 AF/y described in the report text does not match the 37,689 AF/y reduction shown on Figure 7.5.

The previously described issue with use of Elephant Butte Reservoir releases during 1930 - 1937 affects the projection of the 1930 - 1950 data in Figure 7.5 (dashed red line). As previously stated, a double-mass curve can illustrate a change in the relationship between two variables (in this case reservoir releases and Texas diversions); however, it does not provide information on the cause(s) of the change. Dr. Brandes admits that the curve in Figure 7.5 does not clearly establish that the reductions in Texas diversions are caused by New Mexico pumping. As described above, there are many factors other than New Mexico pumping that may have affected downstream water supplies relative to Caballo releases, and these factors would have also affected Texas diversions.

A robust model capable of simulating the dynamic response of the Project to changes in historical conditions is necessary to assess the effects of New Mexico pumping, Texas pumping, or other operations on diversions by Texas and deliveries to Texas farms.

Brandes Opinion 21 – *The deliveries of Project water to Texas that would have occurred in the absence of these apparent effects of groundwater pumping can be derived from the incremental annual increases in the projected extension of the 1938-1950 data curve from 1950 out to 2016 (red dashed line) in Figure 7.5. The resulting annual Texas deliveries without the effects of groundwater pumping are plotted on the bar chart in Figure 7.6 along with the corresponding historical Texas deliveries. As shown, the total deliveries to Texas without the effects of groundwater pumping generally are greater than the historical deliveries, thus demonstrating the adverse impacts of groundwater pumping. As discussed above, the average reduction in Texas deliveries from the projected deliveries without the effects of groundwater pumping in the Rincon and Mesilla basins is about 40,000 acre-feet per year. Since both the historical delivery values and the projected delivery values without groundwater pumping reflect the underlying calculation approach for estimating the historical deliveries of Project water in the El Paso Valley, any inherent uncertainties in this approach are embedded in both sets of total deliveries, which* *suggests that the calculated annual differences between the two sets of total delivery values are likely unaffected by these uncertainties. (Page 45 paragraph 3).*

Response:

Similar to the above criticisms of Figure 5.5 in the Brandes Report, the annual differences between the historical Texas deliveries (actually diversions as described above) and the estimated deliveries without pumping do not make sense in the context of the Project supply conditions. For example, there are significant differences between the green bars and orange bars in each year from 1979 - 1985 and yet these were full supply years under the Project, and Texas would have received the same full allocation with or without the effects of pumping. Further, during 1979 - 1985 EPCWID's Project water deliveries averaged approximately 58,000 AF/y less than its average annual allocation (see **Table 4-3**). During these full supply years that EPCWID left substantial portions of its annual allocations unordered and unused, it is unreasonable to claim that Texas deliveries were being impacted by New Mexico pumping. The annual effects of pumping on Texas deliveries allegedly shown in in Figure 7.6 of the Brandes Report are not consistent with the expected response of the Project to changes in supply, and therefore the annual differences in the bars in Figure 7.6 are not reasonable or reliable indicators of the impact of New Mexico pumping on Texas deliveries or diversions.

I disagree that cancelling of errors in the method used to compute the Texas deliveries causes the results to be unaffected by the errors. Cancelling of errors does not relieve the method of its deficiency in not considering the conveyance losses in delivering water to Texas farmers. There is also the problem of the 1930 - 1950 projection line being skewed by the use of Elephant Butte Reservoir releases. Finally, the 1930 - 1950 projection line inherently assumes there is no variability in the straight-line accumulation of annual values in the dashed red line in the double-mass plot in Figure 7.5. The lack of variation in the dashed red line compared to the inherent annual variability in the green squares likely introduces significant error when deriving annual values from the differences between the projected 1930-1950 line and the accumulation of actual values in the green squares.

12.0 RESPONSE TO MONTGOMERY AND ASSOCIATES REPORT

Staffan W. Schorr and Colin P. Kikuchi, Ph. D. of Montgomery & Associates ("M&A") prepared a May 31, 2019 expert report on behalf of the State of Texas entitled, *Water Budget Estimates in Support of Groundwater Model Development: Rincon and Mesilla Basins, New Mexico, Texas, and Northern Mexico, 1938 Through 2016* ("M&A Report"). Information in the M&A Report was used for three primary purposes. First, M&A compiled much of the hydrologic and water use data for the study area into a database for use by the other Texas experts. Second, M&A prepared water budgets for the Rincon and Mesilla basins for the period from 1938 - 2016 period for the purpose of estimating certain inputs for the Texas Model, including irrigation pumping, and return flows from irrigation and non-irrigation uses. Finally, M&A prepared a water budget analysis of irrigation operations in the El Paso Valley in Texas that was used in analysis of alleged damages to Texas from water quality impacts caused by New Mexico pumping during the period from 1985 - 2016.

SWE was asked by legal counsel for New Mexico to review the water budget analyses and data compilations presented in the M&A Report to identify information or opinions that we disagreed with, and to prepare expert opinions to respond these issues. We attempted to identify and respond to all substantive issues in which there appeared to be differences of opinion, however a lack of response to a particular issue should not be interpreted as tacit agreement with the opinions in the M&A Report.

M&A Opinion 1 *– I prepared separate water budgets for Rincon Basin and Mesilla Basin because the basins are separated by a bedrock constriction, which limits the hydrologic connection between the basins. The overall water budget for each basin comprises three types of budgets: Land-Surface Water Budget, Surface Water Budget, and Groundwater Budget. I used this approach to facilitate budget development by compartmentalizing common components. (Page 3 paragraph 2 and 3).*

Response:

The Montgomery water budget analyses provide comprehensive and detailed accounting of the inflows and outflows of (a) the Land Surface system, (b) the Surface Water system, and (c) the Groundwater system using actual data, estimated data, and water balances, and other calculation and modeling techniques. Certain of the computed water budget terms were used as inputs to the Texas Model and these were the focus of our review of the M&A analyses.

In all water budget analyses the sum of the inflows minus the sum of the outflows equals the change in storage. For the Land Surface Budget, this would be the change in soil moisture storage. For the Ground Water Budget this would be the change in ground water storage in the subsurface aquifers. In the Surface Water Budget, there are no changes in storage at the monthly time scale the budgets were prepared, and there are no reservoirs simulated (Elephant Butte Reservoir and Caballo Reservoirs are upstream of the geographical areas included in the water budget analyses).

Figure 12-1 through **Figure 12-3** summarize that computed average annual values for each of the water budget terms in the M&A Land-Surface Budget, Surface Water Budget, and Groundwater Budget, respectively. Positive values (bars to the right) represent inflows to the system and negative values (bars to the left) indicate outflows from the system. Changes in storage are shown as positive or negative as appropriate.

The bars in **Figure 12-1** through **Figure 12-3** are color-coded in relation to whether and how each of the water budget terms are used in the Texas Model.

- Blue bars – Model inputs that do not change in the reduced pumping model runs.
- Red bars – Model inputs that change in the reduced pumping model runs.
- Yellow bars – Quantities that are simulated in the model.
- Black bars – Quantities that are neither input to or simulated in the model.

For the water budget values that are inputs to the model, the abbreviations at the end of the bars indicate the whether the values are input through the MODFLOW WEL Package as cell-by-cell inputs or through the MODFLOW SFR Package as stream segment inputs.

The size of the bars gives an indication of the relative significance of the water budget terms to the three water budgets and to the modeling. The colors of the bars reflect the importance of the terms to the modeling of alternative scenarios. Model inputs that are changed between model runs (red bars) or are simulated in the model (yellow bars) are most significant. Model inputs that do not change between runs are less significant because they have little effect on the simulated differences between model runs. Obviously, the quantities that are not input or simulated in the model (black bars) are of least importance in the modeling. Note that while the on-farm consumptive use is not simulated in the model, the specified amount of consumptive use in the Land Surface Budget affects the computed pumping and irrigation returns flows (deep percolation and surface runoff) that are inputs to the Texas Model.

M&A Opinion 2 *– A farm water budget analysis was conducted to estimate monthly farm deep percolation and agricultural applied groundwater pumping in each basin (Rincon* *basin and Mesilla basin). In addition, estimates for change in agricultural soil moisture storage and agricultural surface water return flows were also determined by the farm water budget analysis. (Page 16 paragraph 1).*

Response:

The M&A Farm Budget Model was used to compute inputs to the Texas Model for applied ground water pumping for irrigation, and on-farm deep percolation and surface runoff from irrigation in the Rincon and Mesilla basins. The Farm Budget analysis was performed for the period from 1938 - 2016 using a monthly timestep. The monthly results were aggregated to annual values for input to the Texas Model which has annual stress periods.

The M&A Farm Budget Model is similar to the SWE CFB Model (and to the almost identical RiverWare farm budget algorithm) in that both models use a mass balance water budget approach to simulate the on-farm water deliveries, consumptive use, soil moisture storage, and irrigation return flows. In addition, supplemental pumping is assumed to meet unmet irrigation demands after commencement of widespread irrigation pumping in the Rincon basin and Mesilla basin. While there are similarities in the farm budget simulations, there are also some significant differences in model inputs and processes that result in material differences in the farm budget model outputs for irrigation pumping and on-farm irrigation losses due to deep percolation and surface runoff.

M&A Opinion 3 *– A soil water balance model was developed to estimate agricultural groundwater pumping and deep percolation over the time period of interest, 1938 through 2016. The model tracks soil moisture within the maximum extent of irrigated agricultural lands of the Rincon and Mesilla basins on a monthly time step. Four separate models were developed for this analysis: lands inside District boundaries in Rincon Basin, lands outside District boundaries in Rincon Basin, lands inside District boundaries in Mesilla Basin, and lands outside District boundaries in Mesilla Basin. The models follow identical governing equations and differ only in their respective data inputs. (Page 19 paragraph 1).*

Response:

The soil water balance model developed by M&A is a complex, non-linear iterative model. Inputs to the model include precipitation, applied surface water, and ground water pumping; and outputs consist of crop evapotranspiration (“ET”), deep percolation (“DP”), and soil moisture storage. The crop evapotranspiration and deep percolation are computed as functions of the soil moisture storage, and the soil moisture storage depends on the computed ET and DP. Because of these interdependencies, an iterative simulation process is performed in the model to simultaneously solve for the ET, DP, and soil moisture in each monthly stress period.

The soil water balance model simulates "virtual fields" for the Rincon basin and the Mesilla basin (including the Texas portion of the Mesilla basin) that are intended to represent aggregations of all the fields in each basin. Each virtual field is simulated as if it was a gravity-irrigated field as illustrated in Figure 2.3 of the M&A Report. Applied irrigation water (surface water and pumped ground water) is assumed to be introduced at the top of the field (left side in Figure 2.3) and assumed to flow across the virtual field to the bottom of the field (right side in Figure 2.3). Because irrigation water is present at the top of the field longer than at the bottom of the field, the soil water balance model simulates more infiltration of surface water at the top of the field than at the bottom of the field. Thus, the top of the virtual field can be adequately irrigated to bring the soil moisture to a level sufficient to avoid crop stress and meet the full ET demand of the crop, while the lower portion of the field can be insufficiently irrigated resulting in crop stress and a reduction in crop ET.

There are two time-series ET inputs to the soil water balance model that come from Land IQ. The first is the crop-weighted average theoretical ET computed as the reference ET multiplied by crop coefficients obtained from various references. The crop coefficients used by Land IQ were not locally calibrated. The second is an adjusted ET that is roughly 30% less than the theoretical ET until about 1970, with the adjustment transitioning to no adjustment by about 1990.

The parameterization of the soil moisture distribution under each virtual field is adjusted in the M&A soil water balance model during each month of the study period so that the simulated soil moisture across the virtual field is at the levels necessary for the computed aggregate ET to match the adjusted ET from Land IQ. Before 1970, when the target ET for most crops is 30% lower than the theoretical ET, the soil water balance model is calibrated to simulate substantial soil moisture stress in order for the simulated ET to match the target ET. The simulated soil moisture stress is gradually reduced during 1970 - 1990 as the adjusted ET from Land IQ transitions to the full theoretical ET. After that time, there is little or no simulated soil moisture stress and therefore the ET computed in the soil water balance model reaches the full theoretical ET across the entire virtual field.

There are five soil moisture states that represent important soil moisture thresholds in the root zone of an irrigated crop. These soil moisture thresholds are listed below in order from low to high soil moisture levels:

- Residual Moisture – Lowest soil moisture level.
- Wilting Point – Soil moisture level below which the crop is incapable of extracting water through the roots.
- Critical Moisture – Soil moisture level below which the crop will begin to experience stress and a reduction in ET.
- Field Capacity – Approximately maximum soil moisture content that can be retained in the soil against gravity. This typically occurs within a few days after a thorough irrigation or heavy precipitation event after gravity drainage of moisture stored temporarily above the field capacity level.
- Porosity – Maximum soil moisture content in which the soil is saturated and virtually all of the pore spaces between the soil particles are filled.

As described above, the soil water balance model simulates a continuous range of soil moisture across each virtual field creating sufficient stress (or no stress) so that the simulated aggregate ET matched the adjusted ET values from Land IQ. The model generally simulates less soil moisture stress through time as the adjusted ET values become closer to the theoretical ET values.

Figure 12-4 and **Figure 12-5** contain graphs that show the simulated monthly soil moisture in the Rincon and Mesilla virtual fields during the 1938 - 2016 study period. Each graph contains five dotted horizontal lines that represent the five soil moisture states referenced above. The solid black line represents the simulated maximum soil moisture level (θmax) at the top of the virtual field where infiltration would be greatest. The solid grey line represents the simulated minimum soil moisture level (θmin) at the bottom of the virtual field where infiltration would be least. The solid red line is the simulated average soil moisture across the virtual field (θavg).

The graphs for the simulated virtual fields representing the Rincon basin and Mesilla basin are generally similar. The following observations regarding the soil water balance model simulation of the Mesilla virtual field illustrated in **Figure 12-5** are also generally applicable to the simulation of the Rincon virtual field.

1. Maximum Soil Moisture – The simulated maximum soil moisture at the top of the field (black line) fluctuates from month to month, but remains well above the field capacity of the soil, and often reaches the total porosity of the soil. This result is nonsensical as the soil moisture in the root zone of a crop cannot physically remain above field capacity for more than a few days after an irrigation. The soil water balance model simulates the soil moisture at the top of the virtual field well above field capacity for the entire 1938 - 2016 simulation period.

2. Minimum Soil Moisture – The simulated minimum soil moisture at the bottom of the field (grey line) fluctuates from month to month, but remains below the wilting point through the mid-1980s. This is also nonsensical as it indicates that prior to the mid-1980s, significant portions of the fields in the Mesilla basin never had sufficient soil moisture to produce any ET. In other words, the crops were dead in those portions of the fields.
3. Average Soil Moisture – The average soil moisture fluctuates between field capacity and the critical level until around 1970. After that time, the average soil moisture begins fluctuating above field capacity for months at time through about 1985 and then generally remains continuously above field capacity through the remainder of the study period. As described above, this result in nonsensical.

The soil moisture conditions simulated in the M&A soil water balance model are illustrated in another form in the graphs presented in **Figure 12-6**. These figures show the simulated soil moisture conditions across the virtual field from top to bottom for an entire year at 10-year intervals from 1945 - 2015. There are four charts on each page and each chart shows the conditions for a three-month period – Jan-Mar, Apr-Jun, Jul-Sep, and Oct-Dec. The solid lines in each chart display the simulated soil moisture, which is highest at the top of the field and lowest at the bottom of the field. Note that the vertical axis for the soil moisture is reversed so as to intuitively mirror the infiltration of water below the ground surface. For reference, each chart includes horizontal dashed black and grey lines that depict the five key soil moisture states described above.

Also shown in each chart is the simulated crop stress coefficient (Ks) for each month across each virtual field, represented as dotted lines that are read on the right axis. The soil moisture water balance model simulates soil moisture stress when the simulated soil moisture falls below the critical level. The stress coefficient increases linearly from 0% at the critical soil moisture to 100% at wilting point. When the stress coefficient is at 0.0, the ET simulated in the soil water balance model is at the full theoretical value, and when the stress coefficient is at 1.0 the simulated ET is zero.

The following are observations of the conditions during the principal growing season (April - September) in decadal interval charts presented in **Figure 12-6**.

- 1945 - 1965: 40% of the field is above field capacity, 60%-70% of the field is above critical soil moisture with no stress and full theoretical ET. 10%-20% of the field is in a stressed condition with reduced ET. 20% of the field is at or below wilting point, indicating the crop is dead.
- 1975: 40%-50% of the field is above field capacity, 65%-75% of the field is above critical soil moisture with no stress and full theoretical ET. 10%-20% of the field is

in a stressed condition with reduced ET. 20% of the field is at or below wilting point, indicating the crop is dead.

- 1985: 60% of the field is above field capacity, 85% of the field is above critical soil moisture with no stress and full theoretical ET. 10%-15% of the field is in a stressed condition with reduced ET. 5% or less of the field is at or below wilting point, indicating the crop is dead.
- 1995 - 2015: 70% of the field is above field capacity, 95% or more of the field is above critical soil moisture with no stress and full theoretical ET. 5% or less of the field is in a stressed condition with reduced ET. None of the field is at or below wilting point.

The results from the M&A soil water balance model are nonsensical because they depict simulated conditions that are physically impossible and contrary to the conditions that would be expected to exist in a productive and well-managed irrigation district like EBID in the Rincon and Mesilla basins. As described above, it is physically impossible for the moisture content in the crop root zone of a well-drained soil to be above field capacity for more than a few days after an irrigation. It is also wholly unreasonable for 20% of the virtual field representing all fields in the Mesilla basin to be under soil moisture stress and another 20% of the virtual field to be dead during all simulated years through about 1970. This would reflect a level of irrigation incompetence that is not consistent with (a) farmers whose livelihood depends on their work, and (b) the adequate water supply that existed between the available Project supply and the supplemental ground water available to most farmers.

***M&A Opinion 4** – Annual surface water deliveries to farms (farm deliveries) and agricultural groundwater pumping in Rincon and Mesilla basins are shown on Figures 2.9 and 2.10, respectively. Agricultural groundwater pumping in Rincon and Mesilla basins varied through time depending principally on surface water availability. Groundwater pumping generally increased during years when surface water deliveries were low, and vice versa. The largest groundwater withdrawals occurred during the early to mid-1950s, and from 2003 through 2016, when surface water deliveries to farms were small for many consecutive years. The smallest amount of groundwater pumping occurred during the period of full Project allotment from 1979 through 2002. (Page 45 paragraph 2 and 5).*

Response:

Figure 12-7 through **Figure 12-9** summarize and compare various annual values from the M&A Farm Budget Model and the SWE CFB Model. One of the key outputs from the models is the simulated pumping, as the effects of ground water pumping are a primary focus of the case. The differences in the simulated annual pumping in large part reflect the aggregation of all differences in input data and computational methods into a single result. This is because pumping to compute the unmet demand after applied surface water is one of the last steps in both the M&A Farm Budget Model and the SWE CFB Model.

The simulated annual pumping volumes from the M&A Farm Budget Model and the SWE CFB Model for the Rincon and Mesilla basins combined are shown in **Figure 12-7**. The simulated annual pumping in the SWE CFB Model exceeds the pumping in the M&A Farm Budget Model in most years until the early 1980s when the results flip and the M&A Farm Budget Model pumping exceeds the SWE CFB Model pumping in most years through the remainder of the study period.

Most of the differences in the outputs from the M&A Farm Budget Model and the SWE CFB Model, including the differences in pumping, are due to differences in the following:

- Irrigated area,
- Crop evapotranspiration,
- Farm headgate deliveries,
- On-farm seepage losses, and
- Soil moisture simulation procedure.

The M&A Farm Budget Model includes two soil water balance models for each simulated region (e.g., two models for the Mesilla basin Project lands). One model simulates irrigation and evapotranspiration for the cropped area that is being actively irrigated, and another model simulates bare soil evaporation in the non-cropped or fallowed area.

The simulated cropped area varies from month to month depending on the monthly ET for each crop. If there is no ET demand (i.e., during the early spring before the crop has been planted or during the fall and winter after the crop has been harvested) M&A assumed the crop was not irrigated (with some exceptions for simulated pre-irrigation). The land associated with a crop is in the crop model if it is being irrigated and in the non-crop model if it is not being irrigated. As a result, the simulated area in the crop model is highest in the middle of the irrigation season and lowest or zero in the winter. As the simulated irrigated area changes through the year, the simulated soil moisture is transferred between the two soil water balance models based on changes in the overlying areas. When the cropped area increases from one month to the next, a portion of the non-cropped soil moisture is moved to the irrigated model, and when the cropped area decreases, a portion of the cropped area soil moisture is moved to the non-irrigated model.

The upper right chart in **Figure 12-8** compares the sum of the maximum monthly cropped areas in each year in the Rincon and Mesilla basins in the M&A Farm Budget Model to the comparable annual irrigated areas in the SWE CFB Model. The total crop area for the Rincon and Mesilla basins is generally higher in the M&A Farm Budget Model than in the SWE CFB Model until about 1977, when the comparison flips and the area in SWE CFB Model is higher than the M&A Farm Budget Model through the end of the study period.

The upper left chart in **Figure 12-8** compares the simulated annual ET of applied water in M&A Farm Budget Model against the annual values from the SWE CFB Model. There are two lines for the M&A Farm Budget Model values shown in **Figure 12-8**. The solid line reflects the ET of applied water during the growing season for each crop and the dotted line reflects the addition of computed ET on bare ground outside of the growing season within the annual irrigated acreage for each year. This adjustment was made to make the M&A figures more comparable to the SWE values obtained from DE that also included bare ground ET outside of the growing season.

The difference between the M&A and SWE lines in **Figure 12-8** reflect differences in irrigated area, cropping pattern, unit crop ET values, and other factors. The annual ET of applied water in the M&A Farm Budget Model is generally greater than the annual values in the SWE CFB Model through 1984. From 1985 through the end of the study period, the ET of applied water is greater in the M&A Farm Budget Model during most years and this is the primary reason that the pumping in the M&A Farm Budget Model is also greater during this period.

The lower left chart in **Figure 12-8** compares the area-weighted annual unit crop ET for the Rincon and Mesilla basins for the M&A Farm Budget Model and the SWE CFB Model. The unit ET for the M&A Farm Budget Model was computed as the simulated annual ET volume (shown in the upper left chart in **Figure 12-8**) divided by the simulated maximum monthly irrigated area in that year (upper right chart in **Figure 12-8**). As for the upper left chart, there are two lines for the M&A values. The solid line is the computed weighted average ET for the crop ET and the dotted line adds the additional ET on bare ground within the annual irrigated area. The differences in the annual unit ET values reflect the combination of differences in the unit ET values for the individual crops and differences in the annual crop mix. The unit ET values in the M&A Farm Budget Model are less than in the SWE CFB Model until the mid-1980s, and more than in the SWE CFB Model thereafter.

The lower right chart in **Figure 12-8** summarizes the annual FHG delivery inputs to the M&A Farm Budget Model and the annual totals for the SWE CFB Model. The FHG deliveries are very similar between the two models through 1979, after which there are some differences. The post-1979 differences in FHG deliveries are due to differences in how the EPCWID delivery totals were disaggregated between the El Paso Valley and the Texas Mesilla areas. M&A disaggregated the EPCWID deliveries based on irrigated area, and SWE disaggregated the deliveries based on diversions. On average, the M&A farm headgate deliveries are 4% greater than the SWE farm headgate deliveries during the 1985 - 2016 period.

Another difference between the M&A Farm Budget Model and the SWE CFB Model involves an assumption regarding on-farm conveyance losses. M&A assumed a 10% on-farm conveyance loss, and so the surface water applied to the fields was specified as 90% of the FHG deliveries. The SWE CFB Model does not explicitly simulate on-farm seepage losses, but rather any such losses are incorporated in the specified MFE that is part of the irrigation simulation procedure in the SWE CFB Model. Note that the M&A FHG deliveries shown in the lower right chart in **Figure 12-8** are before the 10% on-farm conveyance loss.

The SWE CFB Model and the RiverWare Model both employ a widely used water balance process that simulates the process of delivering irrigation water to the field, limiting the amount of water made available for crop water consumption based on a specified maximum farm irrigation efficiency, and simulating storage of irrigation water in the soil moisture reservoir underlying the field for later use when the surface water supply is inadequate. The simulation algorithm in the SWE CFB Model is described in more detail in Section 6.

Figure 12-9 compares the simulated deep percolation and surface runoff from irrigation in the Rincon and Mesilla Valleys The deep percolation is less in the M&A Farm Budget Model than in the SWE CFB Model before the mid-1980s, and then becomes roughly comparable thereafter. Conversely, the surface runoff in the M&A Farm Budget Model is much greater than in the SWE CFB Model.

M&A Opinion 5 *– A non-farm water budget analysis was conducted to estimate consumptive use, runoff, and deep percolation for urban and non-urban (upland watershed) areas in the Rincon and Mesilla basins, based on measured or estimated water supply and wastewater discharges. Non-farm lands in the study area include urban areas and undeveloped areas consisting primarily of native vegetation. The non-farm water budget is subdivided into urban lands and upland areas that are not classified as farm (agricultural) or urban (i.e., watershed area minus farm and urban areas) (Figure 2.1). The urban water budget is evaluated by water source: applied water and precipitation water. The applied water budget analysis is based on measured or estimated groundwater withdrawals (pumping), measured or estimated wastewater discharges, and estimates for consumptive use and deep percolation. The precipitation water budget analysis uses monthly precipitation and estimates for consumptive use (i.e., effective urban precipitation) and runoff to estimate urban deep percolation of precipitation. Use of* *surface water deliveries for non-farm purposes is minor compared to groundwater use and considered negligible for this analysis. (Page 16 paragraph 1 and Page 52 paragraph 1).*

Response:

The M&A Non-Farm Water Budget analyses were also performed for the period from 1938 - 2016 using a monthly timestep with certain results aggregated to annual values for input to the Texas Model.

The M&A Urban Applied Water Budget was used to prepare inputs to the Texas Model for applied ground water pumping for urban and domestic uses, wastewater treatment plant discharges, and urban deep percolation from applied water. While SWE did not prepare a full urban applied water budget, data were compiled or estimated for urban and domestic pumping, WWTP discharges, and urban deep percolation for the entire LRG Area, including the Rincon and Mesilla basins. Several charts were prepared to compare the values used in New Mexico's ILRG Model to the comparable values developed by M&A for the Texas Model as shown in **Figure 12-10**.

The upper left chart in **Figure 12-10** compares the urban and domestic pumping in the Rincon basin and Mesilla basin that were input to the ILRG Model against the values used in the Texas Model. The urban and domestic pumping volumes in the Rincon and Mesilla basins are similar between the Texas Model and the ILRG Model, with slight variations throughout the study period.

The upper right chart in **Figure 12-10** compares the WWTP discharges input to the ILRG Model in the Rincon basin and Mesilla basin against the values used in the Texas Model. The annual WWTP discharges simulated in the ILRG Model average approximately 1,300 AF more than the values used in the Texas Model. The reason for the difference is that (a) the ILRG Model includes estimates of El Paso Electric WWTP discharges prior to the records that begin in 2004 while the Texas Model does not and (b) the ILRG Model uses actual records of Las Cruces WWTP discharges while the Texas Model uses estimates.

The lower left chart in **Figure 12-10** compares the estimated urban deep percolation inputs for the ILRG Model in the Rincon and Mesilla Valleys against the values input to the Texas Model. On average, the urban deep percolation in the Rincon and Mesilla basins is approximately 5,300 AF/y greater in the Texas Model than the ILRG Model, and the Texas Model shows more variability than the ILRG Model throughout the study period. Reasons for differences between the urban deep percolation estimates are generally two-fold. First, the Texas Model estimates reflect an assumption that all pumping from the Canutillo wellfield is used locally in the Texas portion of the Mesilla basin compared to the values for the ILRG Model that are based on estimates of urban deep percolation from all the EPW supplies distributed evenly across all of the EPW service area. Second, the values for the Texas Model were computed as a residual in an urban water budget calculation compared to the values for the ILRG Model that were computed based on percentages of non-irrigation water use.

The M&A Urban Precipitation Water Budget was used to estimate the urban precipitation runoff and urban deep percolation of precipitation that were input to the Texas Model. The lower right chart in **Figure 12-10** shows the annual urban precipitation runoff and deep percolation values that were input to the Texas Model. While the ILRG Model does not simulate urban precipitation runoff and deep percolation, this not a substantive deficiency for two reasons. First, the combined urban precipitation runoff and deep percolation represents only 0.1% of the total input to the Texas Model. Second, these inputs are not varied in the alternative model runs involving changes in pumping. As a result, the presence or absence of simulated urban precipitation runoff and deep percolation will have very little or no effect on the computed differences between the alternative model runs.

M&A Opinion 6 – *Tributary inflows represent the volume of water that flows into the Rio Grande from ephemeral streams as a result of stormwater runoff in the upland areas of the study area. The watersheds that contribute flow to the Rio Grande were taken from a 1996 study by the U.S. Army Corps of Engineers. The majority of tributary arroyos in Mesilla Basin do not contribute runoff discharges to the Rio Grande. Contributing watersheds in each basin are shown on Figure 3.4. Watershed runoff models require detailed streamflow data and information on physical characteristics for drainages and sub-watersheds. The lack of streamflow gages on the majority of drainages to the Rio Grande within the study area prevents the use of surface water modeling for determining tributary runoff for this water budget. Because of this limitation, we estimated runoff as a percentage of the precipitation falling on the contributing watersheds. Tributary inflow was assumed to be three percent of precipitation, based on results of a rainfall-runoff study conducted by Stone and Brown (1975) in a small semiarid watershed in the Jornada Basin in New Mexico. Annual tributary inflows in Rincon and Mesilla basins are shown on Figure 3.5. The estimated average annual tributary flows are about 5,500 AF in Rincon Basin and about 100 AF in Mesilla Basin. (Page 72 paragraph 1, 2, 4 and Page 74 paragraph 2).*

Response:

Precipitation runoff from undeveloped areas as a percentage precipitation can vary widely depending on slope, soils, vegetation cover, precipitation intensity and other factors. The estimate of 3% runoff from the PRISM precipitation data, while not unreasonable, should be considered approximate and having substantial uncertainty.

The estimated average annual tributary inflows from upland areas totaling 5,600 AF/y for the Rincon and Mesilla basins represents only 0.2% of the simulated average annual inflows to the Texas Model. Also, similar to the urban precipitation runoff and deep percolation, the tributary inflows from upland areas do not vary in the alternative runs of the Texas Model and therefore have little or no difference on the computed differences between the model runs.

M&A Opinion 7 – *Natural aquifer recharge in the Rincon and Mesilla Basins principally occurs as mountain-front recharge along the basin margins near the lateral extent of the Santa Fe Formation. Recharge occurs where runoff from precipitation in the upper portions of the watershed infiltrates into the basin alluvium deposits. Mountain-front recharge in the United States portions of the study area was evaluated using the Hearne-Dewey (1988) regression equation for mean annual recharge of a tributary basin. The Hearne-Dewey regression equation was developed, based on data for 16 basins in northern New Mexico, to estimate average annual basin water yield based on winter precipitation, basin slope, and basin area. The Hearne-Dewey (1988) regression analysis yielded mountain-front recharge rates of about 9,360 AF/year and 5,430 AF/year for the Rincon and Mesilla basins respectively. (Page 97 paragraph 3 and Page 99 paragraph 3).*

Response:

The M&A estimates of mountain front recharge are input as specified inflows around the lateral boundaries of the Texas Model. A comparison of the annual M&A mountain front recharge estimates against the annual mountain front recharge in the Rincon and Mesilla basins in the ILRG Model is provided in **Figure 12-11**.

The annual combined mountain-front recharge for the Rincon and Mesilla basins in the ILRG Model averages 15,700 AF during 1951 - 2016 compared to 14,800 AF in the Texas Model. Given that the average difference of 900 AF/y is only 0.03 % of the total inflows to the Texas Model and the mountain front recharge is not varied in alternative model runs, the differences in mountain front recharge between the Texas Model and the ILRG Model is not significant.

M&A Opinion 8 – *I was asked by counsel to develop farm water budget for two agricultural districts located in El Paso Valley, Texas to support economic analyses by Dr. David Sunding and Dr. Lydia Dorrance. The two districts are El Paso County Water Improvement District #1 (EPCWID#1) and Hudspeth County Conservation and Reclamation District 1 (HCRRD1). EPCWID#1 has lands in both Mesilla Basin and El Paso Valley; this* *farm budget considers only the portion of EPCWID#1 located in El Paso Valley. For the analysis, a farm water budget was developed for agricultural lands in EPCWID#1 and HCRRD1 with the principal goals of estimating (1) agricultural groundwater pumping for irrigation and (2) deep percolation beneath agricultural fields. Due to the lack of historic direct measurements of agricultural applied groundwater (pumping) and agricultural deep percolation, soil water balance models were used to estimate these components, along with surface runoff and soil moisture changes on agricultural lands. The soil water balance models were developed and implemented using GoldSim simulation software. Model results were used to prepare the farm water budgets for EPCWID#1 and HCRRD1. (Appendix G, Page 1, Paragraph 1).*

Response:

The monthly farm budget analyses prepared by M&A for the EPCWID (El Paso Valley) and the HCRRD (a.k.a. HDDRD1) for the period from 1985 - 2016 utilized the same soil water balance model as was used for the farm budget analyses of the Rincon and Mesilla basins. These farm budget analyses were compared to the SWE CFB Model analyses for the same areas to assess differences between the input data and results. The farm budget inputs and outputs during the 1985 - 2016 study period are compared in **Figure 12-12** through **Figure 12-14** for the El Paso Valley and **Figure 12-15** and **Figure 12-16** for the HCCRD.

<u>**El Paso Valley**</u>

Figure 12-12 compares the computed annual supplemental pumping in the M&A Farm Budget Model to the comparable values from the SWE CFB Model during the 1985 - 2016 period. The annual pumping in the M&A Farm Budget Model averages about 78,900 AF compared to an average of 14,300 AF in the SWE CFB Model, a difference of about 64,700 AF. The differences in supplemental pumping are due largely to differences in the ET of applied water between the models.

The simulated pumping in the M&A Farm Budget during the full supply years from 1985 - 2002 is unrealistically high considering the following:

- Full Project water allocations made by Reclamation (see **Table 4-3**),
- Unused EP1 allocations (see **Table 4-3**),
- High FHG deliveries per acre (see **Figure 5-12**), and
- High operational waste through this period (see **Figure 5-23**).

The upper right chart in **Figure 12-13** compares the maximum annual cropped area in the El Paso Valley in the M&A Farm Budget Model to the annual irrigated area in the SWE CFB

Model. The M&A Farm Budget Model simulates much greater irrigated area than the SWE CFB Model until the last ten years when the values are similar. On average, the M&A Farm Budget Model acres for the El Paso Valley are about 14% greater than SWE CFB Model acres.

The irrigated area figures used in the M&A Farm Budget Model were provided by Land IQ. Based on review of the Land IQ data files, it seems possible that the irrigated area data that M&A used for the El Paso Valley portion of EPCWID may also include the EPCWID irrigated area in the Texas portion of the Mesilla Valley. This would explain most of the difference in irrigated area between the models in the El Paso Valley.

The upper left chart in **Figure 12-13** compares the annual ET of applied water in the El Paso Valley. The annual ET of applied water in M&A Farm Budget Model is much larger than the SWE CFB Model values throughout the 1985 - 2016 period, averaging about 47% more. In some years, the ET of applied water in the M&A Farm Budget Model is almost double the SWE CFB Model values. The differences are due largely to differences in irrigated area, unit crop ET, and cropping pattern.

The lower left chart in **Figure 12-13** compares the area-weighted annual unit crop ET in the El Paso Valley for the M&A Farm Budget Model and the SWE CFB Model. The differences in the unit crop ET reflect the combined differences in cropping pattern and the unit irrigation requirements of the individual crops. The unit ET for the M&A Farm Budget Model was computed as the annual ET of applied water volume (shown in the upper left chart in **Figure 12-13**) divided by the maximum monthly irrigated area in that year (upper right chart in **Figure 12-13**). The unit ET values in the M&A Farm Budget Model average almost 30% greater than the SWE CFB Model values during 1985 - 2016.

The lower right chart in **Figure 12-13** compares the annual FHG delivery volumes that are simulated in the M&A Farm Budget Model of the El Paso Valley to the SWE CFB Model values. On average, the FHG deliveries in the M&A Farm Budget Model are about 11% less than the values in the SWE CFB Model. It appears that the reported 2010 FHG deliveries for the El Paso Valley may be in error. If these are corrected, the average difference will be larger than 11%.

A closer look at the differences in the annual FHG deliveries is shown in **Figure 12-14**. The small differences in FHG deliveries that are present from 1985 - 2008 are due to differences in how the records of total Eastside Canal and Westside Canal FHG deliveries were disaggregated between EBID and EPCWID. SWE disaggregated the FHG deliveries based on relative diversions and M&A disaggregated the deliveries based on relative irrigated area.

After 2008, the differences in FHG deliveries are more substantial, and except for 2010, in which the data used by M&A appear to be in error[7], the M&A FHG deliveries are much less than the SWE FHG deliveries. During this time (except for 2010), there are no FHG delivery data for the El Paso Valley or for EPCWID. SWE estimated the FHG deliveries after 2008 for the El Paso Valley based on the reported monthly El Paso Valley diversions reduced by monthly average conveyance loss percentages derived from historical records. M&A estimated the missing data by first estimating the Texas Mesilla FHG deliveries from data and estimates of EBID FHG deliveries, then extrapolating the estimated Texas Mesilla FHG deliveries to total EPCWID FHG deliveries, and finally pro-rating those values to estimates of the El Paso Valley FHG deliveries. The convoluted M&A procedure did not consider that EBID and EPCIWD FHG deliveries were no longer comparable on a per acre basis after the 2008 OA went into effect. As shown in the lower chart in **Figure 12-14**, the M&A procedure results in unrealistically low estimates of El Paso Valley FHG deliveries as a percentage of El Paso Valley canal heading diversions.

HCCRD

Figure 12-15 compares the computed annual supplemental pumping in the M&A Farm Budget Model to the comparable values from the SWE CFB Model during the 1985 - 2016 period. The annual pumping in the M&A Farm Budget Model averages about 19,400 AF compared to an average of 2,100 AF in the SWE CFB Model, a difference of about 17,300 AF. The differences in supplemental pumping are due largely to differences in the ET of applied water and differences in FHG deliveries between the models.

The simulated pumping in the M&A Farm Budget Model during the full supply years from 1985 - 2002 is unrealistically high considering the following:

- High FHG deliveries per acre (see **Figure 5-13**),
- High Ft. Quitman flows (see **Figure 5-3**), and
- High operational waste through this period (see **Figure 5-23**).

The upper right chart in **Figure 12-16** compares the maximum annual cropped area in the HCCRD in the M&A Farm Budget Model to the annual irrigated area in the SWE CFB Model. The irrigated figures are relatively comparable with the M&A Farm Budget Model acres averaging about 3% less than the SWE CFB Model acres.

---

[7] As described in Section 6.4.5, Reclamation records of EPCWID FHG deliveries exceed canal heading diversions in many months and are assumed to be in error.

The upper left chart in **Figure 12-16** compares the annual ET of applied water in the HCCRD. The annual ET of applied water in M&A Farm Budget Model is larger than the SWE CFB Model values throughout the 1985 - 2016 period, averaging about 30% more. The differences are due largely to differences in unit crop ET and cropping pattern.

The lower left chart in **Figure 12-16** compares the area-weighted annual unit crop ET in the HCCRD for the M&A Farm Budget Model and the SWE CFB Model. The differences in the unit crop ET reflect the combined differences in cropping pattern and the unit irrigation requirements of the individual crops. The unit ET for the M&A Farm Budget Model was computed as the annual ET of applied water volume (shown in the upper left chart in **Figure 12-16**) divided by the maximum monthly irrigated area in that year (upper right chart in **Figure 12-16**). The unit ET values in the M&A Farm Budget Model average over 30% more than the SWE CFB Model values.

The lower right chart in **Figure 12-16** compares the annual farm headgate delivery volumes that are simulated in the M&A Farm Budget Model of the HCCRD to the SWE CFB Model values. On average, the farm headgate deliveries in the M&A Farm Budget Model are about 26% less than the values in the SWE CFB Model.

13.0 RESPONSE TO HUTCHISON REPORT

William R. Hutchison, Ph.D., P.E., P.G. prepared a May 31, 2019 expert report on behalf of the State of Texas ("Hutchison Report"). The subjects of the Hutchison Report are generally twofold. First, the report describes the development of a MODFLOW ground water model of the Rincon and Mesilla basins in New Mexico and small portions of Texas and Mexico ("Texas Model") over a study period from 1938 - 2016. Second, the report describes use of the Texas Model to simulate reduced pumping and other scenarios during all or portions of the historical study period. The Hutchison Report includes a main summary report, 17 technical memoranda detailing the development and calibration of the Texas Model, and 4 technical memoranda describing use of the model to simulate reduced pumping and other scenarios.

SWE was asked by legal counsel for New Mexico to review the input data sets for the Texas Model and the model simulations of the reduced pumping scenarios to identify information or opinions with which we disagreed, and to prepare expert opinions to respond these issues. We attempted to identify and respond to all substantive issues in which there appeared to be differences of opinion, however a lack of response to a particular issue should not be interpreted as tacit agreement with Dr. Hutchison's opinion(s).

Hutchison Opinion 1 *– The 1938 condition can be viewed as a combination of three elements: 1) minimal groundwater pumping, 2) a specific number of irrigated acres and a specific distribution of irrigated crops, and 3) a specific amount of irrigation water that was applied (expressed in terms of acre-feet of water per irrigated acre). Simulations with the Texas Model demonstrate that increases in groundwater pumping have had a larger impact to Rio Grande at El Paso flows than increases in agricultural consumptive use. (Page 12 paragraph 1).*

Response:

New Mexico's legal counsel have advised that a 1938 condition is not appropriate for characterizing the water entitlements of the states. Moreover, it would be inappropriate to define a 1938 condition based on historical operations in a single year as Dr. Hutchison does in his analyses.

Hutchison Opinion 2 *– Simulations with the 2007 OSE Model and the Texas Model demonstrate that groundwater pumping resulted in decreased flows in the Rio Grande. Brandes (2019) developed an estimate of hypothetical Rio Grande at El Paso flows that would have occurred under a "without the effects of groundwater pumping" condition.*

Brandes (2019) concluded that the average increase in flow as compared with historic flows from 1951 to 2017 is about 79,000 AF/yr. (Page 12 paragraph 2).

Response:

As described in the response to Brandes Opinion 10 in Section 11, the analyses of historical data by Dr. Brandes unreasonably attributed all changes in Rio Grande at El Paso flow that occurred after 1950 to the effects of New Mexico pumping and did not consider other factors that may have contributed to reductions in flow at El Paso. Likewise, the modeling by Dr. Hutchison does not consider these other factors.

Hutchison Opinion 3 *– Simulations with the Texas Model demonstrate that an overall 60 percent reduction in all pumping would result in a hypothetical increase in Rio Grande at El Paso flow of about 73,000 AF/yr from 1951 to 2016. About 81 percent of the increase (59,000 AF/yr) is attributable to New Mexico pumping, and about 19 percent of the increase is attributable to Texas pumping (13,000 AF/yr). (Page 12 paragraph 2).*

Response:

The reduced pumping simulations performed by Dr. Hutchison are unreasonable and unreliable because the Texas Model does not simulate the dynamic operational responses of the Project and the LRG Area irrigation systems that would occur if pumping was reduced or turned off.

The following is a summary of the changes in inputs that are specified to occur in each of Dr. Hutchison's reduced pumping simulations:

- Irrigation pumping is reduced by a specified percentage (10% to 100%),
- Non-irrigation pumping and the corresponding urban infiltration are reduced by the same percentage, and
- On-farm deep percolation is reduced proportionately based in the reduction in total irrigation supply (SW+GW).

The following are inputs that are not changed in the reduced pumping simulations:

- Releases from Project storage,
- Canal diversions of Project water, and
- Wastewater treatment plant discharges.

The following are the simulated responses in Texas Model resulting from the foregoing changes in model inputs:

- Increased ground water levels and ground water storage,
- Increased riparian ET,
- Increased drain flows,
- Reduced canal seepage and river seepage,
- Increased Rio Grande flow from increased drain flows and reduced river seepage.

Because the reservoir releases and canal diversions are fixed at the historical amounts in the alternative runs, all increases in Rio Grande flow accumulate as increased flow at the downstream end of the model at El Paso. This simple process of the additional river flow running out the bottom of the model is not what happens during the irrigation season in the real world when the supply changes. In the real world, reservoir releases are continually adjusted in response to changing conditions downstream so as to deliver the ordered amounts of water.

The system response to the additional flow that would be in the river with a reduction in pumping would vary depending on whether it occurred in a year with a full allocation of Project water or a year with less than a full allocation. In a year with a full allocation, deliveries of Project water are limited by either the allocated amount or the water demand. In either case, it is reasonable to assume that Project water deliveries in a full allocation year would be about the same in a reduced pumping scenario as they were in the historical operation. Therefore, during a full allocation year in a reduced pumping scenario, the additional flow in the river would allow Reclamation to reduce reservoir releases and still deliver the same amounts to the Project water users. The reduction in reservoir releases would accumulate additional water in storage that would be carried over and allocated to EBID and EPCWID in subsequent years. The additional reservoir storage would also result in increased evaporation due to the greater surface area in the reservoir and would also result in increased spills when the Project storage filled to capacity.

During non-full supply years, the additional water in the river and additional accumulated reservoir storage during prior full allocation years would lead to increased allocations and increased deliveries to Project water users.

Because the Texas Model does not include simulation of reservoir and Project operations, it has no capability to simulate the real-world responses of the Project including changes in allocations, reservoir releases, diversions, and farm headgate deliveries. As a result, the increased river flow that occurs in the reduced pumping scenarios simply runs downstream to El Paso. This causes the Texas Model to overstate the effects of pumping in the Rincon and Mesilla basins on the flow of the Rio Grande at El Paso. The lack of simulation mechanisms in the Texas Model for reasonable dynamic responses to the changes in supply that would occur under conditions that are different from historical conditions renders the results from the Texas Model simulation of alternative scenarios meaningless and not helpful in assessing the effects of reduced pumping or changed conditions on Project operations and deliveries to LRG water users.

Figure 13-1 and **Figure 13-2** were prepared to compare the simulated changes in El Paso flow from the Texas Model and the ILRG Model for the scenario in which all pumping in the Rincon and Mesilla basins is turned off. In each figure the simulated changes in flows in the ILRG Model are summarized to show the changes during March - October (blue bars) and the changes during November - February and during months that the Project storage is spilling (grey bars). The results from the Texas Model are shown as a colored line representing the annual change in El Paso flow (purple line for simulation of no pumping during 1951-2016 and orange line for simulation of no pumping during 1985-2016).

Figure 13-1 compares the simulated change in El Paso flow in the ILRG Model for the a scenario in which all pumping in the Rincon and Mesilla basins is curtailed to the Texas Model simulation of the comparable scenario The average annual change in El Paso flow in the Texas Model during 1985 - 2016 is 124,700 AF compared to 93,900 AF in the ILRG Model (of which 25,100 AF occurs during reservoir release periods and 68,800 AF occurs during the non-release season or during spills). The simulated change in flow in the Texas Model is substantially greater because most of the increased river flow in the no-pumping scenario flows downstream to El Paso. In the ILRG Model with a simulated dynamic response to the changes in river flow, the reservoir releases are reduced in full allocation years and some of the increased flow in non-full supply years is allocated to EBID and as a result, much less of the additional flow makes it to El Paso. The simulated annual changes in El Paso flow in the ILRG Model reflect the expected response of the Project operation with little increased irrigation season flow during full allocation years (e.g., during the much of the 1980s and 1990s). Conversely, in the Texas Model the simulated changes in annual El Paso flow are relatively steady as they represent increases in river flow without the re-operation of the Project.

Figure 13-2 is similar to **Figure 13-1** with the results from the ILRG Model shown for the scenario with no New Mexico pumping (i.e., the pumping in the Texas Mesilla area was left on). The simulated average annual change in El Paso flow in the ILRG Model during 1985 - 2016 of 74,400 AF is about 19,500 AF less than when all pumping in the Rincon and

Mesilla basins is turned off, and only 17,600 AF of the average annual change in flow occurs during periods when reservoir releases are occurring (excluding spills).

Hutchison Opinion 4 *– One of the components of the "1938 condition" is the irrigated acreage and associated consumptive use expressed as acre-foot per acre in 1938. As documented in Technical Memorandum 3, agricultural consumptive use in New Mexico has increased since 1938 as shown in Figure 1. This technical memorandum documents the results of five scenarios where agricultural consumptive use is limited to that of 1938. The simulations were run from 1938 to 2016, but the modifications were applied only after 1950 to provide a means of comparison with other scenarios.*

The agricultural pumping, agricultural deep infiltration, and surface water diversion components of the hypothetical consumptive use scenarios were developed by summing the consumptive use of 1938 (149,005 AF/yr) and the associated canal losses and farm-level infiltration associated with irrigation. For each year, this sum was viewed as a demand and was compared with the annual historic surface water diversions for agricultural use. If the historic surface water deliveries were higher than the new demand, the excess remained in the surface water system (i.e. surface water flow diversions were reduced as compared with historic levels). If the historic surface water deliveries were less than the new demand, groundwater pumping for irrigation was set equal to the deficit. The five scenarios involve alternative urban and domestic groundwater pumping:

- *Scenario 1: limit of 10,000 AF/yr*
- *Scenario 2: limit of 20,000 AF/yr*
- *Scenario 3: limit of 30,000 AF/yr*
- *Scenario 4: limit of 40,000 AF/yr*
- *Scenario 5: limit of 50,000 AF/yr*

(Technical Memo 20 - Page 1 paragraphs 1 and 2; and page 4 paragraph 2).

Response:

Dr. Hutchison's Technical Memo 20 describes simulations under a presumption that New Mexico is entitled to consume for irrigation the same amount of water that it was consuming in 1938, which he estimates was 149,005 AF. When the historical annual surface water diversions during the simulation period were insufficient produce 149,005 AF of irrigation consumptive use, it was assumed that New Mexico water users could pump water to eliminate the deficit. Conversely, if the surface historical water supply was more than needed to produce 149,005 AF of consumptive use, then the diversions were reduced by the excess amount.

New Mexico's legal counsel have advised that a 1938 condition is not appropriate for characterizing the water entitlements of the states. Moreover, it would be inappropriate to define a 1938 condition based on historical operations in a single year.

The Alternative Consumptive Use scenarios imply that New Mexico should be limited to the irrigation consumptive use that allegedly existed in 1938 (149,005 AF), even if that means that New Mexico would have to reduce its use of Project water. However, Texas has provided no technical support for the notion that New Mexico's Project deliveries should be limited to the 1938 level.

Further, the simulations of reductions in New Mexico diversions of surface water in the Texas Model are nonsensical because there is not a corresponding reduction in simulated reservoir releases. Therefore, when the New Mexico diversions are reduced, the volume of the reduced diversion is left in the Rio Grande to run downstream to El Paso. In reality, if New Mexico's irrigation consumptive use was somehow limited under a 1938 condition, the reservoir releases would be reduced as necessary to limit the consumptive use of surface water and there would be no increase in El Paso flow during such years.

In addition, as described in the response to the reduced pumping scenarios, any change in pumping from what occurred historically would result in a dynamic response of the Project operation that would change the available surface water supply resulting in changed Project water allocations, diversions, and deliveries to Project water users. The Texas Model is not capable to simulating this dynamic response.

Because of the limitations of the Texas Model, the results of the simulations described in in Technical Memorandum 20 are of little value in assessing any alternative consumptive use scenarios based on a 1938 condition or otherwise.

It is unclear if the Alternative Consumptive Use scenarios are presented to illustrate Dr. Hutchison's analysis of how to achieve potential Compact compliance for New Mexico. It is also unclear whether Dr. Hutchison is proposing an analogous consumptive use cap for all Texas Project lands based on his 1938 condition.

***Hutchison Opinion 5** – The preferential use of surface water and the use of groundwater to meet demand deficits is the definition of conjunctive use. The simulations documented in this technical memorandum evaluated alternative hypothetical conjunctive use scenarios where historic groundwater pumping only occurred in years with less than specified amounts of surface water availability (i.e. pumping only in dry years to meet* *demand deficits). For purposes of these simulations, five scenarios were developed as follows:*

- *Scenario 1 assumed that groundwater pumping is zero when annual releases from Caballo are above 790,000 AF/yr (i.e. no pumping in 13 years, historic pumping in 66 years)*
- *Scenario 2 assumed that groundwater pumping is zero when annual releases from Caballo are above 700,000 AF/yr (i.e. no pumping in 30 years, historic pumping in 49 years)*
- *Scenario 3 assumed that groundwater pumping is zero when annual releases from Caballo are above 600,000 AF/yr (i.e. no pumping in 52 years, historic pumping in 27 years)*
- *Scenario 4 assumed that groundwater pumping is zero when annual releases from Caballo are above 500,000 AF/yr (i.e. no pumping in 60 years, historic pumping in 19 years)*
- *Scenario 5 assumed that groundwater pumping is zero when annual releases from Caballo are above 400,000 AF/yr (i.e. no pumping in 66 years, historic pumping in 13 years)*

(Technical Memo 21 - Page 2 paragraphs 1 and 5).

Response:

The Conjunctive Use scenarios described in Technical Memorandum 21 are similar to the 100% reduced pumping scenario described in Technical Memorandum 18 except that the pumping is only turned off in selected years rather than every year. Therefore, the same criticisms of the reduced pumping scenarios described above also apply to the Conjunctive Use scenario simulations. The lack of a mechanism in the Texas Model to simulate a dynamic response in the Texas Model to changing water supply renders the results of the Conjunctive Use scenarios as unreasonable.

It is also unclear if the Conjunctive Use scenarios are presented to illustrate Dr. Hutchison's analysis of how to achieve potential Compact compliance. It is also unclear whether Dr. Hutchison is proposing the same type of conjunctive use limits for Texas.

14.0 RESPONSE TO DORRANCE REPORT

Lydia R. Dorrance, Ph. D. prepared a May 31, 2019 expert report on behalf of the State of Texas ("Dorrance Report"). There were two primary subjects covered in the Dorrance Report. First, the report described analyses to translate simulated changes in the annual flows of the Rio Grande at El Paso flow computed by the Texas Model into changes in monthly surface water deliveries to EPCWID farmers in the El Paso Valley, farmers in the HCCRD, and municipal water users in the EPW service area. Second, the report described the effect that changes in the monthly surface water deliveries would have on the salinity of the mixed surface water and ground water supplies of farmers and municipal water users.

SWE was asked by legal counsel for New Mexico to review the analysis by Dorrance to translate modeled annual changes in El Paso flows into changes in deliveries of surface water to irrigation and municipal water users in the El Paso Valley to identify information or opinions with which we disagreed, and to prepare expert opinions to respond these issues. We attempted to identify and respond to all substantive issues in which there appeared to be differences of opinion, however a lack of response to a particular issue should not be interpreted as tacit agreement with Dr. Dorrance's opinion(s).

Dorrance Opinion 1 – *Modeling results provided by Dr. Bill Hutchinson demonstrate that in an alternative scenario in which pumping in the Rincon and Mesilla Valleys is reduced every year between 1985 and 2016 by 60% relative to that which was historically recorded, surface flow at El Paso increases. I evaluated how this increase in flow would impact the salinity of water applied for agriculture in EP1 and HCCRD1 under the alternative scenario. (Page 19 paragraph 3).*

Response:

The modeling results provided by Dr. Hutchison and used by Dr. Dorrance in her analysis were from a scenario in which 60% of all pumping in the Rincon and Mesilla basins was reduced, including irrigation and municipal pumping in the Texas portion of the Mesilla basin (including the Canutillo wellfield pumping). Therefore, the analyses by Dr. Dorrance of the effects of increased El Paso flows on deliveries to Texas users do not represent the effects of New Mexico pumping because they also include the effects of Texas Mesilla pumping. This results in inflated impacts attributed to New Mexico pumping that also inappropriately inflate the subsequent damage analyses by Dr. Sunding that are based on the results from the Dorrance analysis.

In addition, because of the absence of re-operation of the Project in Dr. Hutchison's modeling of the reduced pumping scenarios, the additional annual flows from simulation of the 60% reduced pumping scenario that Dr. Dorrance used in her analysis are unreliable and unusable for estimating the impacts of New Mexico pumping on irrigation and municipal water users in Texas.

In addition to the improper attribution of effects of pumping in the Texas portion of the Mesilla basin to New Mexico ground water pumping and the lack of re-operation of the Project in the Texas modeling results, the following additional responses are presented to the analyses by Dr. Dorrance.

Dorrance Opinion 2 *– The additional Rio Grande at El Paso flow in any given month would be delivered to EP1 under the Rio Grande Project. The delivery of additional water to EP1 would also result in additional surface water being made available for HCCRD1, and the historical ratio of surface water use between EP1 and HCCRD1 would remain unchanged in the alternative scenario. This assumption is supported by the clear positive correlation between discharge at El Paso and surface water use by to both EP1 and HCCRD1, such that both districts receive more surface water in years with greater flow at El Paso (See Figure 4). (Page 19 paragraph 4).*

Response:

Because the Texas Model operates with annual stress periods, Dr. Dorrance had to disaggregate the additional annual flows at El Paso from the Texas Model into monthly values introducing further error and uncertainty in her analysis. This disaggregation was based on percentages computed as historical monthly El Paso flows divided by the annual El Paso flow in each year. This presumes that the additional Rio Grande flow at El Paso that may result from a reduction in pumping in the Rincon and Mesilla basins would accrue in the same monthly proportions as the historical flows. However, Dr. Dorrance did not present any evidence to support this assumption.

It is possible that the additional flows with a reduction in upstream pumping would arrive with significantly different monthly timing. For example, the additional flow might allow the districts to begin reservoir releases earlier in the year, or to save water in storage for an additional release of water later in the irrigation season. In a full supply year, there may be no additional flow in any months because no additional deliveries would be appropriate in such a year. This is an example of why a model capable of simulating the dynamic response of the system to changes in supply is needed.

Further, the analysis by Dr. Dorrance presumes that nearly all of the simulated additional flow at El Paso in the reduced pumping scenario would be available for use by EPW, EPCWID, and HCCRD. This is contrary to the historical records that show on average only 64% of the monthly flow, after delivery of water to Mexico at the Acequia Madre, was delivered for use by EPW, EPCWID, and HCCRD during the March - October period in non-spill years.

Historical records of the monthly and annual flows of the Rio Grande at El Paso (less deliveries to Mexico) are shown in the black line in **Figure 14-1**. The monthly and annual deliveries to EPW, EPCWID, and HCCRD are shown in the stacked bars in **Figure 14-1**. The reason that an average of only 64% of the adjusted flow at El Paso was delivered to the Texas water users is because of the conveyance losses and other inefficiencies in the EPCWID and HCCRD delivery systems. Note that the 2010 historical farm delivery amounts in the Dorrance analysis are suspect as the sum of the deliveries significantly exceeds the total flow at the El Paso gage.

Figure 14-2 contains similar graphs showing the monthly and annual increased El Paso flows simulated in the Texas Model as a result of a 60% reduction in the Rincon-Mesilla pumping from 1985 - 2016 (black line) and the portions of that flow that Dr. Dorrance computed to be available for delivery to EPW, EPCWID, and HCCRD (stacked bars). The graphs show that Dr. Dorrance made available almost all of the additional flow at El Paso for delivery to the Texas water users. On average, 97% of the increased El Paso flow was determined by Dr. Dorrance to be available for delivery to Texas water users during the March - October period compared to the historical average of 64% of the El Paso flows that were actually delivered to Texas water users. Note that Dr. Dorrance also did not make any of the simulated increases in El Paso flow available for delivery to Mexico.

Finally, **Figure 14-3** compares the simulated increased monthly and annual El Paso flows (black line) and the amount of the increased flow that Dr. Dorrance estimated would actually be delivered for use by EPW, EPCWID, and HCCRD (stacked bars). The amount of the increased El Paso flow available to EPW in **Figure 14-3** that would have been delivered for use by EPW was limited so that the sum of the historical delivery plus the increased delivery did not exceed the historical maximum monthly EPW deliveries. The amounts of the increased El Paso flow delivered to EPCWID and HCCRD were limited to the simulated historical pumping by each district. In other words, it was assumed that each district would use the same amount of water that they did historically (surface water plus estimated pumping) and the additional surface water deliveries would only replace the portion of their supply that was historically pumped. As indicated in **Figure 14-3**, during many years most or all of the increased El Paso flow is assumed by Dr. Dorrance to be delivered for use during many or all months of the irrigation season. The full amount of the increased flow at El Paso (100%) was assumed delivered to the Texas water users in 37% of the March - October study period months. The full amount of the additional El Paso flow is assumed by Dr. Dorrance to be delivered to Texas users when there is sufficient historical unmet demand (i.e., historical pumping that can be replaced by surface water deliveries). In months that the simulated increased El Paso flow is greater than the total historical unmet demand, the excess El Paso flow goes undelivered in the Dorrance analysis, apparently as an increase in operational waste.

It is unreasonable for Dr. Dorrance to assume that most or all of the increase in El Paso flow that would occur by reducing pumping in the Rincon and Mesilla basins could be delivered for use by Texas water users undiminished by conveyance loss (i.e., as indicated in **Figure 14-3** when the stacked bars reach or nearly reach the black line). As a result, Dr. Dorrance's analysis overstates the effect that a reduction in pumping in the Rincon and Mesilla basins would have on increasing the supply of surface water to Texas users that they could use to replace what they historically pumped. Because the increase in deliveries to Texas water users from a reduction in Rincon-Mesilla pumping is overstated, so too are the computed damages from that pumping on Texas water users computed by Dr. Sunding.

Dorrance Opinion 3 *– In a given month and year, applied agricultural water in EP1 and HCCRD1 consists of a combination of surface water and groundwater (and can consist of exclusively surface water or groundwater) and groundwater is pumped to compensate for the shortfall between surface water agricultural application and total agricultural water application. In other words, groundwater is only pumped when there is not enough surface water delivered. (Page 19 paragraph 5).*

Response:

Figure 14-4 compares the annual changes in El Paso flow that Dr. Dorrance obtained from the Texas Model simulation of a 60% reduction in pumping in the Rincon and Mesilla basins during 1985 - 2016 to the simulated annual changes in El Paso flow from the ILRG Model simulation of the No New Mexico Pumping scenario. The average annual changes in El Paso flow during 1985 - 2016 are similar, with the Texas Model average being approximately 4% less than the ILRG Model average. While changes in flow are similar, the amounts of pumping turned off to produce the changes in flow were substantially greater in the ILRG Model than in the Texas Model. Because of the re-operation of the Project in the ILRG Model, a significant portion of the increased river flow in the no-pumping run was allocated to and used by EBID water users. The simulated change in flow at El Paso in the ILRG Model reflects increased allocations and deliveries to EPCWID and JID, increased winter flows and increased spills. Conversely when pumping is turned off in the Texas Model, most of the increase in river flow runs downstream to El Paso because there is no re-operation. Therefore, turning off a smaller amount of pumping in the Texas Model can produce a similar increased in average flows at El Paso as turning off a larger amount of pumping in the ILRG Model.

Figure 14-5 through **Figure 14-7** compare the increased deliveries to Texas users (EPCWID for irrigation, EPW, and HCCRD) computed by Dr. Dorrance from the Texas Model simulated increased El Paso flows against the comparable changes in Texas deliveries from the ILRG Model simulation of the No New Mexico Pumping scenario. In each figure, the annual changes from the Texas analyses during 1985 - 2016 are shown as an orange line and the annual results from the ILRG Model are shown as blue bars.

Figure 14-5 compares the estimates by Dr. Dorrance of changes in deliveries to EPCWID irrigation users in the El Paso Valley to the simulated changes in deliveries from the ILRG Model. The average annual change in deliveries from the ILRG Model (4,100 AF) is much less than the Dorrance estimate (28,000 AF). The reasons for the differences are primarily three-fold. First, as described previously, Dr. Dorrance makes virtually all of the simulated increase in El Paso flow available for delivery to the Texas users without conveyance losses. Second, contrary to the ILRG Model, the M&A farm budget analysis shows substantial unmet demand in all years during the historical period and so the additional flow in the reduced pumping scenario is used to meet the unmet demand. Third, much of the simulated increase in flows in the ILRG Model occurs during the non-release season and during spills, and so these supplies are not usable to meet unmet irrigation demands that may exist.

Figure 14-6 compares the changes in simulated deliveries to EPW between the Dorrance analysis and the ILRG Model. The Dorrance analysis shows much greater changes in EPW deliveries because she assumed EPW would receive certain percentages of the simulated additional El Paso flow. Conversely, the ILRG Model delivers additional flow to EPW only in years when there is an increase in the EPCWID Project water allocation. Because there were full allocations during 1985 - 2002, there are no simulated increases in allocations in these years and therefore no simulated increases in deliveries to EPW.

Figure 14-7 compares the changes in simulated deliveries to HCCRD between the Dorrance analysis and the ILRG Model. The Dorrance analysis shows much greater changes in HCCRD deliveries because she assumed HCCRD would receive certain percentages of the simulated additional El Paso flow to replace the M&A estimates of historical pumping. Conversely, the ILRG Model delivers additional flow to HCCRD only when there is unmet demand which is rare during most years during the 1985 - 2016 period.

Dorrance Opinion 4 – *The ratio of surface water supplied to the City of El Paso and the El Paso Valley irrigation districts (EP1 and HCCRD1) for a given month would be the same in the alternative scenario as was historically observed. This ratio can therefore be used to allocate excess surface water in the alternative scenario between the City of El Paso and the El Paso Valley irrigation districts. However, if, based on this partitioning, the City of El*

Paso's surface water delivery would exceed its maximum recorded delivery for a given month (as described below), the surplus would be allocated to the El Paso Valley irrigation districts. (Page 20 paragraph 2).

Response:

It is unreasonable to assume that the historical proportions between monthly El Paso flows and monthly EPCWID deliveries, EPW deliveries, and HCCRD deliveries would be preserved as to any increased El Paso flows. For example, HCCRD receives as its supply waste and drain flows leaving the EPCWID service area. The flows to the HCCRD can be significantly variable in response to the amount of water leaving the EPCWD service area. It is unreasonable to assume that a large historical spike in the historical supply reaching the HCCRD would be proportionally increased by any additional flow that the EPCWID would have available. It is more likely that the EPCWID would not waste more water, but rather would take delivery of that water at times it could be more beneficially used.

In addition, it is our understanding that EPW has been selling water to HCCRD since at least 2001 (Lopez, 2019). The historical records of deliveries to HCCRD likely reflect these deliveries, and therefore the proportioning method used by Dr. Dorrance would improperly allocate a proportion of the increased El Paso flow to HCCRD because of these sales.

In summary, the methodology applied by Dr. Dorrance over-allocates and improperly distributes the increased annual El Paso flows from the Texas Model (that have already been shown to be unreliable) among EPW, EPCWID, and HCCRD1. Therefore, the results from the Dorrance analysis are unreliable and unsuited for use in the analyses of economic damages that were conducted by Dr. Sunding.

In order to reasonably estimate the timing and amount of increased surface water deliveries to the Texas water users that would occur in a reduced pumping scenario, it is necessary to simulate this scenario using a robust model like the ILRG Model that is capable of simulating the dynamic response of the Project and the LRG irrigation systems to changes in flow. It is essential that such modeling include simulation of the El Paso Valley downstream of El Paso rather than using simple historical proportions.

15.0 RESPONSE TO SUNDING REPORT

David L. Sunding, Ph.D. prepared a May 31, 2019 expert report on behalf of the State of Texas ("Sunding Report") that describes his analysis of economic damages to Texas resulting from excessive pumping in New Mexico during the years 1985 - 2016. Damages were computed to agricultural water users, customers of the EPW, and to the broader West Texas regional economy.

SWE was asked by legal counsel for New Mexico to review Dr. Sunding's description of El Paso municipal water use and his characterization of the effects of excessive New Mexico pumping on Texas water users to identify information or opinions with which we disagreed, and to prepare expert opinions to respond these issues. We attempted to identify and respond to all substantive issues in which there appeared to be differences of opinion, however a lack of response to a particular issue should not be interpreted as tacit agreement with Dr. Sunding's opinion(s).

Sunding Opinion 1 *– Because of the seasonal nature of surface water deliveries, the configuration of El Paso's conveyance system differs between the summer irrigation season and the rest of the year. Figure 7 shows the typical distribution of water supply in El Paso during summer and winter, respectively. The map on the left side of Figure 7 shows how the city delivers water when surface water is available. The southern parts of the city are delivered surface water from the Jonathan Rogers Water Treatment Plant as shown in grey, and the central parts of the city are delivered surface water from the Robertson/Umbenhauer Surface water treatment plant as shown in Orange. The northwestern parts of the city are delivered shallow groundwater from the Upper Valley Water Treatment Plant supplied by the Canutillo Wellfield. However, the righthand panel shows the distribution pattern that is typical in winter, and also during periods of summer when surface water is unavailable. (Page 24 paragraph 2)*

Response:

The map in Figure 7 of the Sunding Report gives the impression that there are distinct areas where Project water is delivered when it is available. In reality, the delivery of water to various portions of the City varies continuously depending on the relative amounts of water available from the City's sources and fluctuations in water demand. In addition, there are not bright lines between where surface water is delivered and ground water is delivered. According to John Balliew (EPW president and CEO), different water sources can mix in the distribution system and a blend of surface water and ground water is delivered to many areas when surface water is available (Balliew, 2019 p. 21).

Sunding Opinion 2 *– Figure 8 shows the average production of water in El Paso for each month of the year. Water use in El Paso is highest during summer, when high temperatures cause demand for irrigation and cooling to peak. During summer EPWU can cover this peak demand with surface-water from the Rio Grande during years that it receives its full allocation of project water. During winter, demand is significantly lower, less than half of peak summer demand. The city has to rely entirely on groundwater during the winter when there are no surface water deliveries. However, because the peak in summer demand often outstrips available supply from the Rio Grande, groundwater demand also peaks during the summer. As a result, any shortfalls in Rio Grande supply during summer require additional capital investments in groundwater capacity to make up the difference. (Page 25 paragraph 1)*

Response:

Project water supplies can be very low during extended drought periods with or without the effects of New Mexico pumping. EPW's drought planning is based on a conservative assumption that no project water would be available to meet the peak summer demand (Balliew, 2019; pp. 210-211, 276). This condition could exist with or without pumping impacts on Project supplies. In very dry years with low Project water allocations, the typical operational practice is to aggregate the Project releases into two or three short releases during the irrigation season to minimize river conveyance losses. During such years, the reservoir gates can be shut for weeks at a time with no Project water deliveries. During these periods of no Project water deliveries, which can occur during times of peak summer demand, the EPW would have to meet its water demands solely from ground water pumping. Therefore, the City's ground water infrastructure would be necessary without or with the effects of New Mexico pumping.

Sunding Opinion 3 *– To evaluate the economic impacts on Texas from New Mexico's excessive groundwater pumping, I compare the historical deliveries of Rio Grande water above El Paso to a hypothetical scenario that assumes New Mexico significantly reduced groundwater pumping. The hypothetical water supply scenario was provided to me by Dr. Bill Hutchison and it assumes a 60 percent reduction in New Mexico groundwater pumping between 1938 and 2016. Figure 9 shows the historical and hypothetical Rio Grande flows at the border and is taken directly from Dr. Hutchison's calibrated model. The difference between water supply scenarios is most pronounced during dry years. Dr. Hutchison's model shows that under this hypothetical scenario, between 1985 and 2016, an additional 71,000 acre-feet of water would flow across the Texas-New Mexico border on average each year. (Page 27 paragraph 2)*

Response:

The historical and simulated annual Rio Grande at El Paso flows are from Dr. Hutchison's simulation of 60% reduction of all pumping in the Rincon and Mesilla basins, including irrigation pumping in the Texas portion of the Mesilla basin, and the municipal pumping from the Canutillo wellfield. As a result, Dr. Sunding's analyses of Texas damages in the El Paso Valley inappropriately includes damages from pumping by Texas farmers in the Mesilla basin and by City of El Paso pumping from the Canutillo wellfield.

Note that the 71,000 AF/y of average additional El Paso flow is an annual figure comprised of flows in both the irrigation season and non-irrigation season. The simulated increased flows at El Paso from the Texas Model and the disaggregation of these flows by Dr. Dorrance to increased deliveries to EPW, EPCWID, and HCCRD are unreliable and overstated for the reasons described in Sections 13 and 14 above.

Sunding Opinion 4 *– Excessive groundwater pumping in New Mexico caused EPCWID and HCCRD to receive reduced deliveries from the Rio Grande; consequently, they must deliver less surface water to their agricultural customers. In her expert report, Dr. Dorrance estimates that every additional 100 acre-feet of water delivered to the Texas-New Mexico border results in EPCWID and HCCRD delivering 58 and 20 additional acre-feet respectively to each of their districts. Dr. Dorrance's numbers indicate that had New Mexico reduced its excessive groundwater pumping, EPCWID and HCCRD would have delivered an average of around 45,000 and 14,000 additional acre-feet of water, respectively, every year between 1985 and 2016. (Page 30 paragraph 1 and 2)*

Response:

As described in Section 14, the portion of Hutchison's modeled increase in flow at El Paso that would be delivered to EPCWID, HCCRD, and EPW is overstated because Dr. Dorrance assumed that virtually all of the increased El Paso flow would be available for delivery to Texas water users without loss. This compares to the historical deliveries that averaged 64% of the flow at El Paso using the historical flow data presented in the Dorrance report.

Dr. Sunding misstates the results of the Dorrance analysis when he asserts the analysis showed that deliveries to EPCWID would increase by 45,000 AF/y and deliveries to HCCRD would increase by 14,000 AF/y in every year between 1985 – 2016. These are average annual increases in deliveries from the analysis by Dr. Dorrance. Further, as described previously, the Dorrance results are unreliable because they are based on results from Dr. Hutchison's Texas Model that lack the capability to re-operate the Project and LRG irrigation systems in response to changes in water supply.

Sunding Opinion 5 *– EPWU conjunctively uses groundwater and surface water to meet its demands. There is seasonality in EPWU's water supply portfolio. The share of customers supplied by surface and groundwater changes throughout the year, as previously shown in Figure 8, and also between wet and dry years. During the irrigation season, EPWU delivers the available surface water supply to its customers, and then pumps groundwater to meet remaining demand. (Page 45 paragraph 2)*

Response:

The chart in Figure 8 of the Sunding Report shows the monthly average EPW production of surface water and ground water. **Figure 15-1** shows the same information for each month of each year of the period from 1985 - 2016. As shown in this closer look of EPW production, monthly surface water deliveries vary significantly from month to month and year to year. During the full supply years of the 1980s, EPW's peak monthly Hueco pumping approached 10,000 AF per month. During the recent dry years, there was only one month with Hueco pumping in excess of 10,000 AF. Based on these comparisons there seems to be little connection between the peak monthly Hueco pumping and EPW's use of Project water.

The characterization that EWPU delivers surface water supply to customers and then pumps ground water to meet remaining demand may be true for portions of the EPW operations. However, based on EPW's current infrastructure, certain areas of the city are supplied only by ground water and many areas receive a blend of ground water and surface water when surface water is available (Balliew, 2019 p 21).

Sunding Opinion 6 *– Since the shallow wells in the Upper Valley in the Mesilla Aquifer are hydraulically connected to flow in the Rio Grande, my estimates assume that all additional groundwater comes out of wells in the Lower Valley wells, connected to the Hueco aquifer. (Page 47 paragraph 2)*

Response:

EPW operates its water supply sources to meet demands that vary throughout its service area. Because of the interconnected distribution system, many areas of the City receive a blend of water from different sources depending on the available supply, particularly the available surface water supply. As to the Canutillo wellfield, pumping from this source is generally used in the northwest portion of the City, but is also delivered into the downtown area when surface water supplies are limited. (Balliew, 1999 p. 189)

Sunding Opinion 7 *– In 2007, El Paso Water in partnership with the Fort Bliss military base, opened a state of the art desalination plant, which uses reverse osmosis to remove salts* *from brackish groundwater. The plant uses five reverse osmosis skids, which give it a maximum capacity of 27.5 MGD. The construction of the Kay Bailey Hutchison desalination plant cost $91 million, which I have omitted from my analysis because the plant was partially built for strategic military purposes. However, the economic case for continued operation of the plant is not, and instead is a result of unreliable supply of the Rio Grande water during peak summer months. In my discussions with EPWU's President and CEO John Balliew, he stated that the decision to operate Kay Bailey Hutchison was marginal, and that if EPWU had received a more reliable supply of water, then the plant would have been removed from active use and put into a condition of long-term preservation. (Page 48 paragraph 2)*

Response:

The Kay Bailey Hutchison Desalination Plant ("KBH Plant") was built for a variety of reasons, not solely because of low surface water supply in drought years. Importantly, the KBH Plant prevents brackish water intrusion into freshwater portions of the Hueco Bolson. John Balliew testified that it would be necessary to operate the KBH Plant even if EPW had more surface water because of the function of the KBH Plant to manage the brackish water intrusion problem (Balliew, 2019 p. 277).

Deliveries of surface water from the Project to EPW will never be reliable with or without New Mexico pumping due to the unreliable nature of snowmelt and rainfall runoff upstream of Elephant Butte Reservoir. Further, the records of EPW water production indicate that the KBH Plant operates in years of high and low deliveries of Project water to EPW. Since 2008 (the first full year of operation of the plant), the plant delivered an average of about 4,200 AF/y in the 5 years with surface water deliveries greater than 50,000 AF/y and an average of 5,900 AF/y in the 4 years of surface water deliveries less than 50,000 AF/y. While this shows some increased use of the plant in years of low surface water deliveries, it also shows that it would be unreasonable to attribute the continued use of the plant solely due to the effects of New Mexico pumping.

Sunding Opinion 8*– Prior to 2003, El Paso had many groundwater wells in the lower valley which had fallen into disuse, either because they required maintenance and rehabilitation in excess of their costs or because they produced water with levels of arsenic and salt above Safe Drinking Water Act standards. As a result of increasingly unreliable Rio Grande deliveries during months of peak summer demand, the city decided to rehabilitate many of these wells, even going so far as to begin a program of installing reverse osmosis wellheads at 11 previously productive wells which had suffered brackish water intrusion. (Page 50 paragraph 1).*

Response:

The reduction in Project water deliveries that commenced in 2003 was due in large part to a severe multi-year drought that affected the Lower Rio Grande Basin. As shown in **Figure 5-1**, the inflows to Elephant Butte Reservoir at the San Marcial Gage have been below average during most years since 2003. Further EPW's drought planning assumes that there will be no surface water available to meet peak summer demands. As a result, it is unreasonable to attribute the cost to rehabilitate wells when the drought commenced to the effects of New Mexico pumping. The EPW wells would have needed to be rehabilitated with or without the effects of New Mexico pumping.

Sunding Opinion 9 *– As discussed in Section III.E, the Franklin Mountains, lying between the northwest parts of El Paso and the rest of the city, present a major geographical barrier to water distribution in the area. To bridge this divide the city undertook a series of investments to improve conveyance of water between groundwater wells in the Mesilla Aquifer and downtown El Paso, which is typically served in summer by surface water. The Paisano Water Line brings water from the Upper Valley Water Treatment Plant along Paisano Drive to be distributed in Downtown and East El Paso. The old Paisano line had reliability issues, which led El Paso Water to decide to replace it in 2013. During droughts, when there was peak demand and no surface water available to supply downtown El Paso, the line was a bottleneck for transmitting water from the Upper Valley WTP to downtown El Paso. Consequently, El Paso Water decided to replace the line with a 48" pipe rather than the 36" pipe that previously existed. The incremental cost of installing the larger pipe was $1.54 million in 2016 dollars. There was an additional bottleneck in distributing water that supplied the Upper Valley Treatment Plant from the Canutillo wells. Building a water transmission line to break this bottleneck and supply additional water to the city during drought periods cost the city $14.56 million in 2016 dollars. El Paso Water also drilled two wells supplying Upper Valley Water Treatment Plant in 2011, near the peak of a major drought. Wells 208 and 312 were drilled and installed at a cost of $1.77 million in 2016 dollars. (Page 51 paragraph 3-5).*

Response:

The deposition testimony of John Balliew directly contradicts the Dr. Sunding opinion about why the capacity of the Paisano Water Line was increased. Balliew testified that the capacity of the original 36-inch pipeline was sufficient to deliver water from the Canutillo wellfield south and into the downtown El Paso area. The reason that the pipeline capacity was enlarged was to be able to deliver additional surface water from the Robertson/Umbenhauer WTP to areas further north that are currently supplied by the Canutillo wellfield. (Balliew, 2019 p. 320-321).

Sunding Opinion 10 *– Surface water that EPWU delivers to its customers is less salty than groundwater. According to data provided by EPWU, the average salinity of its delivered surface water is 675 mg/L TDS and the average salinity of its delivered groundwater is 862 mg/L TDS. This difference of 187 mg/L TDS in salinity over a prolonged period of time imposes a cost on customers. Based on data from Dr. Dorrance, under the hypothetical scenario, the share of surface water delivered to customers would increase by 7.6 percent. As seen in Figure 7, these additional surface water deliveries would be localized to specific parts of the city. Based on these observations, I assume that 7.6 percent of EPWU's customers would experience a reduction in salinity in the hypothetical scenario from 862 to 675 mg/L TDS. This share of the customer base corresponds to 13,890 residential accounts, 1,453 commercial and municipal accounts and 11 industrial accounts. (Page 53 paragraph 2)*

Response:

Dr. Sunding appears to assume that an average 7.6% increase in EPW's surface water supply without New Mexico pumping would result in 7.6% of EPW customers experiencing a reduction in salinity because their supplies would be converted from ground water to surface water. Assuming EPW did receive an increase in surface water without New Mexico pumping it seems unlikely that particular customers would see their supply switch from ground water to surface water. Instead, any increases in surface water would affect the blend of surface water and ground water that many customers receive.

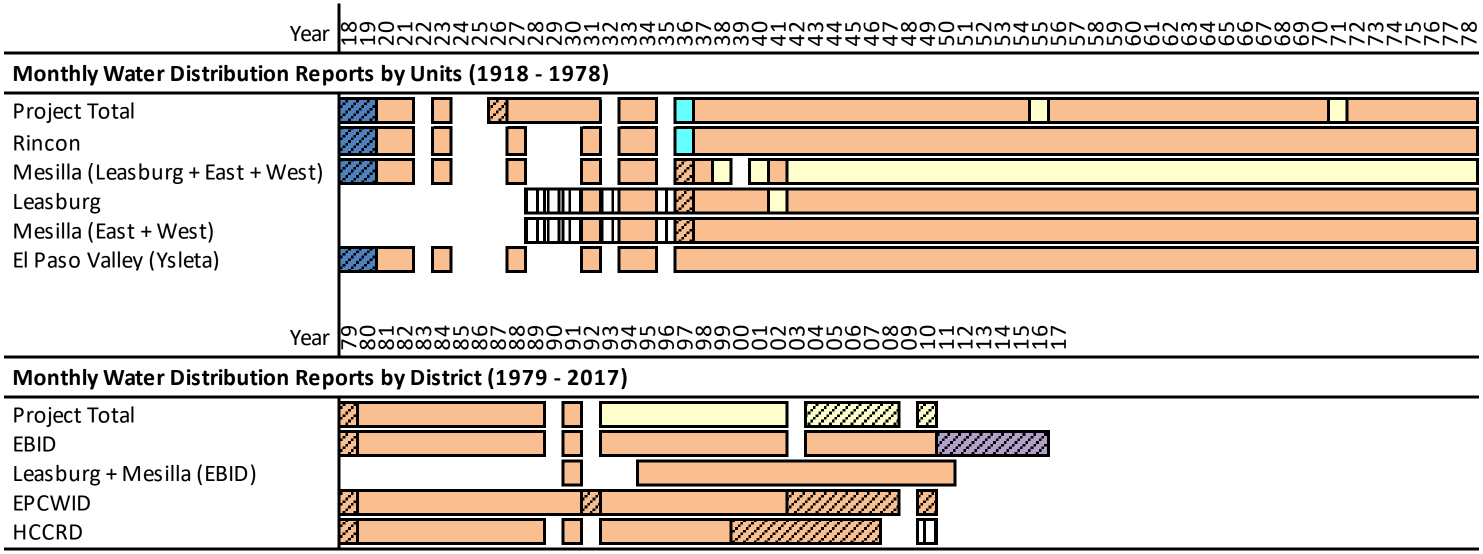
Water Distribution Report Data (1918 - 2017)



Key:

- Water Distribution Report is available and monthly data for year are compiled.
- Annual farm delivery data only.
- Annual acreage and river headgate diversion data only.
- Water Distribution Report is available but values are illegible.
- Water Distribution Report is not available but values are estimated using reports for other units.
- Hashed where only annual data are available or only part of the records are available (e.g., only river headgate diversions are available).
- Acreage data only.

Notes: There may be some missing months within certain years.
Project totals include total for Rincon, Leasburg, Mesilla, and El Paso Valley (pre-1979), and EBID plus EPCWID (post-1979).
Pre-1979, Mesilla (East + West) includes lands in New Mexico and Texas under the Eastside and Westside canal systems.
Mesilla (East + West) includes lands in New Mexico and Texas under the Eastside and Westside canal systems.

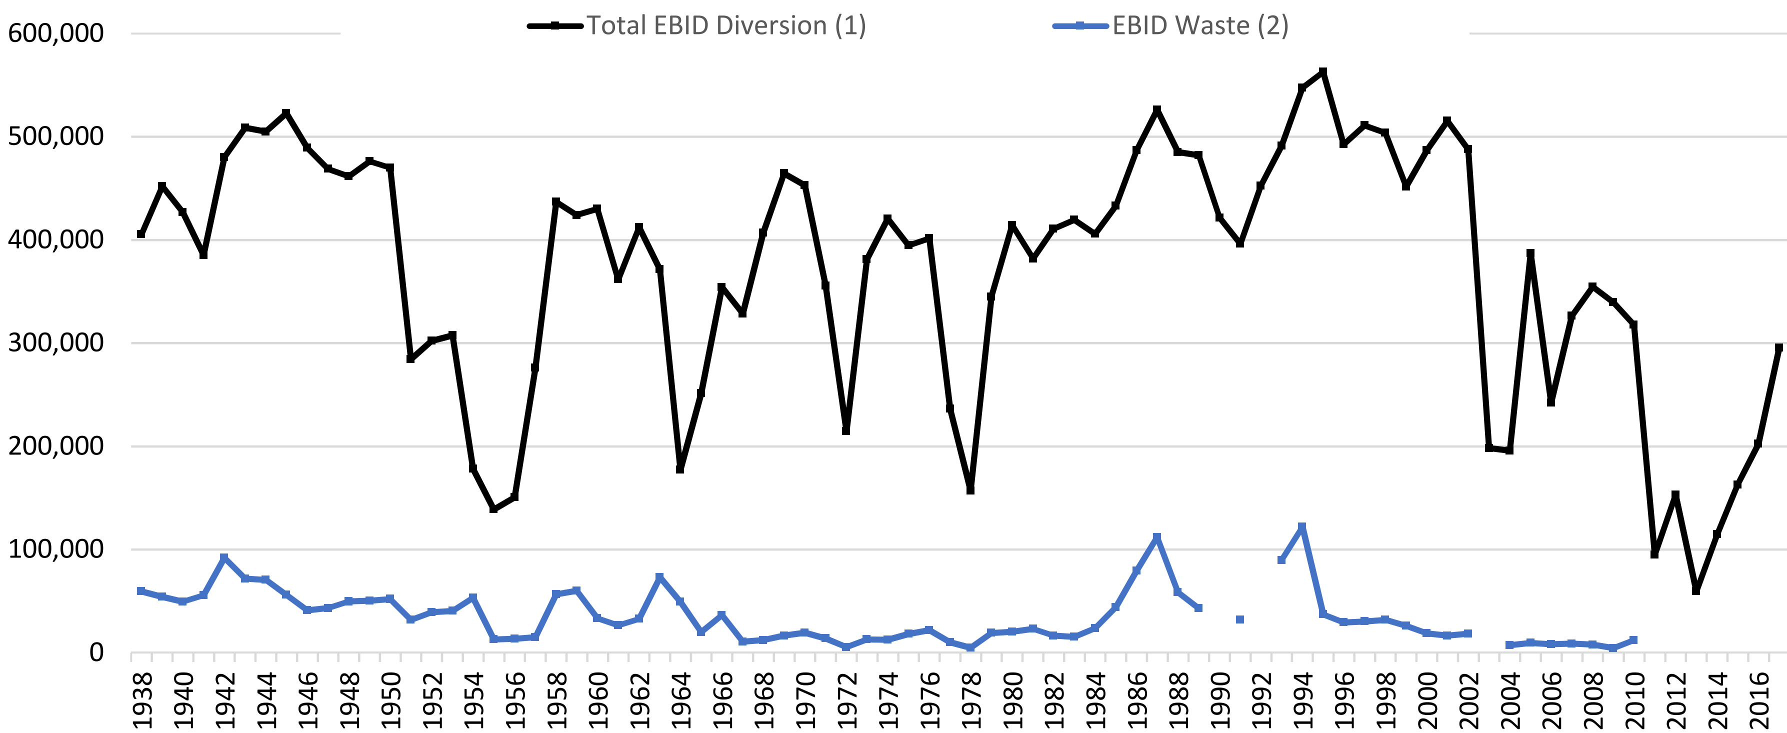
Figure 5-20

Annual EBID Diversions and Waste
Irrigation Season
1938 - 2017
(acre-feet)



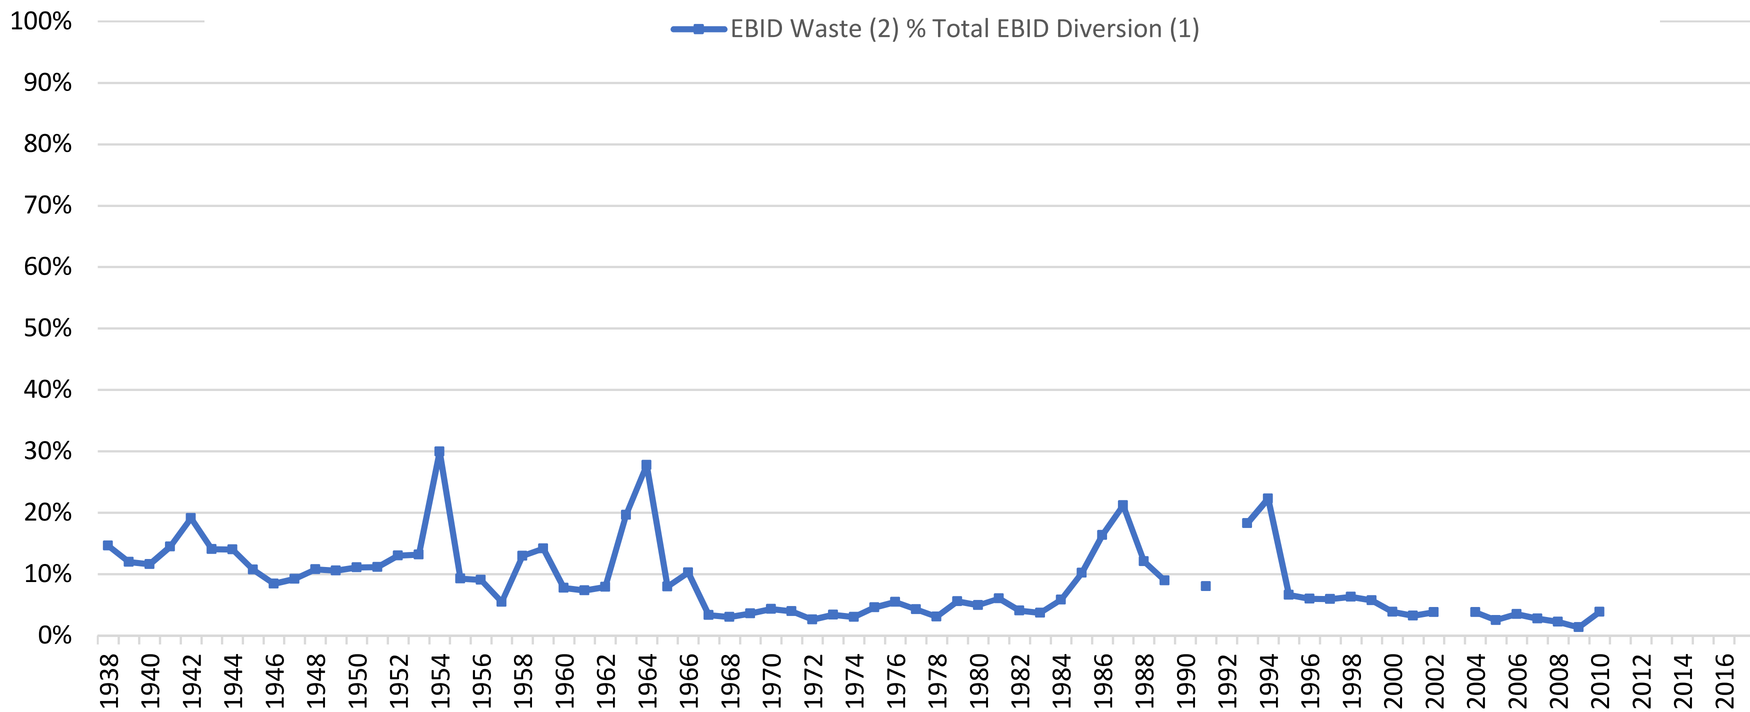
Notes:

(1) Total EBID diversions computed as the sum of diversions for Rincon, Leasburg, and NM portion of the Mesilla diversions. NM portion of the Mesilla diversions are proportional to NM irrigated acres in the Mesilla.

(2) Reported operational waste from Water Distribution Reports (missing for 1990 and 1992). Pre- 1979, waste was computed as the sum of Rincon waste, Leasburg waste, and NM portion of Total Mesilla Waste (NM portion of the total waste is proportionally to the NM irrigated acres in the Mesilla).

Figure 5-21

Annual EBID Waste (% Diversions)
Irrigation Season
1938 - 2017
(% EBID Diversions)



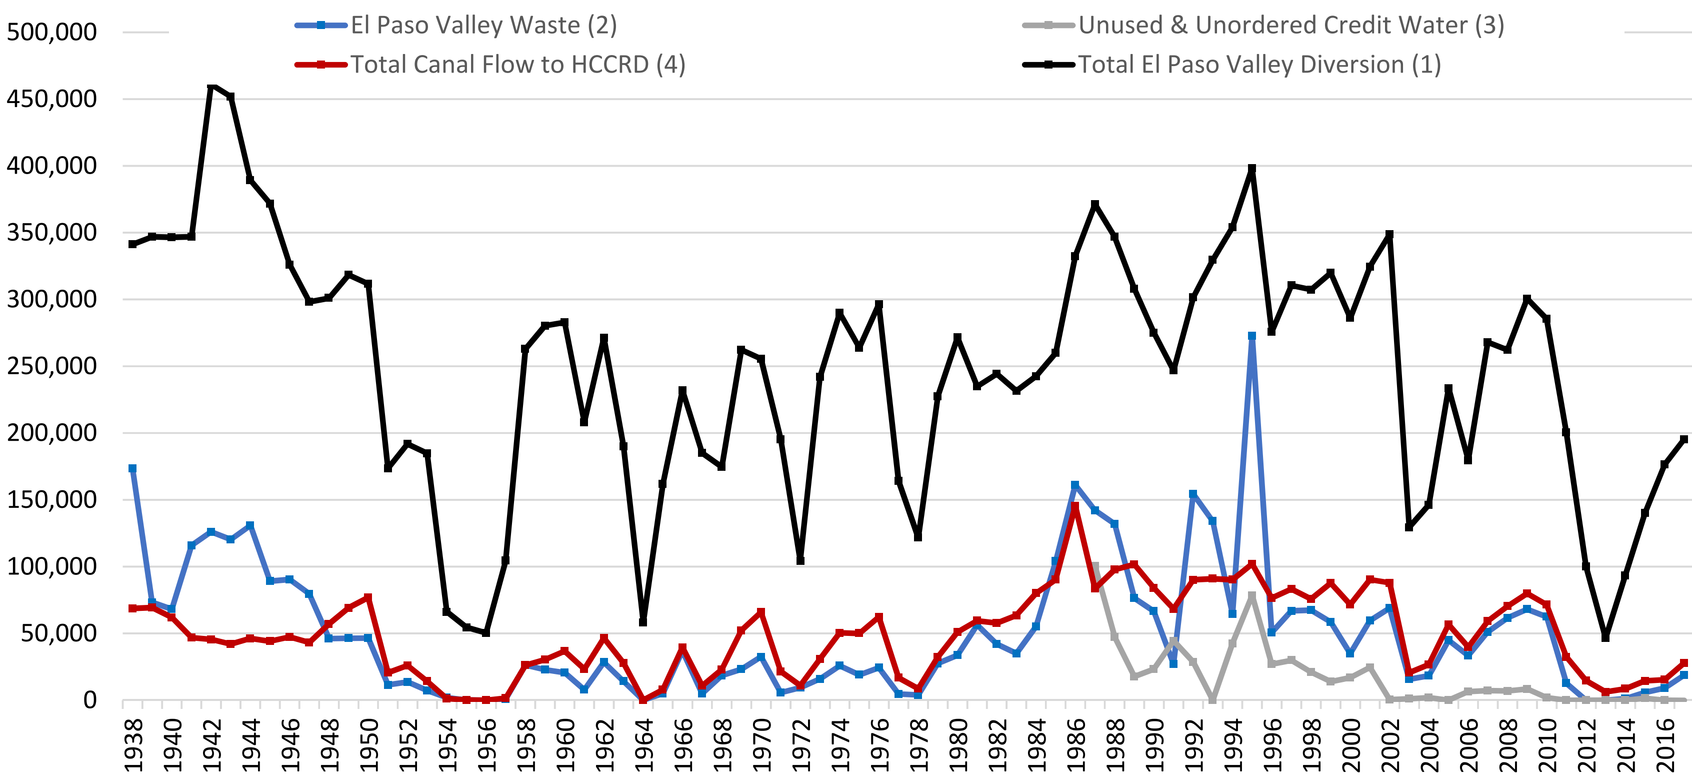
Notes:

(1) Total EBID diversions computed as the sum of diversions for Rincon, Leasburg, and NM portion of the Mesilla diversions. NM portion of the Mesilla diversions are proportional to NM irrigated acres in the Mesilla.

(2) Reported operational waste from Water Distribution Reports (missing for 1990 and 1992). Pre- 1979, waste was computed as the sum of Rincon waste, Leasburg waste, and NM portion of Total Mesilla Waste (NM portion of the total waste is proportionally to the NM irrigated acres in the Mesilla).

Figure 5-22

Annual El Paso Valley Diversions and Waste
Irrigation Season (March - October)
1938 - 2017
(acre-feet)



Notes:

(1) Total El Paso Valley diversions computed as Franklin Canal diversions minus Ascarate Wasteway (pre-ACE completion/2000) flows plus Riverside Canal gaged flows plus City of El Paso Diversions.

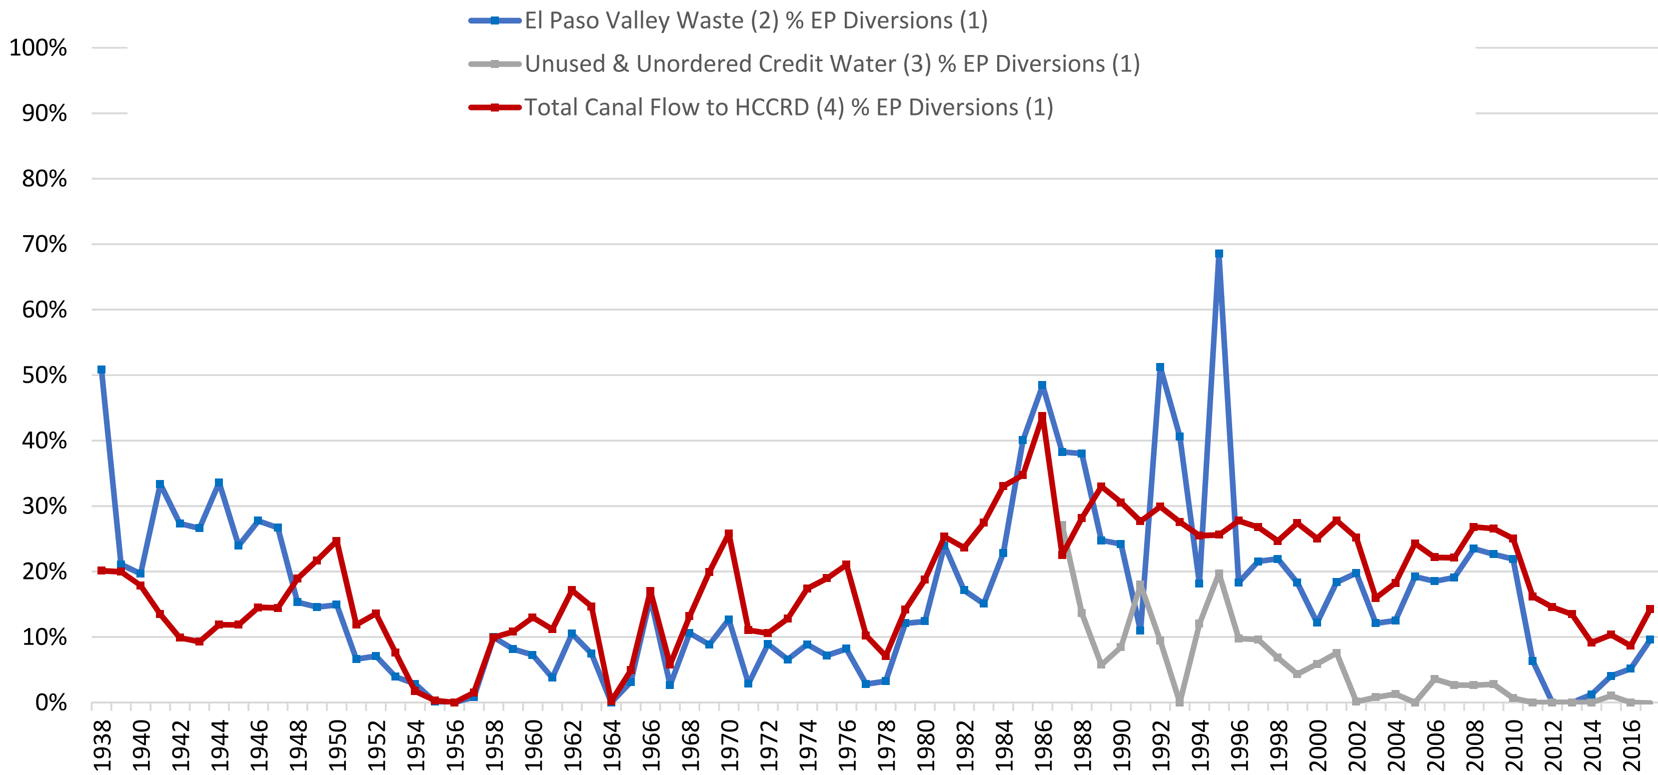
(2) Reported operational waste from Water Distribution Reports. Calculation varies per WDR notes and generally includes Riverside wasteway flows to river plus a portion of the flows to Hudspeth. Values estimated after 2002 based on regression with Hudspeth supply.

(3) Credit water to EPCWID from Accounting Reports for unused and unordered Project water.

(4) Hudspeth (Tornillo End) flows from 1938 - 4/1947 and sum of Hudspeth Feeder Canal and Tornillo Canal at AA from 5/1947 - 2017 (does not include Tornillo Drain flow).

Figure 5-23

Annual El Paso Valley Waste (% Diversions)
Irrigation Season
1938 - 2017
(% El Paso Valley Diversions)



Notes:

(1) Total El Paso Valley diversions computed as Franklin Canal diversions minus Ascarate Wasteway (pre-ACE completion/2000) flows plus Riverside Canal gaged flows plus City of El Paso Diversions.

(2) Reported operational waste from Water Distribution Reports. Calculation varies per WDR notes and generally includes Riverside wasteway flows to river plus a portion of the flows to Hudspeth. Values estimated after 2002 based on regression with Hudspeth supply.

(3) Credit water to EPCWID from Accounting Reports for unused and unordered Project water.

(4) Hudspeth (Tornillo End) flows from 1938 - 4/1947 and sum of Hudspeth Feeder Canal and Tornillo Canal at AA from 5/1947 - 2017 (does not include Tornillo Drain flow).

Figure 5-24

Excess El Paso Valley Waste
Irrigation Season (March - October)
1938 - 2017
(acre-feet)

	1980-2017 Average	
Summary	**all years**	**w/o spills (5)**
Total El Paso Valley Waste	62,287	51,163
El Paso Valley Waste > 10%	38,074	28,023
EBID Portion (57%)	21,702	15,973
EPCWID Portion (43%)	16,372	12,050

Notes:

(1) Waste from WDR reports (1938 - 2002). Waste estimated from 2003 - 2017 using 1938 - 2002 regression with total flow to Hudspeth.

(2) Tabulated waste in excess of 10 percent of total river headgate diversions. Total river headgate diversions for EPCWID computed as Franklin Canal gaged flows minus Ascarate Wasteway (pre-ACE completion/2000) flows plus Riverside Canal gaged flows plus EPW Diversions of Project Water.

(3) EPV Waste in Excess of 10% (2) multiplied by 57 percent.

(4) EPV Waste in Excess of 10% (2) multiplied by 43 percent.

(5) Spill years were 1986, 1987, and 1995.

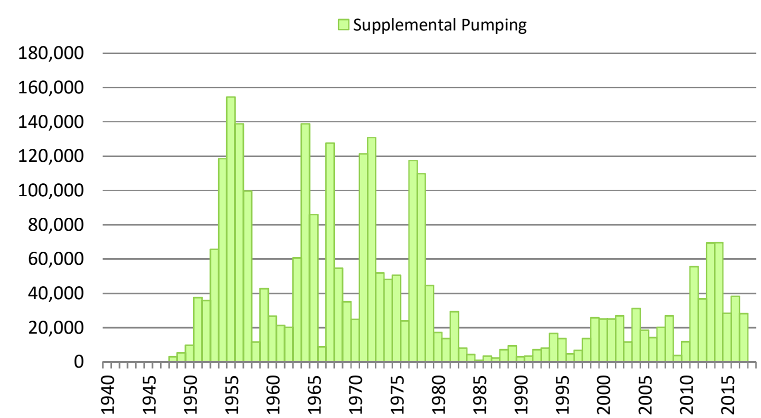
Annual Pumping (acre-feet)



Model Version: LRG Model v106 Operational Run - Base Run (All Pumping On).

Notes:

(1) Canal loss calculations occur at top of canal and are not in the surface water budget for Mesilla Texas. However a portion of the canal seepage accrues to the ground water objects for Mesilla TX.

(2) Canal Returns % is equal to canal returns divided by the sum of the canal diversions plus drain flows to canal.

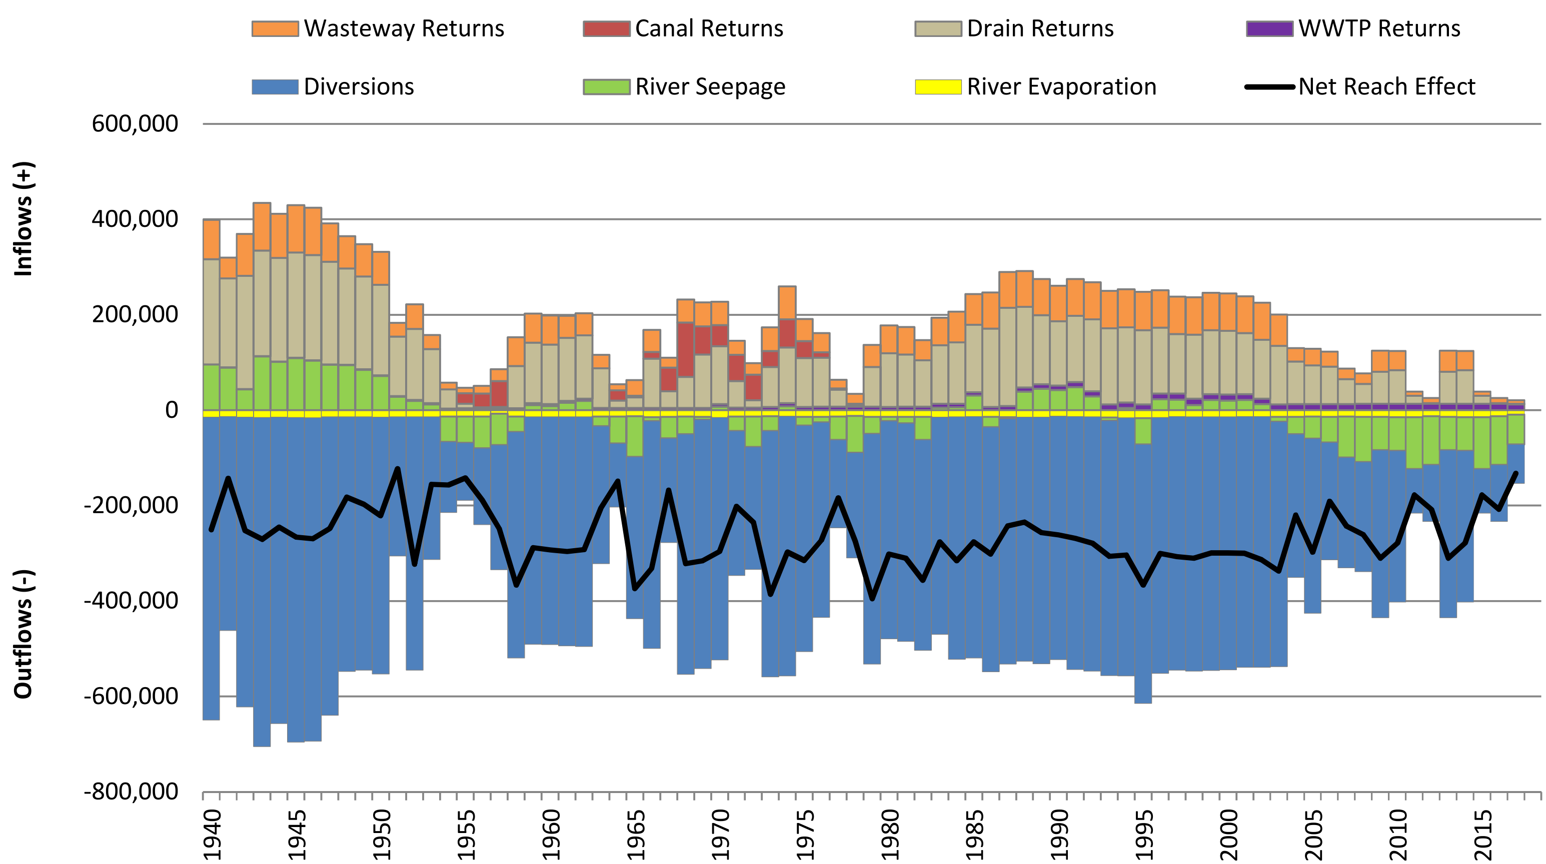
Annual River Budget Summary
Historical Base Run
Integrated LRG Model

1940 - 2017 (acre-feet)

Total Rincon-Mesilla (Below Caballo to El Paso)



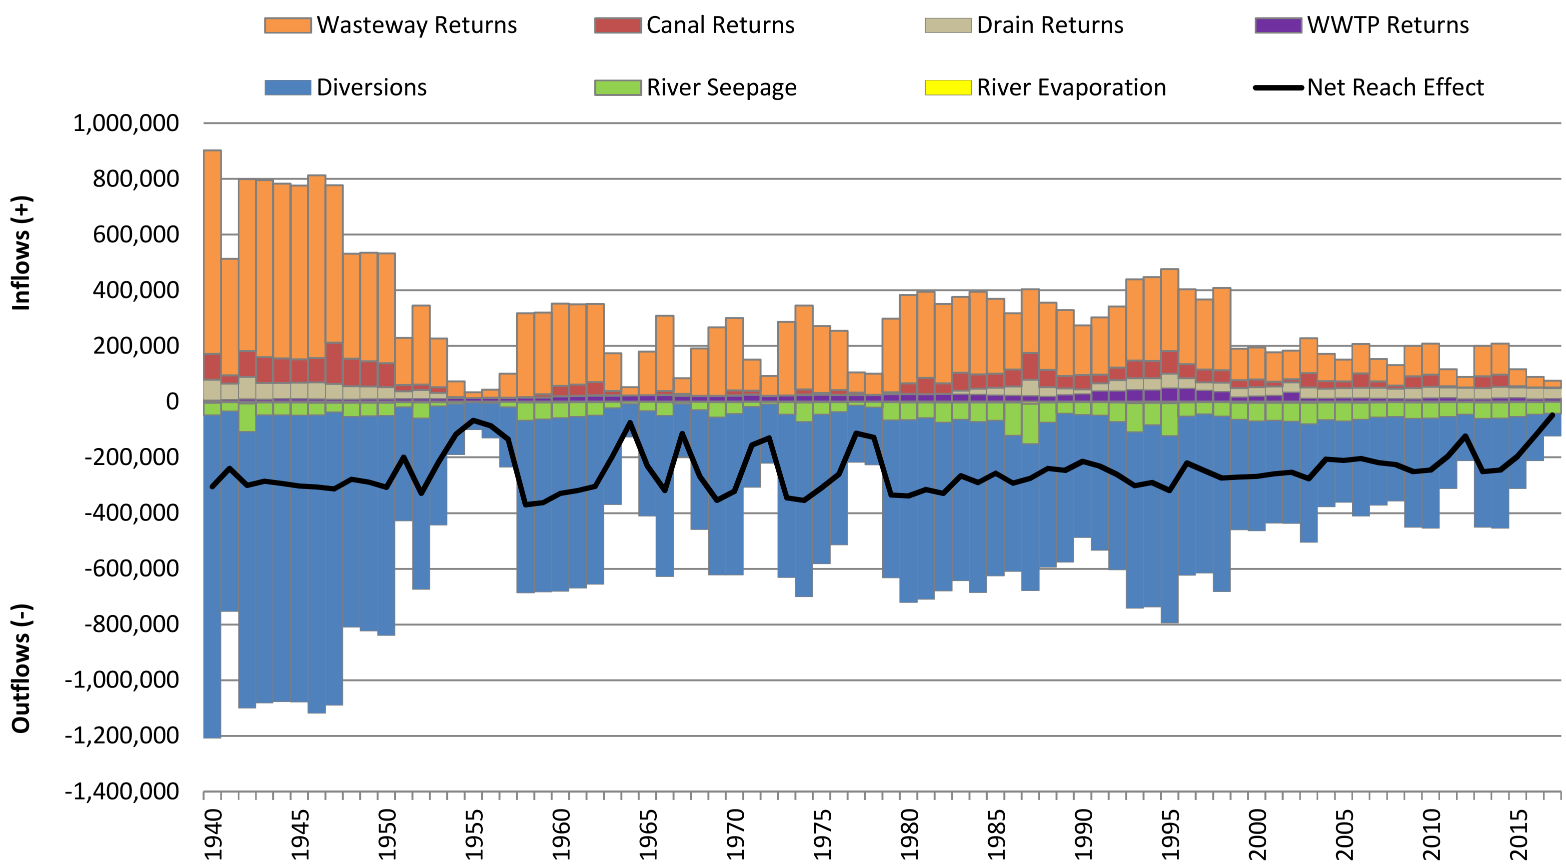
Notes:
Net Reach Effect is the change in streamflow through the stream reach, equal to total inflows minus total outflows.
River inflows and outflows not shown on graph.
Model Version: LRG Model v106 Operational Run - Base Run (All Pumping On).

Figure 9-8

Annual River Budget Summary
Historical Base Run
Integrated LRG Model

1940 - 2017 (acre-feet)

Total El Paso Valley (El Paso to Fort Quitman)



Notes:
Net Reach Effect is the change in streamflow through the stream reach, equal to total inflows minus total outflows.
River inflows and outflows not shown on graph.
Model Version: LRG Model v106 Operational Run - Base Run (All Pumping On).

Model Version: LRG Model v106 Operational Run - Base Run (All Pumping On).

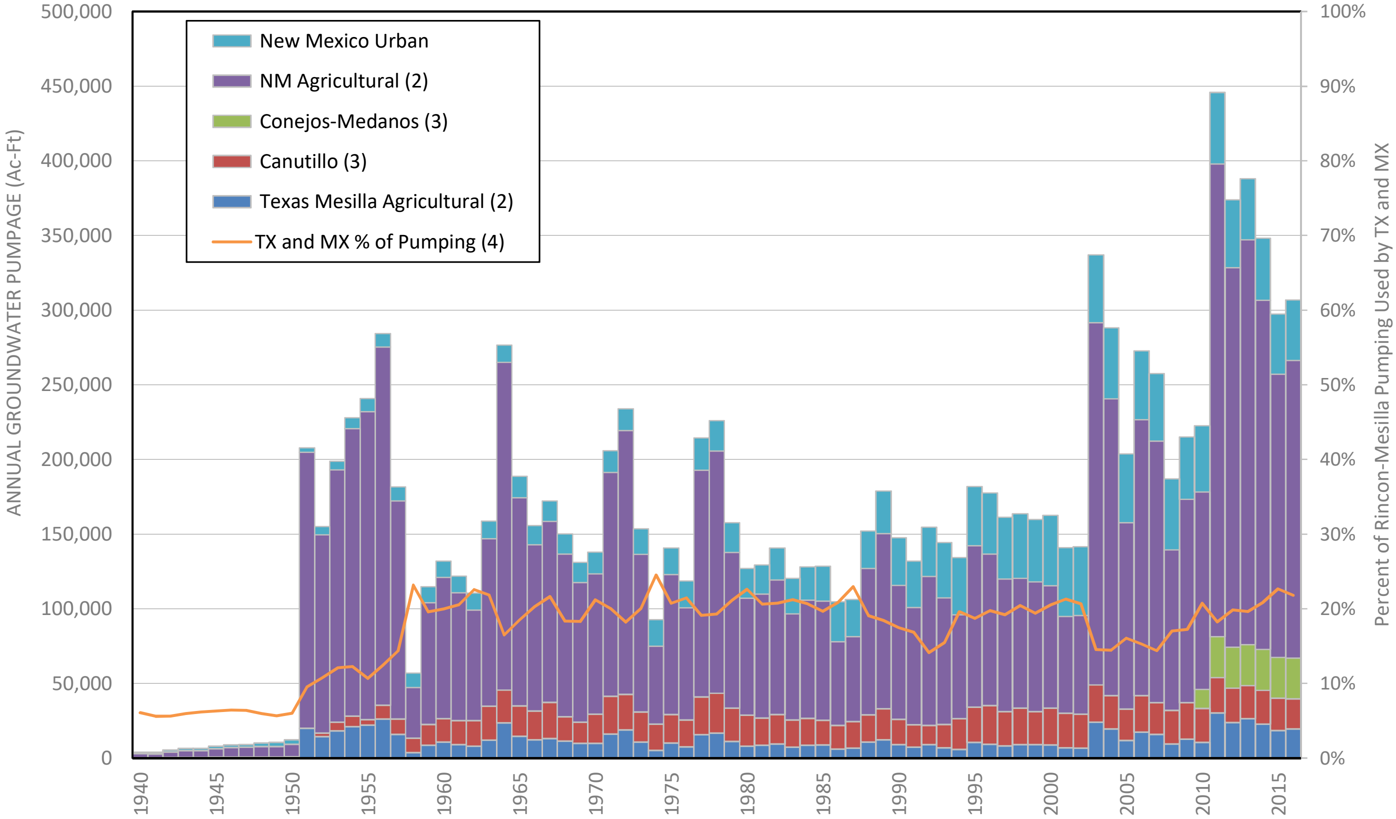
Figure 11-1

Total Annual Groundwater Pumpage for Irrigation and Urban Uses (Texas Estimates) in Rincon and Mesilla Basins 1940 - 2016

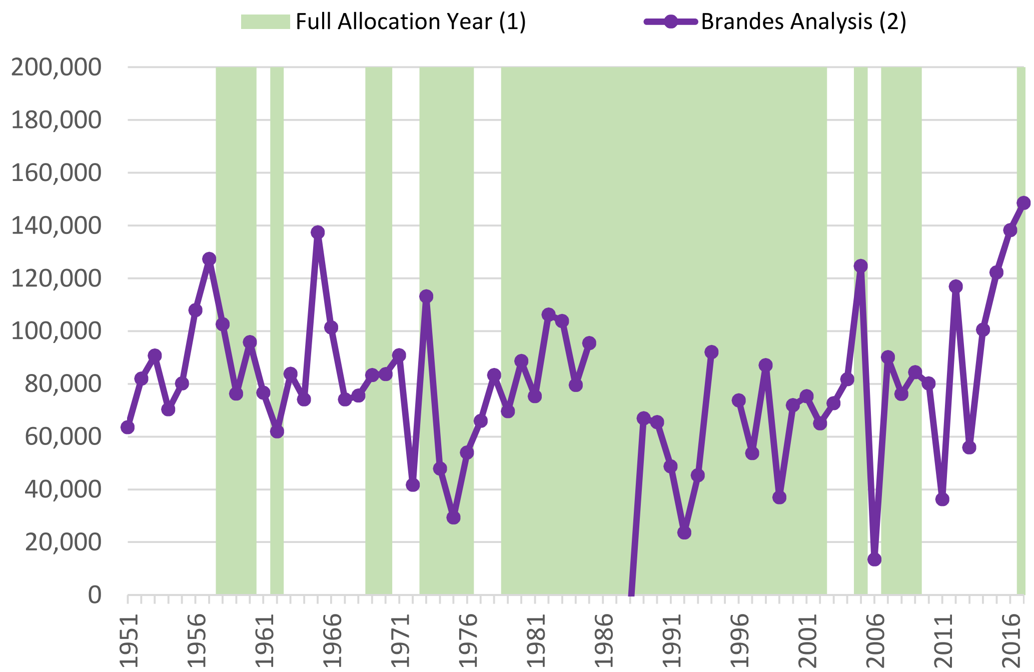


Notes:

(1) Data from Figure 4.5 in Expert Report of Robert J. Brandes disaggregated into NM, TX, and MX portions.
(2) Agriculture groundwater pumping split based on acreage according to Montgomery and Associates file FD_disagg_RinMes.xlsx.
(3) Canutillo and Conejos-Medanos data from Montgomery and Associates file tbl4.3_M&I_Pumping_Summary.xlsx.
(4) Calculated as sum of Texas Mesilla Agricultural, Canutillo, and Conejos-Medanos pumping by total Rincon-Mesilla Pumping.

Figure 11-2

Annual Impact of Pumping on Rio Grande at El Paso Flows
Brandes Double-Mass Curve Analysis
1951 - 2017
(acre-feet)



Averages	Annual Average	
1985 - 2016	71,996	(3)
1951 - 2017	78,667	(3)

Notes:

(1) Difference between historical flows and estimates flows without effects of pumping from Figure 5.5 of the Brandes report.

(2) See Section 4.3 of SWE report for description of how full allocation years are defined.

(3) Annual average values exclude spill years (1986, 1987, and 1995).

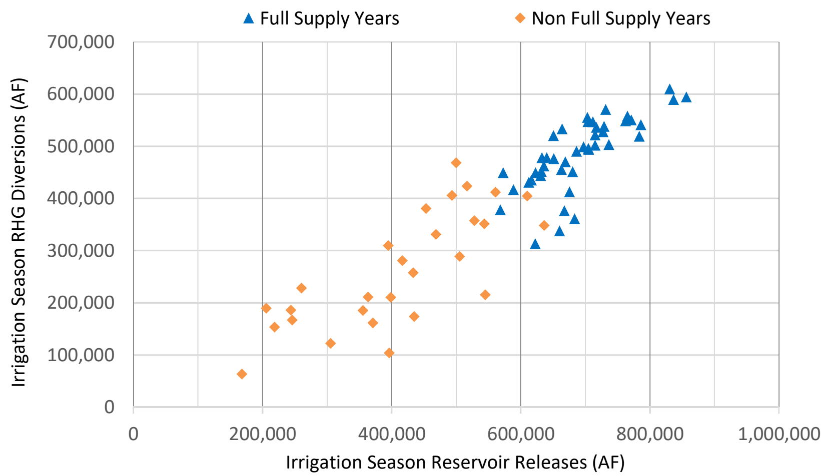
Figure 11-3

River Headgate Diversions v. Reservoir Releases

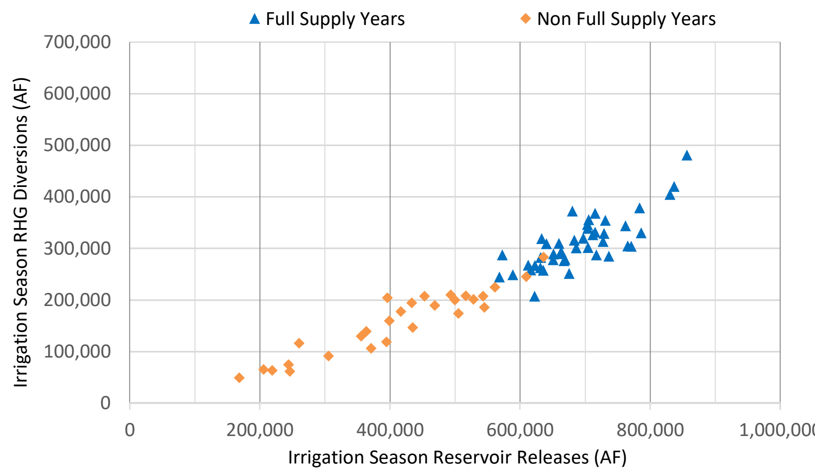
Historical Project Data

March-October 1940 - 2017 (acre-feet)

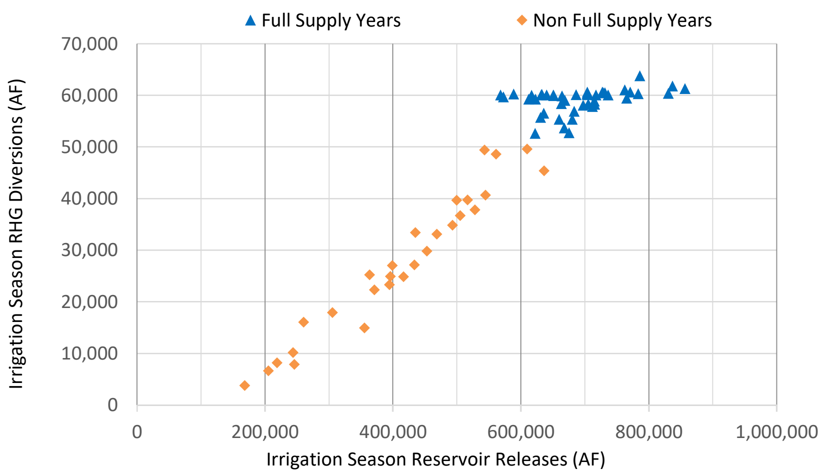
EBID Total (1)



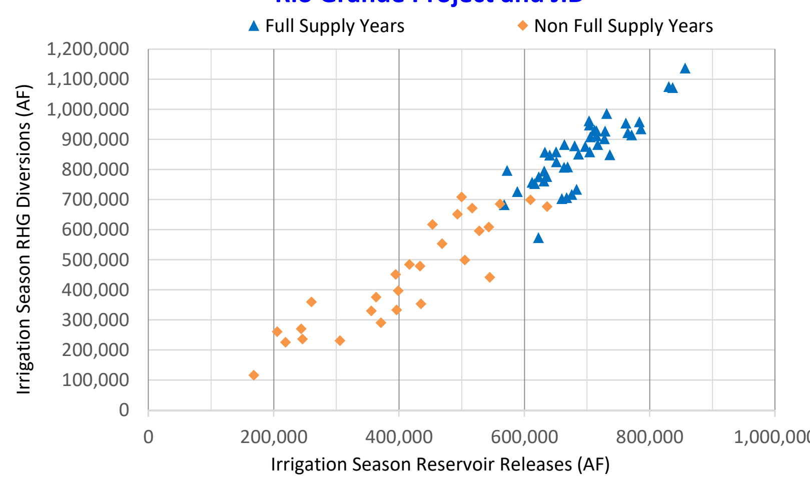
EPCWID Total (2)



JID (3)



Rio Grande Project and JID



***Note different scales.**

Notes:

(1) EBID Total RHG Diversions include diversions at Percha, Leasburg and Mesilla Dams minus Mesilla flows to TX.

(2) EPCWID Total RHG Diversions include Mesilla flows to TX, Franklin Canal minus Ascarate Wasteway (pre-ACE), Riverside Canal, and EPW diversions.

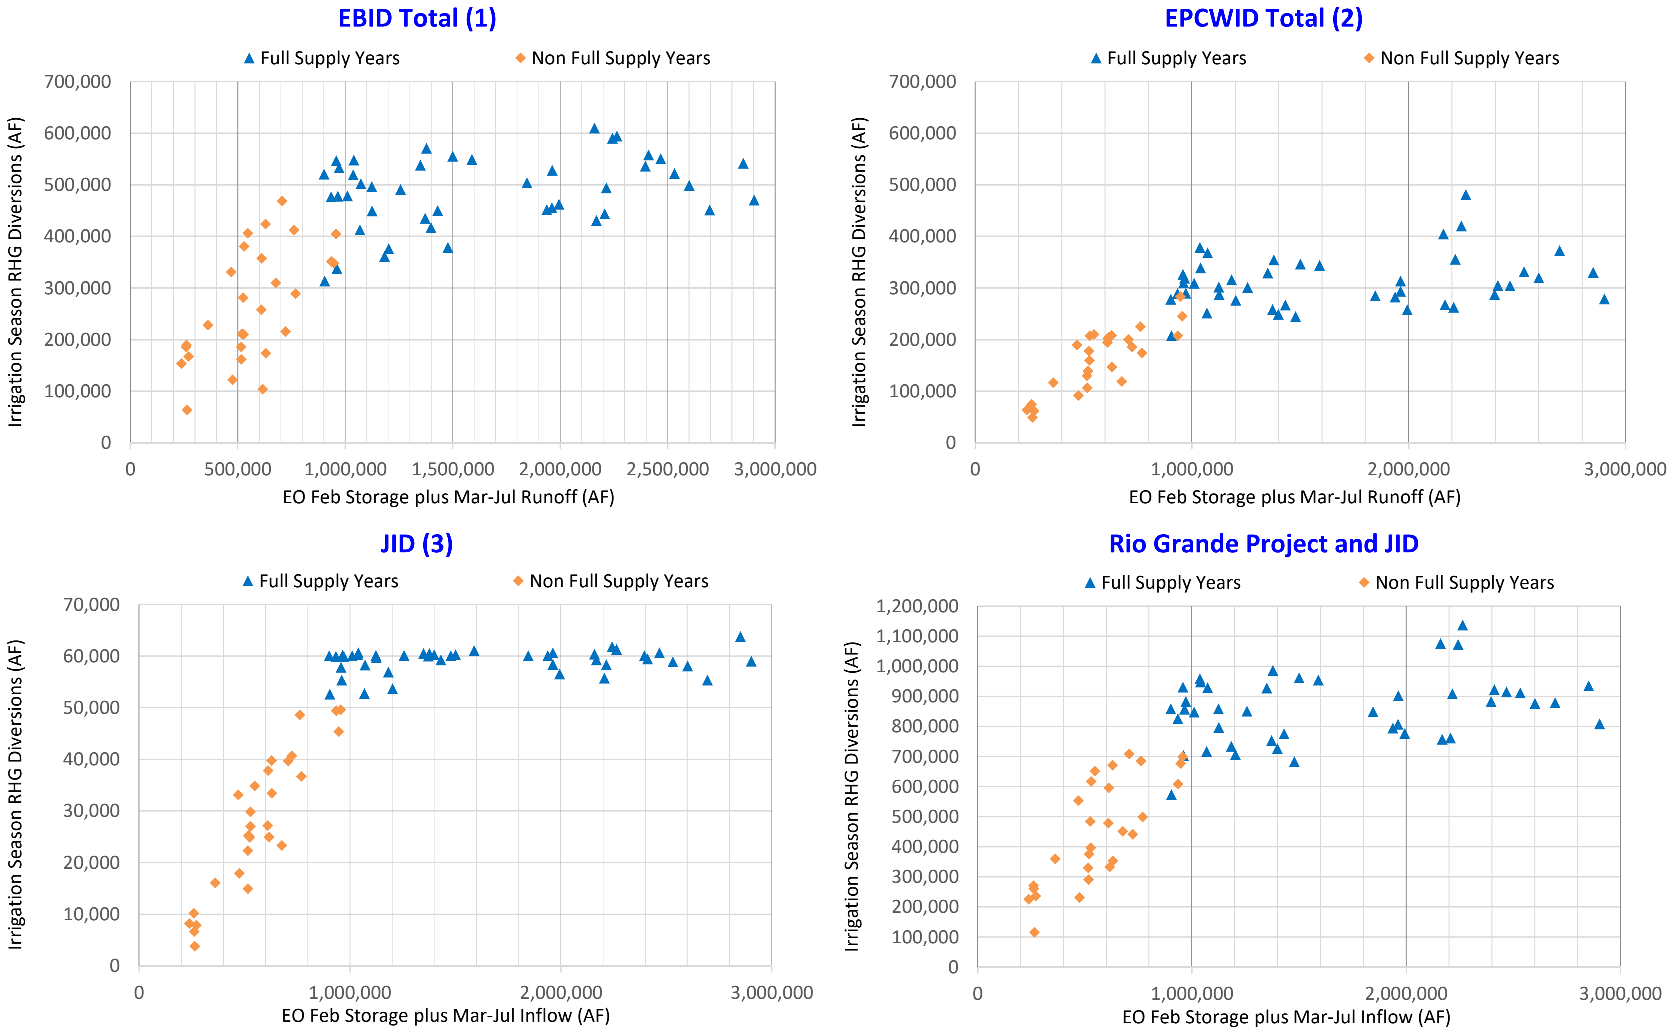
(3) JID RHG Diversions consist of Acequia Madre diversions only.

Figure 11-4

River Headgate Diversions v. Project Supply

Historical Project Data

March-October 1940 - 2017 (acre-feet)



***Note different scales.**

Notes:

(1) EBID Total RHG Diversions include diversions at Percha, Leasburg and Mesilla Dams minus Mesilla flows to TX.

(2) EPCWID Total RHG Diversions include Mesilla flows to TX, Franklin Canal minus Ascarate Wasteway (pre-ACE), Riverside Canal, and EPW diversions.

(3) JID RHG Diversions consist of Acequia Madre diversions only.

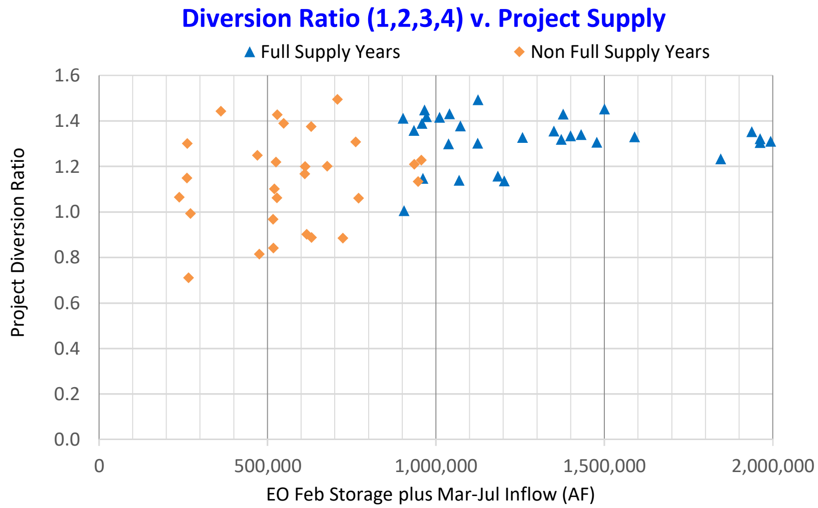
10/25/2019

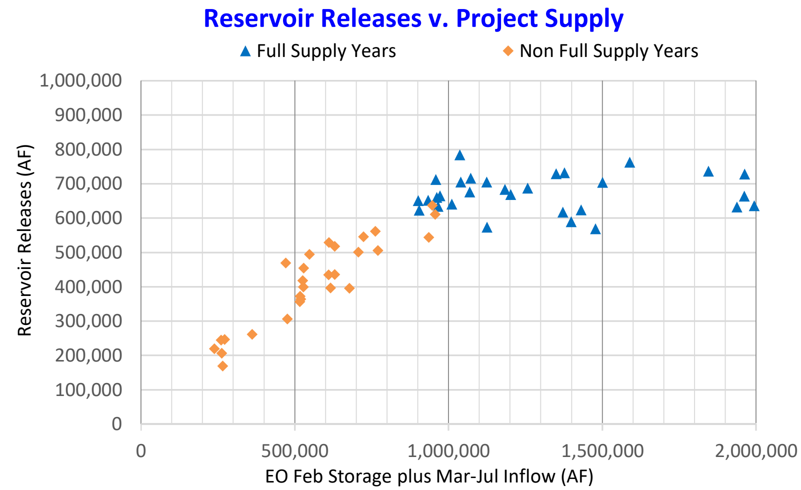
Figure 11-5

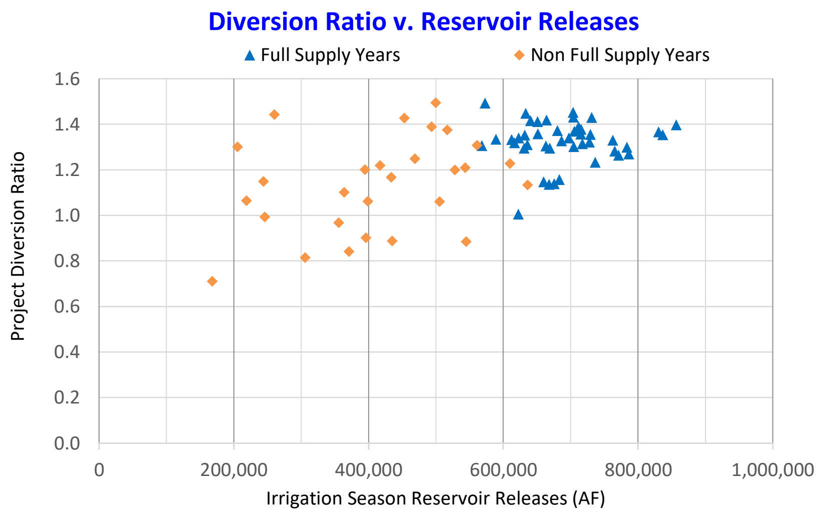
Comparison of Diversion Ratio, Project Supply, and Reservoir Releases

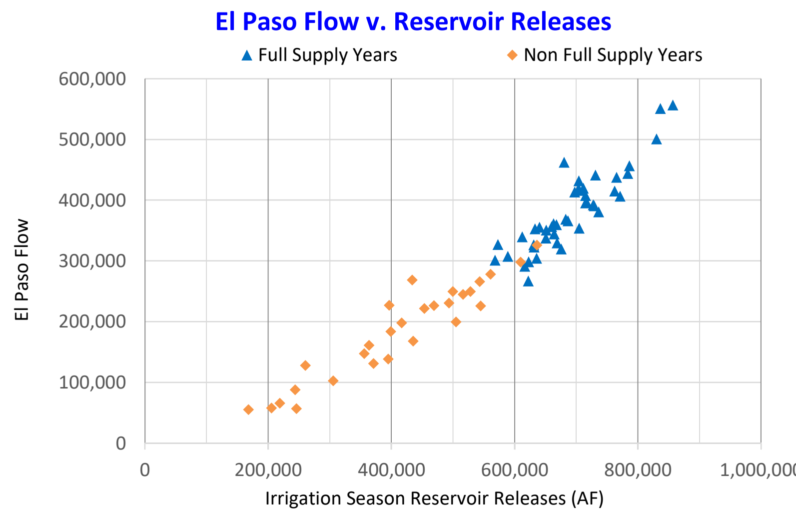
Historical Project Data

March-October 1940 - 2017 (acre-feet)









Notes:

(1) Diversion ratio is computed as the total RHG diversions (EBID, EPCWID, and JID) divided by Caballo Reservoir releases.

(2) EBID Total RHG Diversions include diversions at Percha, Leasburg and Mesilla Dams minus Mesilla flows to TX.

(3) EPCWID Total RHG Diversions include Mesilla flows to TX, Franklin Canal minus Ascarate Wasteway (pre-ACE), Riverside Canal, and EPW diversions.

(4) JID RHG Diversions consist of Acequia Madre diversions only.

(3) Volume of bare ground ET within footprint of maximum monthly crop acres.
(4) M&A FB irrigated area is the maximum monthly crop acreage during each year.

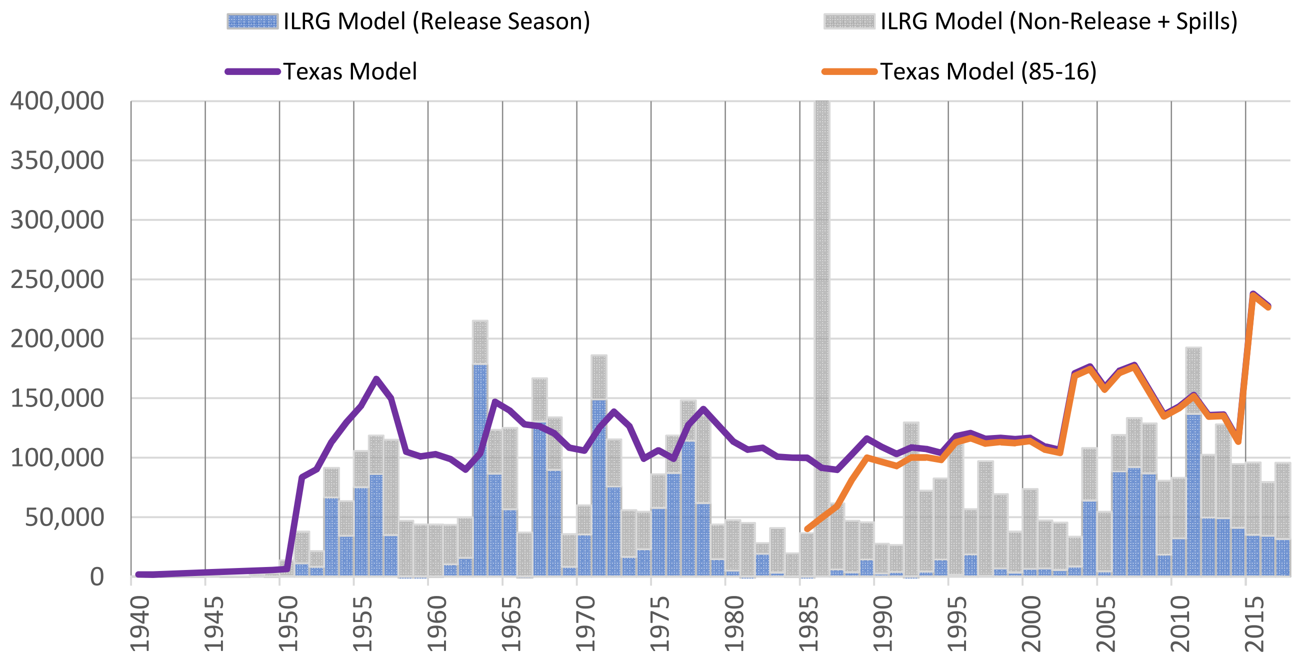
Figure 13-1

Annual Impact of Pumping on Rio Grande at El Paso Flows
Integrated LRG Model (No R-M Pumping)
vs.
Texas Model (100% Reduction in R-M Pumping)
(acre-feet)

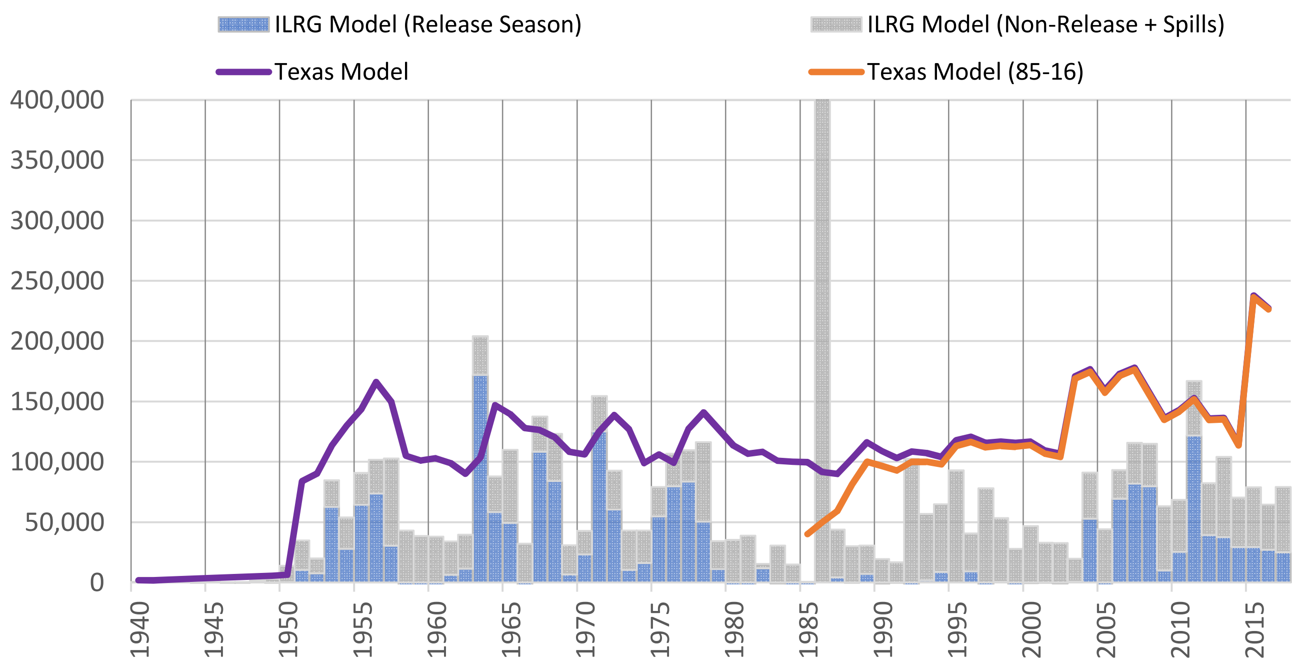


Averages	(1) ILRG Model (No R-M Pump)	(2) Texas Model (100% Reduction)	(3) Texas Model 85-16 (100% Reduction)
1985 - 2016 Annual (af):	93,910	132,866	124,658
1951 - 2016 Annual (af):	87,697	124,667	
1985 - 2016 Release Season (af):	25,098		
1951 - 2016 Release Season (af):	35,448		

Notes:
(1) ILRG Model change is computed as flows in Run 6 (no Rincon-Mesilla pumping) minus Run 1 (Historical Base Run).
(2) Texas Model (1938 - 2016 run) change is computed as the simulated flows with reduced pumping (100%) minus flows with no pumping reduction (historical simulation).
(3) Texas Model (1985 - 2016 run) change is computed as the simulated flows with reduced pumping (100%) minus flows with no pumping reduction (historical simulation).

Figure 13-2

Annual Impact of Pumping on Rio Grande at El Paso Flows
Integrated LRG Model (No NM Pumping)
vs.
Texas Model (100% Reduction in R-M Pumping)
(acre-feet)



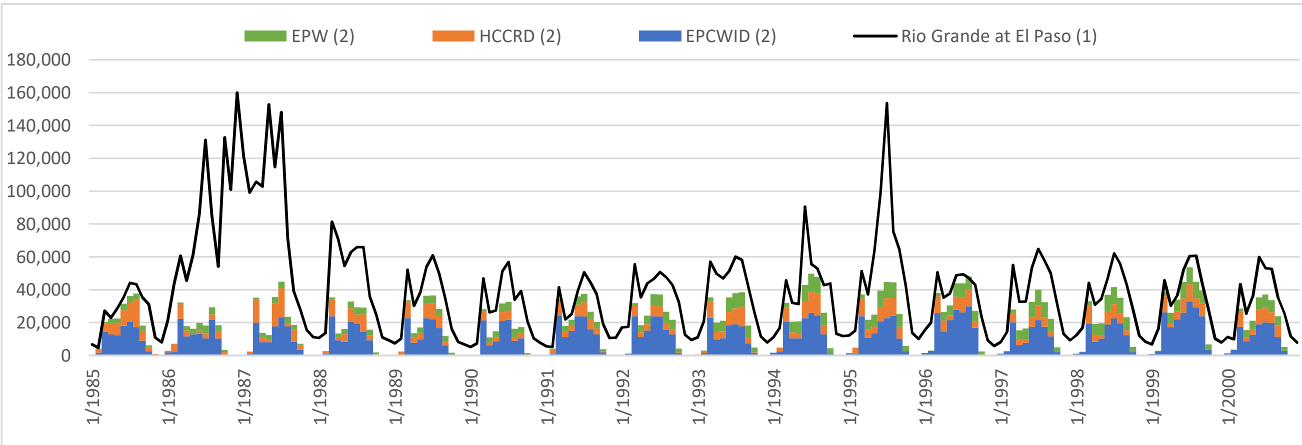
Averages	(1) ILRG Model (No NM Pump)	(2) Texas Model (100% Reduction)	(3) Texas Model 85-16 (100% Reduction)
1985 - 2016 Annual (af):	74,402	132,866	124,658
1951 - 2016 Annual (af):	71,169	124,667	
1985 - 2016 Release Season (af):	17,560		
1951 - 2016 Release Season (af):	27,523		

Notes:
(1) ILRG Model change is computed as flows in Run 3 (no New Mexico pumping) minus Run 1 (Historical Base Run).
(2) Texas Model (1938 - 2016 run) change is computed as the simulated flows with reduced pumping (100%) minus flows with no pumping reduction (historical simulation).
(3) Texas Model (1985 - 2016 run) change is computed as the simulated flows with reduced pumping (100%) minus flows with no pumping reduction (historical simulation).

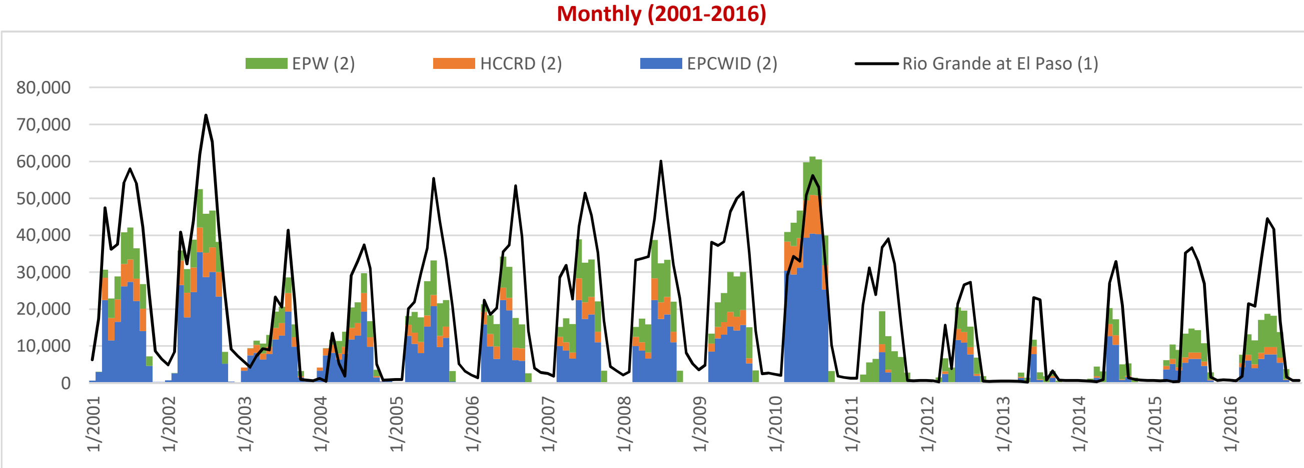
Figure 14-1

Historical Adjusted Rio Grande at El Paso Flows and Texas Deliveries
Dorrance Analysis
(acre-feet)

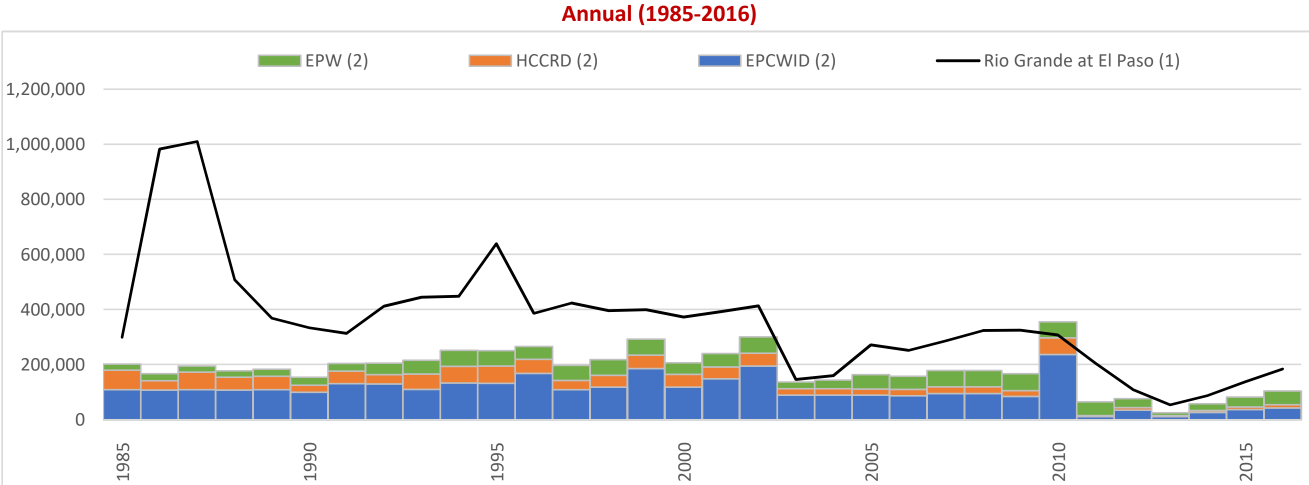
Monthly (1985-2000)



Monthly (2001-2016)



Annual (1985-2016)



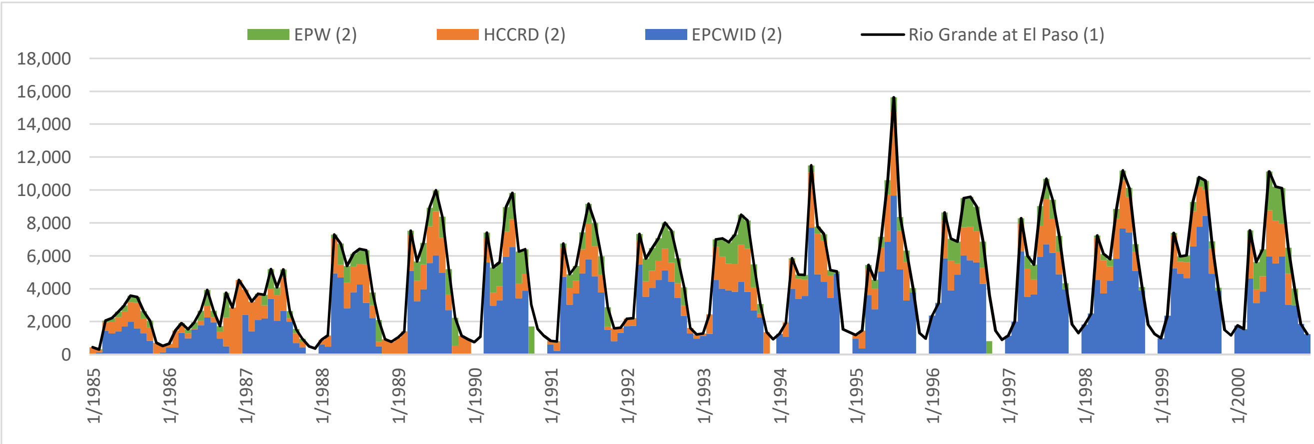
Notes:

(1) Rio Grande at El Paso is equal to historical Rio Grande at El Paso flow minus Acequia Madre diversions.
(2) Actual and estimated deliveries to Texas water users.

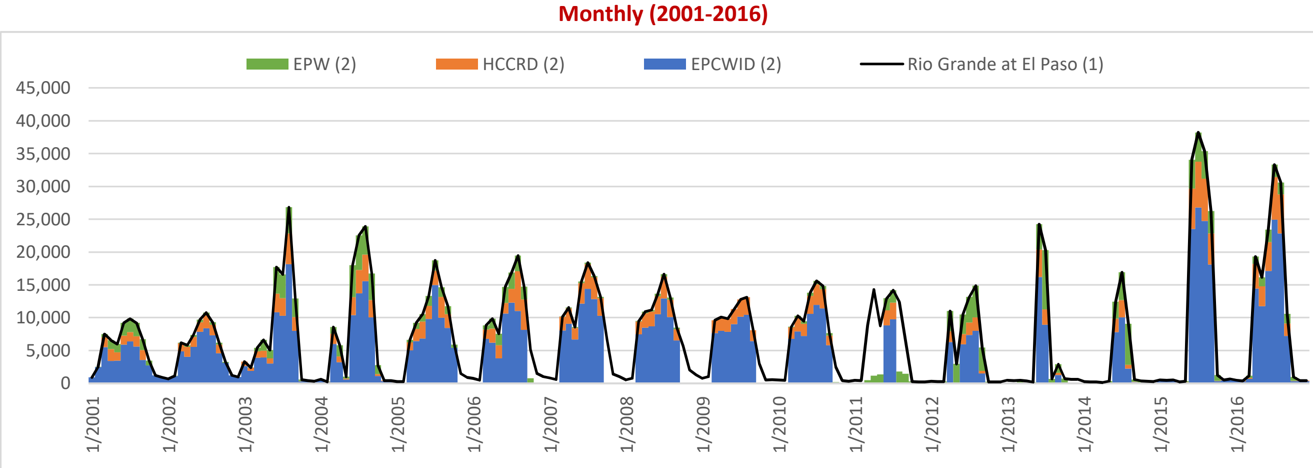
Figure 14-2

Increased Rio Grande at El Paso Flow and Amounts Made Available to Texas Water Users
Dorrance Analysis
(acre-feet)

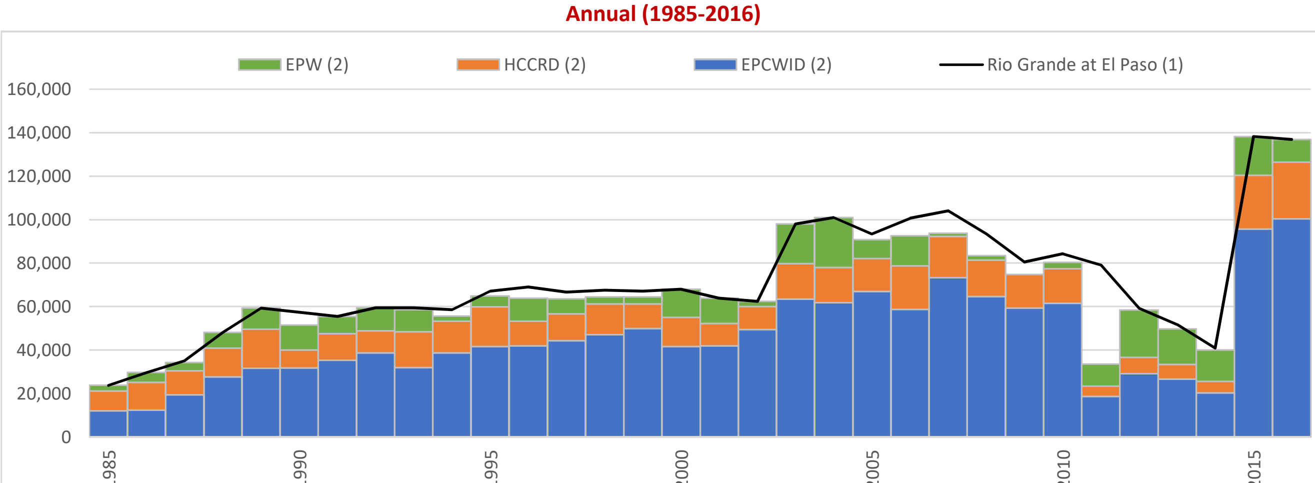
Monthly (1985-2000)



Monthly (2001-2016)



Annual (1985-2016)

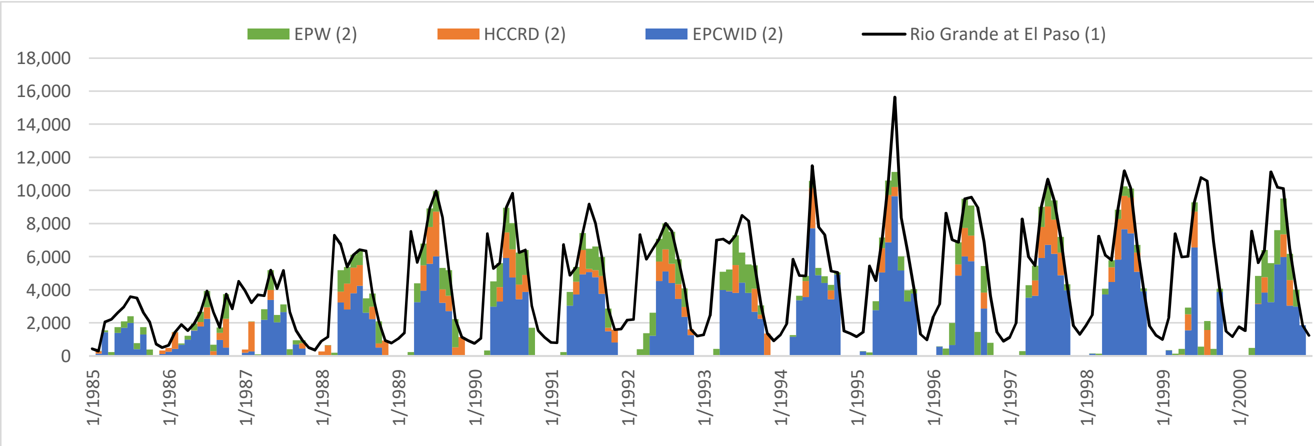


Notes:
(1) Increased Rio Grande at El Paso flow in 60% Rincon-Mesilla pumping reduction scenario simulated in Texas Model.
(2) Amounts of increased Rio Grande at El Paso flow made available for delivery to Texas water users.

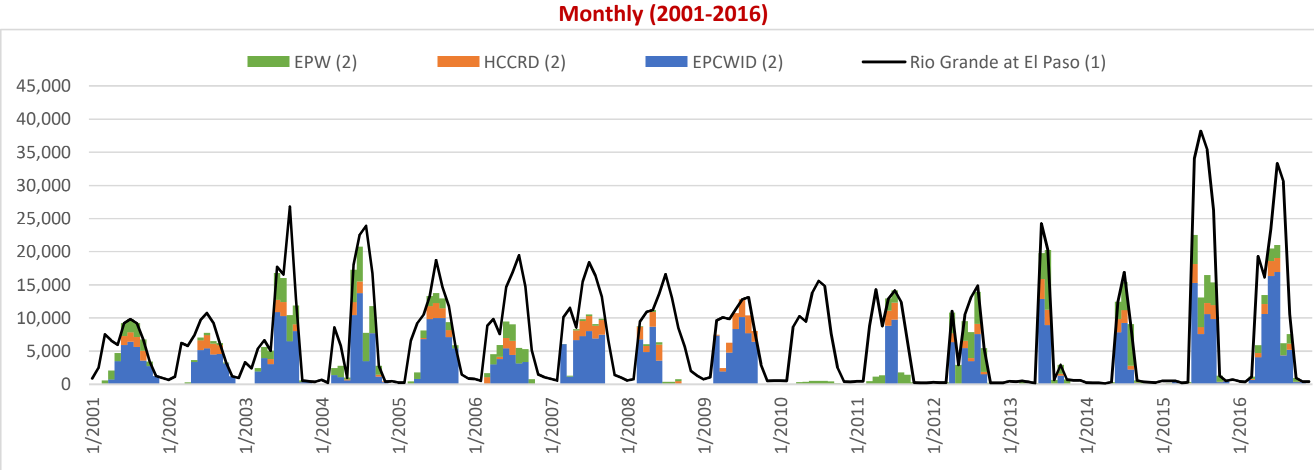
Figure 14-3

Increased Rio Grande at El Paso Flow and Increased Deliveries to Texas Water Users
Dorrance Analysis
(acre-feet)

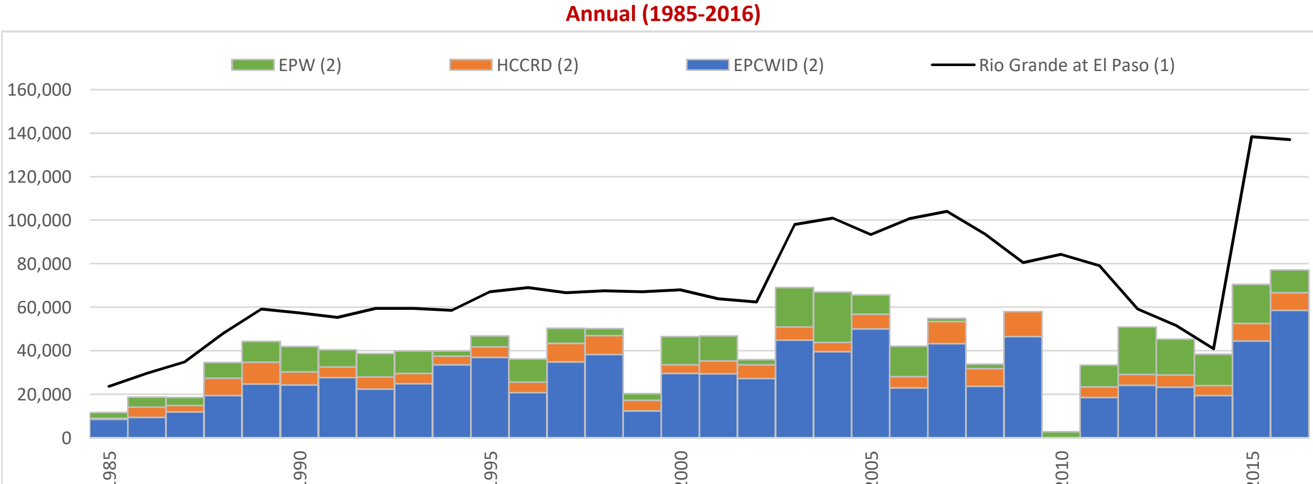
Monthly (1985-2000)



Monthly (2001-2016)



Annual (1985-2016)



Notes:

(1) Increased Rio Grande at El Paso flow in 60% Rincon-Mesilla pumping reduction scenario simulated in Texas Model.
(2) Amounts of increased Rio Grande at El Paso flow assumed delivered to Texas water users to replace historical pumping.

Figure 14-4

Annual Impact of Pumping on Rio Grande at El Paso Flows
Integrated LRG Model (No NM Pumping)
vs.
Dorrance (60% Reduction in R-M Pumping)
(acre-feet)

	(1) ILRG Model (No NM Pump)	(2) Dorrance (60% Reduction)
1985 - 2016 Average Annual (af):	74,402	71,232

Notes:
(1) ILRG Model change computed as flows in Run 3 (no New Mexico pumping) minus Run 1 (all pumping on).
(2) Dorrance change computed as the increase in El Paso gage flows (Texas Model simulation of 60% reduction in R-M pumping minus historical El Paso gage flows) from 1985 - 2016 only.

Figure 14-5

Annual Impact of Pumping on EPCWID Irrigation Deliveries
Integrated LRG Model (No NM Pumping)
vs.
Dorrance (60% Reduction in R-M Pumping)
(acre-feet)

	(1) ILRG Model (No NM Pump)	(2) Dorrance (60% Reduction)
1985 - 2016 Average Annual (af):	4,084	28,007

Notes:

(1) ILRG Model change computed as the El Paso Valley EPCWID farm deliveries in Run 3 (no New Mexico pumping) minus Run 1 (all pumping on).

(2) Dorrance change computed as the increase in El Paso gage flows (Texas Model simulation of 60% reduction in R-M pumping minus historical El Paso gage flows) distributed monthly using historical ratios of monthly to annual El Paso flows and ratios to historical EPCWID El Paso Valley deliveries.

Figure 14-6

Annual Impact of Pumping on EPW Deliveries
Integrated LRG Model (No NM Pumping)
vs.
Dorrance (60% Reduction in R-M Pumping)
(acre-feet)

	(1) ILRG Model (No NM Pump)	(2) Dorrance (60% Reduction)
1985 - 2016 Average Annual (af):	3,547	8,984

Notes:

(1) ILRG Model change computed as flows in Run 3 (no New Mexico pumping) minus Run 1 (all pumping on).

(2) Dorrance change computed as the increase in El Paso gage flows (Texas Model simulation of 60% reduction in R-M pumping minus historical El Paso gage flows) distributed monthly using historical ratios of monthly to annual El Paso flows and ratios to historical EPW deliveries. EPW deliveries limited maximum historical monthly deliveries.

Figure 14-7

Annual Impact of Pumping on HCCRD Deliveries
Integrated LRG Model (No NM Pumping)
vs.
Dorrance (60% Reduction in R-M Pumping)
(acre-feet)

	(1) ILRG Model (No NM Pump)	(2) Dorrance (60% Reduction)
1985 - 2016 Average Annual (af):	223	5,844

Notes:

(1) ILRG Model change computed as the HCCRD farm deliveries in Run 3 (no New Mexico pumping) minus Run 1 (all pumping on).

(2) Dorrance change computed as the increase in El Paso gage flows (Texas Model simulation of 60% reduction in R-M pumping minus historical El Paso gage flows) distributed monthly using historical ratios of monthly to annual El Paso flows and ratios to historical HCCRD deliveries.

Notes:

Data from Bureau of Reclamation accounting is typically irrigation season only and may not contain any winter diversions.

(1) Availability of data has not yet been determined.
Annual data only or only annual data available for certain years.
Blue text indicates that records for this gage have been updated through 2017.
(2) Gage numbers from U.S.G.S. or IBWC for river gages and some canals and NPDES permit numbers for WWTP returns
(3) Unique identifier from the NM OSE database.
(4) Period of data record in data compilation. There may be missing data within the available period of record.
(5) Y = location known from USGS, EBID, IBWC, or GPS coordinates.
* = approximate location known.
(6) Approximate start date of site (structure/gage/outfall).
(7) Average annual volume throughout period of available records. Annual volume converted to a rate assuming the volumes for river gages and WWTP returns are year-round (365 days); canal diverisons, wasteways, WTP diversions, and reservoir releases occur for an average of 245 days per year; and, drain flows occur for an average of 275 days per year.
(8) Records for periods of missing data estimated for use in modeling. Efforts are ongoing to obtain actual flow data for the missing records.
** = one or more additional missing months in dataset.

Table 3-3
Summary of Estimated Data for Surface Water Dataset
Rio Grande Project, Hudspeth County, and Mexico
1903 - 2017

Structure	Start	Period of Record	Missing Data	Method for Estimating Missing Data
Canals - Hueco				
Acequia Madre	Pre-1903	1924 - 1925, 1930 - 1936, 6/1938 - 2006, 2008 - 2017	1903 - 1923, 1926 - 1929, 1937 - 5/1938, 2007	1903 -1923: Used 1924 - 1925 monthly regression with Courchesne gage capped at an estimated diversion capacity (300 cfs) and limited to season of use Mar 1 – Nov 30.
				1926 - 1929 and 1937: Used 1930 - 1936 monthly regression with Courchesne gage capped at an estimated diversion capacity (300 cfs) and limited to season of use Mar 1 – Nov 30.
				1/1938 – 5/1938: Used 1938 annual value less data for period of record in 1938 distributed from Mar - May using Franklin Canal flows.
				2007: Used reported 2007 annual diversion in Rio Grande Compact Commission Report distributed monthly using Franklin Canal diversions.
Franklin Canal	1889	1914 -1916, 1918 - 2017*	1903 – 1913, 1917	1903 -1913 and 1917: Used 1938 - 1949 monthly regression with Courchesne gage capped at an estimated diversion capacity (320 cfs) and limited to season of use Mar 1 – Nov 30. Do not have complete winter diversions in recent years - these winter diversions were not estimated.
Tornillo Canal at Alamo Alto	1947	1947 - 2016*	Various months 1995 – 1996 and 2004 – 2005	Various months 1995 - 1996 and 2004 - 2005: Used 1985 - 1994 monthly regression with Riverside Canal.
Hudspeth Feeder Canal	May-47	5/1947 - 2010	2011 - 2012	2011 - 2012: Used 2005 - 2010 monthly regression with Franklin Canal.
Hudspeth Canal (Tornillo End)	1925	1935 - 1947 (ann)	1925 - 1934	1925 - 1934: Estimated flow using water balance (Tornillo Canal heading flow less seepage loss (15%*Tornillo Canal heading) less crop demand for Tornillo acres (CIR*acres/irrigation efficiency) less Tornillo Waste End flows).
				1935 - 1947: Annual data distributed monthly using Tornillo Canal heading flows.

Table 3-3
Summary of Estimated Data for Surface Water Dataset
Rio Grande Project, Hudspeth County, and Mexico
1903 - 2017

Structure	Start	Period of Record	Missing Data	Method for Estimating Missing Data
Canals - Hueco (cont.)				
Juarez River Diversions (below International Dam)	Pre-1903	Annual estimates 1930-1936, 1938-1947, and 1950-1984	1903 - 1929, 1937, 1948-1949, 1985 - 2016	1903 - 1929: Estimated flows based minimum of unmet demand (Farm Budget spreadsheet) limited by estimated flow below International Dam (Courchesne minus Franklin Canal minus Acequia Madre) minus Riverside Canal when applicable.
				1930-1936, 1938-1947, and 1950-1984: Distributed annual estimates monthly using Acequia Madre flows.
				1937: Set equal to 1936 annual estimate.
				1948 - 1949: Estimated flows based on gage differences from Island Station to Fort Quitman.
				1985 - 2016: Did not estimate because there are no gage records.
Wasteways - Hueco				
Franklin Settling Basin WW	1938?	No data		6/1938 – 1998: Data provided by Peggy Barroll, NMOSE. Computed using water balance approach (American Canal diversions less Franklin Canal diversions less City of El Paso municipal diversions). Split total computed waste 50/50 between Franklin Settling Basin and Leon St. wasteways. Estimates do not consider transit losses.
Leon St WW	1938?	No data		
Ascarate WW	1916?	1938 - 1954 (ann), 1955 - 2005*	1916 - 1937, 2004, 2005 - 2017	1916 - 1937: Used annual regression (1938 - 1949) with Franklin Canal and distributed annual data into monthly values proportional to Franklin Canal flows.
				1938 - 1955: Distributed annual data into monthly values proportional to Franklin Canal flows.
				2004 and 2006 - 2017: Assumed no Ascarate Wasteway flows until more data become available due to little to zero flows reported since the completion of the American Canal Extension.

Table 3-3
Summary of Estimated Data for Surface Water Dataset
Rio Grande Project, Hudspeth County, and Mexico
1903 - 2017

Structure	Start	Period of Record	Missing Data	Method for Estimating Missing Data
Wasteways - Hueco (cont.)				
Riverside WW#1	1928?	1938 - 1955 (ann combined)**, 1981 - 1984, 1993 - 2017*	Pre-1938, 1956 - 1980,1985 - 1982, 2004	1928 – 1937: Used annual regression for combined Riverside WW#1 and WW#2 with Riverside Canal (1938 - 1949) and distributed annual data into monthly values using Riverside Canal diversions. Split between WW#1 and WW#2 using 1981 - 2013 average annual split. Assumed Riverside WW#2 flows do not start until 1930.
				1938 – 1955: Distributed annual data into monthly values proportional to Riverside Canal diversions. Split between WW#1 and WW#2 using 1981 – 2013 average annual split.
Riverside WW#2	1930?			1956 - 1980, 1985 - 1992, and 2004: Used annual regression for combined Riverside WW#1 and WW#2 with Riverside Canal (1991 - 2003) and distributed annual data into monthly values using Riverside Canal diversions. Split between WW#1 and WW#2 using 1981 - 2013 average annual split.
Municipal - Hueco				
Northwest WWTP Returns	1987	9/2002 - 2017*	1987 - 8/2002	1987 - 8/2002: Data provided by Nabil Shafike, NMISC - computed using regression with Mesilla EPWU ground water pumping.
Haskell WWTP Returns (1)	1923	1936 - 1939, 1940 - 1948**, 1949 - 1959, 1960 - 1975**, 1977 - 2017*	1923 - 1935, 1976, 1/1998 - 9/1998	1923 - 1935: Used annual 1936 - 1940 regression with EPWU pumping. Distributed annual data evenly in each month (divide by 12).
				1976: Used average 1975 and 1977 monthly flow data (i.e., Jan 1976 flow = average Jan 1975 and Jan 1977).
				1/1998 - 9/1998: Used average 1997 and 1999 monthly flow data.
Bustamante WWTP Returns	1991	9/1995 - 2017*	1991 – 8/1995	1991 - 1994: Annual volume derived from reported 1996 influent in gallons per day per capita scaled to Bustamante service area proportion of total City of El Paso population and subtracted Socorro WWTP flows (1991 - 1993). Annual volume divided by 12 to obtain monthly values.
				1/1995 - 8/1995: Annual reported value minus sum of remainder monthly flows (9/1995-12/1995) divided by 8.

Table 3-3
Summary of Estimated Data for Surface Water Dataset
Rio Grande Project, Hudspeth County, and Mexico
1903 - 2017

Structure	Start	Period of Record	Missing Data	Method for Estimating Missing Data
Municipal - Hueco (cont.)				
Socorro WWTP	1967?	1989 - 2/1993	1967 - 1988; 10/1991	1967 - 1988: Annual volume derived from reported 1996 influent in gallons per day per capita scaled to Bustamante service area proportion of total City of El Paso population. Annual volume divided by 12 to estimate monthly values.
				10/1991: Computed as average 9/1991 and 11/1991 flows.
Juarez Sewage to river	1926?	1940 - 1950 ann	1926 - 1939; 1951 - 2013	1926 - 1939: Data not estimated (not enough information available to estimate).
				1940 - 1950: Distributed annual reported estimates evenly into each month (divided by 12).
				1951 - 2013: Assume zero (discharge zero by late 1940s).
Juarez Sewage to canals	1926	1950 - 1984	1926 - 1949 and 1985 - 2017	1950 - 1984: Annual reported estimates divided by 12.
				1926 - 1949 and 1985 - 2017: Used JMAS pumping provided by MMA multiplied by 49% (same methodology as IBWC 1989 report) minus Juarez Sewage to river (1940 - 1950).
Robertson-Umbenhauer WTP (aka Canal St. WTP)	Nov-43	11/1943 - 2017**	Records for total El Paso WTP prior to 2007	1943 - 1992: Robertson-Umbenhauer WTP equal to total City of El Paso until Jonathan Rogers comes online in 1993.
Jonathan Rogers WTP	1993	1993 - 2017**		1993 - 2006: Split total City of El Paso into each WTP using distribution from available data from 2007 - 2013.
Fabens WWTP	2001	2001 - 2017**	1/2001 - 5/2001, 7/2004, 10/2004	1/2001 - 5/2001 , 7/2004, and 10/2004: Computed using monthly averages from prior and subsequent year.
Municipal - Rincon-Mesilla				
Hatch WWTP	1940	2000 - 2017*	1940 - 1999	1940 - 1999: Computed using regression with population (no pumping data available).
			1/2000 - 9/2000, 11/2005, 10/2013	1/2000 - 9/2000, 11/2005, and 10/2013: Computed using monthly averages from prior and subsequent year.
Las Cruces WWTP	1940	1976 - 2017*	1940 - 3/1976, 5/1979 - 6/1979, 4/1985, 9/1985 - 10/1985	1/1976 - 3/1976, 5/1979 - 6/1979, 4/1985, and 9/1985 - 10/1985: Computed using regression with pumping.
Anthony NM WWTP	1989	1989 - 2017*	1989-1995	1989 - 1995: Computed using regression with pumping.

Table 3-3
Summary of Estimated Data for Surface Water Dataset
Rio Grande Project, Hudspeth County, and Mexico
1903 - 2017

Structure	Start	Period of Record	Missing Data	Method for Estimating Missing Data
Municipal - Rincon-Mesilla (cont.)				
Anthony TX WWTP	1953	1953 - 2017*	1953-2004, 1/2005-4/2005, 2/2006, 11/2006, 8/2007, 8/2016-12/2017	1953 - 2004: Computed using regression with pumping. 1/2005 - 4/2005, 2/2006, 11/2006, 8/2007, and 8/2016 - 12/2017: Computed using monthly averages from prior and subsequent year.
El Paso Electric WWTP	1950	1950 - 2017*	1950 - 2003, 2/2005, 10/2005 - 12/2005, 8/2006, 5/2009	1950 - 2003, 2/2005, 10-12/2005, 8/2006, 5/2009: Computed using regression with pumping. 2/2005, 10/2005 - 12/2005, 8/2006, and 5/2009: Computed using monthly averages from prior and subsequent year.
Gadsden School District WWTP	1992	1992 - 2017*	1/2016 - 4/2016, 11/2016, 1/2017, 6/2017, 12/2017	1/2016 - 4/2016, 11/2016, 1/2017, 6/2017, 12/2017: Computed using monthly averages from prior and subsequent year.
Total Sunland Park + Santa Teresa	1972	2004 - 2017	1972 - 2003	1972 - 2003: Computed using monthly averages from prior and subsequent year.

Notes:
All estimated data calculations in source folder: LRG.Doc.SW118.
*Missing months of data within period of record.
**Records combined with other flows, split total diversions out by structure.
(1) Records from 1940 - 1948 and 1960 - 1975 include Ascarate and Yselta EPCWID plant discharges.
(2) Annual estimates from Rio Grande Joint Investigations (1938), Carreno (1957), and IBWC (1989).

Note: (1) From 1979 - 2005 full supply years are years with Mexico allocations (rounded to nearest 1,000) equal to or greater than 60,000 acre-feet. From 2006 - 2018, full supply years are years with EPCWID current year allocation greater than 360,000 acre-feet.
(2) Annual total allotment for 1979 from USBR table (USBR handout in DC_11282012.pdf).
(3) Full supply year per reported allotment to EBID of 3.00 af/acre.

Notes:

(1) Corresponding WWTP returns and urban deep percolation returns are also turned off (no UDP simulated in Mexico).

(2) Including Texas Mesilla (EPCWID Mesilla and EPW Canutillo Wellfield).

(3) Including Texas Mesilla and Mexico Conejos-Medanos.

(4) Project allocation procedure simulated for 1948-2017.

Appendix 1A
Professional Resume of
Gregory K. Sullivan, P.E.

Gregory K. Sullivan, P.E.

Principal Water Resources Engineer

Education: M.S., Civil Engineering, 1990, University of Colorado - Denver.
B.S., Civil Engineering, 1985, Colorado State University.

Professional Registration:

Professional Engineer in Colorado #26802, Idaho #8387, Nevada #10868, and New Mexico #22620

Professional Experience:

1990 - Present: ***Spronk Water Engineers, Inc., Principal and Senior Water Resources Engineer***

Mr. Sullivan is responsible for the management and successful completion of water rights engineering and water resources planning projects. Projects include water supply planning, changes of water rights, plans for augmentation, historical consumptive use and stream depletion analyses, water rights evaluations and appraisals, water supply planning, reservoir operations studies, ground water modeling and water rights accounting. Mr. Sullivan has extensive experience in litigation support and has provided expert testimony before courts and state agencies on numerous occasions.

Summary of Experience:

Mr. Sullivan has over thirty years of experience completing a wide variety of water resources engineering projects. Mr. Sullivan has extensive experience performing historical consumptive use analyses, stream depletions analyses, and reservoir operations studies. Mr. Sullivan serves as the primary consultant to numerous water providers for water supply planning and water rights engineering. In that role, he has been responsible for technical analyses in supporting changes of water rights, exchanges, augmentation plans, and other water right matters. He has led the development of complex surface water operations models that simulate municipal water demands and how those demands maybe met by available water supplies and water rights. Mr. Sullivan has served on the Eastern Snake Hydrologic Modeling Committee that guides the development and use of a regional ground water model of the Eastern Snake River Plain Aquifer since 1996. Mr. Sullivan has provided expert testimony in the U.S. Supreme Court, Colorado Water Courts, Snake River Basin Adjudication Court (Idaho), and in administrative hearings before the Idaho Department of Water Resources.

Gregory K. Sullivan, P.E.

Principal Water Resources Engineer

Description of Representative Projects:

Change of Water Rights, City of Loveland

Mr. Sullivan was the principal investigator for ditch-wide historical use analyses of the major Big Thompson River irrigation ditches that serve lands in and around the City of Loveland. These analyses served as the basis for successful changes of water rights that were approved by the Division 1 Water Court to allow the City to divert its ditch shares at the City's municipal water intakes to help meet its water supply needs.

Water Supply Yield Modeling, City of Loveland

Mr. Sullivan led the development of a model to simulate the daily water supply and demand of the City of Loveland over a study period from 1950 - 2017. The water supplies that are simulated in the model include the ditch shares that have been changed to municipal use, Colorado-Big Thompson Project units, Windy Gap Project units, and the operation of the City's Green Ridge Glade Reservoir. The model is used by the City to evaluate the firm yield of its water supply, and how that yield can be increased through acquisition of additional supplies, development of additional storage, changes in water supply operations and other actions.

Water Supply Planning, ACWWA

Mr. Sullivan has provided water resources and water rights consulting for the Arapahoe County Water and Wastewater Authority ("ACWWA") for almost 30 years. ACWWA serves lands in the Cherry Creek basin south of Denver through a combination of shallow alluvial wells and deep nontributary Denver Basin wells. Water use from these sources is integrated and optimized through operation of a complex plan for augmentation that provides for replacement of out-of-priority depletions to Cherry Creek to protect downstream senior water users. Mr. Sullivan has performed numerous analyses to evaluate the yield of ACWWA's water supplies, including completion of a raw water master plan in 2018.

Plan for Augmentation, Upper Cherry Creek Water Association

Mr. Sullivan led the development of an umbrella plan for augmentation for five major water users in the Cherry Creek Basin upstream of Cherry Creek Reservoir. The members have pooled their augmentation sources to replace the combined out-of-priority depletions resulting from alluvial well pumping and out-of-priority storage in Cherry Creek Reservoir. The plan includes an innovative method of computing depletions that considers times when Cherry Creek is dry in the area of the member wells.

Gregory K. Sullivan, P.E.

Principal Water Resources Engineer

Cherry Creek Aquifer Modeling Project
Mr. Sullivan led the development of a basin-wide simulation model of the hydrology and water use in the Cherry Creek basin upstream of Cherry Creek Reservoir. The model simulates the water supplies and water rights of the all of the municipal water providers in the study area and optimizes the alluvial pumping of the water users and the use of Denver Basin ground water replacement supplies. The model also simulates the operation of Cherry Creek Reservoir and Rueter-Hess Reservoir. The model is used by the study participants to evaluate changes in water supply operations and acquisition of new water supplies.

Snake River Delivery Calls, City of Pocatello, Idaho
Mr. Sullivan has provided technical analysis and expert testimony to the City of Pocatello in their participation in complex litigation involving water right delivery calls by senior surface water users on the Snake River in Idaho. Pocatello's water supply is derived primarily from junior priority wells that are tributary to the Snake River, and its water supply is threatened by the delivery calls. Mr. Sullivan analyzed the historical operation of seven major irrigation districts that placed the delivery calls to assess the extent of their claimed irrigation water shortages. The irrigation districts serve a combined area of 560,000 acres with annual diversions averaging 3.2 million acre-feet per year.

ESPA Cities Mitigation Plan, Idaho
Mr. provided technical expertise and analysis to develop a mitigation plan for Pocatello, Idaho Falls, and more than a dozen other cities to mitigate the impacts of pumping ground water from the Eastern Snake Plain Aquifer in Idaho. The plan relies largely on aquifer recharge to mitigate the impacts of aquifer depletions from pumping that is projected to increase from about 60,000 acre-feet per year to over 120,000 acre-feet per year over the next 50 years.

Division 3 Rules Case, Rio Grande Basin, Colorado
Mr. Sullivan represented a group of surface water right owners that opposed the enactment of administrative rules governing the withdrawal and use of ground water in the Rio Grande Basin in Colorado (Water Division 3). The primary basis for their opposition was that the rules did not provide for mitigation of impacts to a large spring that was the source of their surface water rights and which dried up in conjunction with the large-scale development of ground water irrigation in the area. Mr. Sullivan's work included analysis of the historical irrigation water use by his clients, review of hydrologic data and records, and review of a ground

water modeling of the San Luis Valley performed by the State of Colorado. Mr. Sullivan provided expert testimony on behalf of his clients in a trial before the Division 3 Water Court.

Administration of Rocky Hill Seepage and Overflow Ditch, Rio Grande Basin, Colorado

Mr. Sullivan represented a majority owner of the Rocky Hill Seepage and Overflow Ditch in the northwestern portion of the San Luis Valley in an action brought to overturn a change in administration by the Division 3 Engineer that curtailed use of the ditch on the basis that the source of water for the ditch that has been used for almost 100 years is not described in the decree for the ditch. Mr. Sullivan's work involved research of historical documents related to adjudication of the water right and historical disputes among water users in the vicinity, compilation and analysis of historical hydrologic data, and development of opinions on the decreed source of the water for the ditch. Mr. Sullivan provided expert testimony in a trial over the dispute in the Division 3 Water Court.

Surface and Ground Water Modeling, Kansas v. Colorado

Mr. Sullivan was involved in the refinement and use of the H-I Model of the Arkansas River system in Colorado that was developed to support claims by the State of Kansas that Colorado was violating the terms of the 1948 Arkansas River Compact. The model simulates daily operation of irrigation water uses under approximately two dozen canal systems along the Arkansas River in Colorado between the City of Pueblo and the Colorado-Kansas from 1950 to the present. In addition, the model simulates the operation of sole-source and supplemental irrigation wells, and the impact of those wells on the flow of the Arkansas River. Mr. Sullivan provided expert testimony before a Special Master appointed by the U.S. Supreme Court regarding the use of the H-I Model to evaluate the effects on state-line flows resulting from post-compact well development in Colorado.

Injury Analysis, Kansas v. Colorado

Mr. Sullivan developed a model that was used as part of an analysis to compute the economic impacts and monetary damages to Kansas resulting from the compact violations by Colorado that were determined in the Kansas v. Colorado lawsuit. The model was used to translate monthly depletions to usable stateline flows during 1950 - 1994 into impacts to (a) surface water users in Kansas, (b) to supplemental pumping demands in Kansas and (c) to recharge of the regional ground water system. Mr.

Gregory K. Sullivan, P.E.

Principal Water Resources Engineer

Sullivan testified before the Special Master regarding the model development, operation, and results.

Analysis of Replacement Plans, Kansas v. Colorado
In order to continue their use of post-compact Arkansas River alluvial wells, the well owners were required to develop Replacement Plans to offset the impacts of pumping on senior surface water rights in Colorado and on usable stateline flows to Kansas. Mr. Sullivan analyzed the adequacy of these replacement plans through preparation of historical use analyses, water budgets, and other analyses. In addition, Mr. Sullivan used the H-I Model to simulate the effectiveness of the replacement plans in meeting Colorado's delivery obligations under the Arkansas River Compact. Mr. Sullivan provided expert testimony before the Special Master concerning his analyses of the Colorado Replacement Plans.

1985 – 1990: ***J. W. Patterson & Associates, Inc., Water Resources Engineer***
Performed water supply, hydraulic and hydrologic analyses for agricultural, industrial, commercial and municipal developments. Managed yield and impact analyses of water rights adjudications, transfers, exchanges and plans for augmentation. Conducted ground water studies including aquifer testing, project dewatering and water well design and construction monitoring.

Continuing Education

Applied Ground-Water Flow Modeling. International Ground Water Modeling Center, Colorado School of Mines, Golden, CO. March 1993

Introduction to Simulation Training in RiverWare, Center for Advanced Decision Support for Water and Environmental Systems, University of Colorado, May 2016.

List of Expert Reports Authored by
Gregory K. Sullivan, P.E.
During the Last Five Years

Report Date	Name of Report	Applicant	Case No.	Client

Appendix 1B
Professional Resume of
Adelheid M Welsh

Heidi M. Welsh, P.H.

Senior Watershed Scientist

Education: B.S. Watershed Science, 2007, Colorado State University

Professional Registration: Professional Hydrologist, American Institute of Hydrology

Professional Experience:

2009 - Present: ***Spronk Water Engineers, Inc., Senior Watershed Scientist***
Responsible for compilation and analysis of water resources, water rights and hydrologic data including climatological data, streamflow data, diversion records, cropping patterns, call records, water rights tabulations and decrees. Analyses include quantification of historical consumptive use, crop evapotranspiration calculations, water availability analyses, stream depletion modeling, point flow modeling, and other surface water modeling. Assists with water rights protection, substitute water supply plans, augmentation plans, and water rights accounting. Responsible for GIS mapping and modeling related to water resources including georeferencing and digitizing, delineation and quantification of irrigated area, hydrologic analyses, and geospatial analysis.

Summary of Experience:

Ms. Welsh has over ten years of experience working in the water resources field in Colorado, Wyoming, New Mexico, Montana, and Idaho. She has provided engineering support and assistance with water rights protection, substitute water supply plans, and augmentation plans. She is experienced in the review, development and maintenance of water rights accounting. She has extensive experience in GIS applications and modeling related to water resources and has prepared numerous court exhibits.

Description of Representative Projects:

Town of La Salle, Water Supply Consulting.
Assisted the Town in developing a water supply for irrigation of parks, ballfield, and subdivision lawns. Assisted with a substitute supply plan and assisted in change of Godfrey Ditch and Union Reservoir water rights

Heidi M. Welsh, P.H.

Senior Watershed Scientist

application to allow use of an irrigation well, replacing depletions with leased water supplies from the reservoir. Engineering analyses include calculation of water demands, water consumption and timing of stream depletions to the South Platte River. Responsible for daily augmentation plan accounting.

City of Pocatello, Water Rights Protection and Water Supply.
Assists in preparation of exhibits and water rights analyses for administrative hearings. Engineering analyses include analysis and review of water rights data and water measurements, summarizing and mapping depletions using Eastern Snake Plain Aquifer Model runs, and mapping water rights data.

State of New Mexico, Rio Grande Compact.
Responsible for review, compilation, and maintenance of surface water data. Assists in the review of surface water modeling efforts, including RiverWare modeling.

Cherry Creek Project Water Authority.
Assists with analysis and mapping of the Cherry Creek Basin in support of water rights applications and basin modeling. Analyses include water availability analyses, point flow modeling, consumptive use analyses, and stream depletion modeling.

Climax Molybdenum, Plan for Augmentation in Division 2.
Assists with analysis in support of a water rights application. Analyses include computation of current and historical depletions, point flow and exchange potential modeling, and probability analyses. Responsible for GIS analyses and mapping for the project.

Centennial Water & Sanitation District, Water Rights Protection.
Assists with review of water court applications and substitute water supply plans for water rights protection. Analyses include return flow and consumptive use calculations, delineation of irrigated area, compilation of diversion records, and stream depletion modeling.

Yellowstone River Compact.
Delineated current and historic irrigated fields along the Powder and Tongue Rivers in Montana. Compiled and analyzed historical agricultural data from the U.S. Agricultural Census.

Heidi M. Welsh, P.H.

Senior Watershed Scientist

2007 – 2009: ***AATA International, Inc., Environmental/GIS Specialist***
Compiled and interpreted social and environmental data for preparation of large-scale environmental impact assessments and other technical reports. Responsible for collection and maintenance of databases. Conducted impact analysis, assessed water supply sources, and developed mitigation and monitoring plans for natural resource development projects. Utilized GIS software in mapping and analyses of environmental data and prepared numerous figures for technical reports.

2006 – 2007: ***USDA Forest Service, Hydrologic Technician***
Completed soil, stream crossing, and stream health surveys for timber sale units. Managed grazing by the completion of soil inventories for NEPA compliance. Mapped streams and forest roads using GPS and GIS. Evaluated Best Management Practices for feasibility and effectiveness.

2006: ***Teton Science School, Hydrology Intern***
Measured stream discharge, monitored ground water well levels and collected water quality samples weekly at twelve sites. Entered and analyzed data for technical documentation. Taught watershed science and hydrology field methods to adults and children.

Professional Memberships:
American Institute of Hydrology
American Water Resources Association
Colorado Ground Water Association

Appendix 4B
El Paso Valley Unit
Diversions and Waste Notes from Water Distribution Reports

Appendix 4B
El Paso Valley Unit
Diversions and Waste Notes from Water Distribution Reports

1919:

[1]Measured at *1 [2]Measured at [3]Measured at Measured at

REMARKS: *1 Monthly deliveries to farms per acre apply to areas irrigated each month; No estimate for March; Apr. - 15,240 acres; May 15,588; June 18,114; July 14,926; Aug. 17,195; Sept. 8,226; Oct. 220; Nov. 1,198; During last months of year the irrigated acreage was reported each month by ditchriders. *2. This flow includes wasteways: - Montoyo, Escarate, River, Clint Lateral, Salatral Lateral, San Elizario Wasteways No. 2, 3 and 4. Of this flow that of the Montoyo and Escarate Wasteways join the flow that is available for diversion to the El Paso Valley system. The remainder is available for diversion to the Independent Tornillo Irrigation District.

Remarks: Under acre feet tabulation apply here.

1920:

[1]Measured at Montoya Headgate, Mexican Dam, San Elizario Headgate [2]Measured at Lateral Headgates [3]Measured at Farm Tap Boxes Measured at

REMARKS: *5 Some wasted into the Rio Grande above Canal intakes, the rest wasted past the end of the Project.
*7 Areas irrigated per month as follows:

Jan.	201	ac.	Apr.	16,548	ac.	July	21,192	ac.	Oct.	4,989	ac.
Feb.	724	"	May	19,270	"	Aug.	15,508	"	Nov.	687	"
Mar.	8,555	"	June	16,052	"	Sept.	10,891	"	Dec.	1,146	"

*8 Not including Tornillo, Ft Hancock nor uncontracted part of Island

1953:

1/ Does not include "Pumped from Drains".
Revised May 13, 1954

1954:

1/ Does not include watdr pumped from drains.

1964:

1/ Does not include water pumped from drains.

1965:

1/ No water pumped from drains during 1965.

Note: River operation in no manner is reflected in this tabulation. All figures are the result of summations of operating records of the Rincon, Leasburg, Mesilla and Ysleta Units of the Project and in no manner do any of the figures represent loss from the river.

The only measured quantities on this tabulation are the "Diverted from Stream" and "City of El Paso Water Treatment Plant." All other data estimated except "Charged to Farms" which is based on spot current measurements and individual farm deliveries.

The City of El Paso owns 2,000 acres of water right land on the Project and also obtains the water rights of land classified under the contract between the City and the El Paso County Water Improvement District No. 1 of December 20, 1962, No. 14-06-500-762. This land is withdrawn from Project irrigation, and water deliveries are made to the City of El Paso Water Treatment Plant.

1966:

[illegible] drains [illegible]

IN REPLY REFER TO: 410

DEC 19 1984

Mr. Bill Saad, Treasurer-Manager
Elephant Butte Irrigation District
PO Drawer A
Las Cruces, NM 88001

Dear Mr. Saad:

The allocation of Rio Grande Project water for 1985 is 100%.

The following amounts have been determined available for diversion at the headings:

Mexico	60,000 AF
EBID	478,037 AF
EPCWID	363,963 AF

Sincerely,

Roger K. Patterson
Project Superintendent

cc: IBWC

From USBR "Annual Operating Plan 1984 Operations, 1985 Outlook"

D. Crop Production and Water Utilization

1. Project

a. The initial release of water from Caballo Reservoir for the irrigation season was made on February 9, 1984. A full allotment of 902,000 AF was declared available for Mexico and the U.S. Districts on February 4, 1984. A total amount of 653,153 AF was released from storage during 1984 to satisfy water user orders. A gross amount of 761,141 AF was delivered at the diversion points within the project. The Caballo Dam was closed on October 3, 1984 ending the irrigation season.

b. Of the 159,650 acres of water right land for the U.S. Districts, 90,640 acres are allocated to the EBID and 69,010 acres are allocated to the EPCWID. A total acreage of 126,395 acres were in production for an overall crop value of $111,679,417. An average crop value for all crops grown by the U.S. Districts amounted to $884 per acre. (Crop value information is from preliminary data.)

2. EBID

a. Of the EBID 90,640 acres of water right land, 79,201 acres were irrigated during 1984. The district had 1305 full time and 1071 part time farms operating during the year. The district utilized a gross total of 411,128 AF of their allocated 478,037 AF of irrigation water during the year.

b. Crop production realized in the Rincon and Mesilla Valleys, for all crops, amounted to $81,121,835 (estimated), not including multiple crops. The average crop value was $1,024 per acre.

c. The major crops grown in Rincon and Mesilla Valley were:

(1) Vegetables (17,260 acres) (peppers, onions and lettuce)	$40,908,329
(2) Pecans (13,160 acres)	$17,849,734
(3) Forage (24,355 acres) (alfalfa and silage)	$11,973,014
(4) Field Crops (18,510 acres) (cotton)	$ 9,789,041 (Estimate)

3. EPCWID

a. Of the 69,010 acres of water right land, 47,194 acres were irrigated during 1984. The district had 705 full time and 1202 part time farms operating during the year. The district utilized a gross total of 289,976 AF of their allocated 363,963 AF of irrigation water during 1984.

b. Crop production realized in the El Paso Valley and Upper Valley (Texas), for all crops, amounted to $30,557,582 not including multiple crops. The average crop value was $647 per acre.

c. The major crops grown were:

(1) Field crops (23,105 acres) (cotton)	$17,514,415
(2) Pecans (5,031 acres)	4,851,142
(3) Forage (11,003 acres) (alfalfa, pasture and silage)	4,168,411
(4) Cereals (10,082 acres) (wheat, sorghums, oats, corn and barley)	3,640,520

SUBJECT: **Final Allocation** of the 2004 Rio Grande Project Water Supply Based on End of July Data

Dear Gentlemen:

The combined total Rio Grande Project water storage at Elephant Butte and Caballo Reservoirs for **July 31, 2004 was 210,365 acre-feet (AF).** We have released 275,793 AF of storage water for irrigation from March 12 to July 31, 2004.

Nearly all of the combined Rio Grande Project (Project) storage in Elephant Butte and Caballo Reservoirs is available for allocation. The only waters that cannot be allocated are: 1,050 AF of Rio Grande Compact credit waters; and 6,315 AF of San Juan-Chama water, both in Elephant Butte Reservoir.

We have gained only 16,118 AF in the net supply available for allocation from July 1 through July 31, 2004. Further, comparing actual deliveries of Project supply to the canal headings and Caballo Dam releases during March through July of 2004 has resulted in a slight increase in the delivery efficiency to 0.704 (or a 29.6% loss rate). The last update of the allocation (for end of June data) indicated a river efficiency of 0.6875 (31.25% losses). The river losses for the present net supply available for allocation have decreased by 2,852 AF since last month's allocation update. However, this decrease in river losses (2,852 AF) and increase in net supply (16,118 AF) totaling 18,970 AF still is less than the increase in river losses last month (44,537 AF). Therefore, Reclamation will not increase the allocation due to continuing decreased river efficiency of delivering Project supply to the Project canal headings. As agreed in our meeting with Elephant Butte Irrigation District, El Paso County Water Improvement District No. 1, the International Boundary & Water Commission, and Mexico on July 30, 2004, **Reclamation declares the allocation of last month's update as the final allocation for the 2004 irrigation season**. The following is the final allocation:

ACRE-FEET

Mexico..	27,197
Elephant Butte Irrigation District..................................	185,507
El Paso County Water Improvement District No. 1......	141,240
TOTAL:	353,944

This final allocation represents only 37.98% of a full irrigation season supply for the entire Project. Last month's updated allocation was the same.

Please find enclosed:

- Enclosure No. 1 which summarizes modifications in the allocation procedures.
- Enclosure No. 2 which provides the details of the calculations for this month's allocation.
- Enclosure No. 3 which details the estimated Rio Grande Compact credit waters and San Juan-Chama water, both in Elephant Butte Reservoir.
- Enclosure No. 4 which summarizes the 2004 allocations to date.

Actual provisional flow data at the San Marcial gauging stations indicate that the flow for the 2004 spring runoff (March – July) was approximately 240,390 AF (41.95% of the 30-year average flow). Since 1996, we have

now had 8 years with below normal runoff into Elephant Butte Reservoir. The only year with above normal runoff was 1997. Enclosed is Reclamation's latest Project reservoirs operational plan with projections of the reservoirs' storage levels for the remainder of 2004. Elephant Butte Reservoir's low point is projected to be 48,450 AF on September 29th.
See Enclosure No. 5.

Sincerely,

for Norma A. Sosa

Filiberto Cortez
Manager, El Paso Field Division

^ Figures Current as of April 30, 2015

* Estimated per URGWOM Model - NM Credit = 9,998 AF CO Credit = 5,762 AF July 6,. 2015

** Estimated San Juan Chama water as of July 6, 2015

+ 2014 Weighted Diversion Ratio

// Figure Based on MultiYear Drought Analysis

ENCLOSURE NO. 1

Status Check of 1906 Treaty Obligation to Deliver Proportionately the Same Amount of Water Supply to the U. S. Lands & Mexico's Canal Heading

U. S. Districts Proportional Delivery to Lands

Water Supply to U. S. Irrigation Districts' Lands = 311,540 - 35,355 = 276,184

Current Allotments as Percentage of Full Supply Allotments to U. S. Lands =

276,184	/	155,000	=	1.78183	AF/acre
1.78183	/	3.024	=	**58.92%**	

Mexico's Proportional Diversion at Its Canal Heading

Mexico's Acequia Madre Heading Allotment = 35,355

Current Allotment as Percentage of Full Supply Allotment to Canal Heading =

35,355	/	60,000	=	**58.93%**

Appendix 6A
Inputs for Hueco Annual CFB Models
1903 – 1937

1. Introduction

The CFB Models contain canal and farm budget calculations on an annual time-step for units overlying the Hueco ground water basin, including El Paso Valley (EPCWID), HCCRD, and JID Units 1 – 3. The annual Hueco CFB Models are from 1903 – 1937. This appendix describes the inputs used in the annual Hueco CFB Models.

2. Annual Hueco CFB Model Inputs

2.1 Surface Water Supplies

Surface water supplies were input into the CFB Models using flow data from the surface water dataset ("SWDataSet") prepared by SWE. The following table summarizes the annual surface water supplies used in the Hueco CFB Models for the 1903 – 1937 period.

Irrigation Unit	Surface Water Supplies (1903 – 1937)
El Paso Valley (EPCWID)	Franklin Canal (1903 – 1937) - Ascarate Wasteway (1916 – 1937) + Riverside Canal (1928 – 1937)
HCCRD	1915 – 1924: Calculated (irrigated acres x 4 feet) 1925 – 1937: Tornillo Canal Waste End + Tornillo Drain
JID Unit 1 JID Unit 2 JID Unit 3	Acequia Madre (1903 – 1937) + Cuidad Juarez Sewage (1926 – 1937) + River Diversions (1930 – 1937); split proportionally between units using irrigated acreage

Available surface water flows from 1903 – 1937 have been compiled, but there are significant data gaps during this period. SWE coordinated with MMA to estimate the missing 1903 – 1937 annual data. The start dates for different canals, wasteways, and drains were provided by MMA. These estimates are described in detail below.

<u>El Paso Valley 1903 – 1937</u>

Annual data for the Franklin Canal date back to 1914 (missing data in 1917). Prior to the construction of the American Dam in 1938, the Franklin Canal diverted at the International Dam. Franklin Canal diversion data from 1903 – 1913 and 1917 were estimated using an annual 1918 – 1938 regression with streamflows for the Rio Grande at El Paso gage. The Franklin Canal diversions were estimated as the minimum of the computed canal flow using the regression and the estimated capacity of the canal (320 cubic feet per second ["cfs"]). The Franklin Canal diversions were also limited to an irrigation season of March to November.

The Ascarate Wasteway was constructed around 1916, but annual flow records are only available after 1938. Annual Ascarate Wasteway flows from 1916 – 1937 were estimated using a 1938 – 1949 annual regression with the Franklin Canal.

The Riverside Canal was constructed around 1928 and the annual records for the Riverside Canal from 1928 – 1937 are complete.

<u>Hudspeth County 1903 – 1937</u>

Irrigation in HCCRD commenced around 1915 with the construction of ditches that diverted water from the Rio Grande and HCCRD was organized in 1924 (Reclamation, 2013). The HCCRD flows were measured starting in the 1920s. Measurement of the Tornillo Drain flows began in 1923 and measurement of the Hudspeth Canal (Tornillo End) began in 1925. The total flow to HCCRD was assumed to be the sum of the Tornillo Drain and the Hudspeth Canal (Tornillo End). According to the HCCRD water supply schematic (see report **Figure 6-4)**, the Hudspeth Canal (Tornillo End) began in 1925. There are no Hudspeth Canal (Tornillo End) flow records from 1925 – 1934. The Hudspeth Canal (Tornillo End) flows are estimated from 1925 – 1934 using a water balance approach, calculated as the Tornillo Canal heading flow minus an assumed seepage loss minus farm headgate demands for the Tornillo acres minus Tornillo Waste.

Various regression equations to estimate diversions for the Tornillo Drain and Hudspeth Canal (Tornillo End) from 1915 – 1924 were tested and did not yield good fits. Therefore, the diversions from 1915 – 1924 were estimated as the total irrigated acres multiplied by four feet.

<u>Juarez Units 1903 – 1937</u>

Diversion records for Acequia Madre are available from 1924 – 1925 and 1930 – 1936. Missing data for 1903 – 1923, 1926 – 1929, and 1937 were estimated using an annual 1930 – 1936 regression with the Rio Grande at El Paso gaged flows. The Acequia Madre diversions were estimated as the minimum of the computed canal flow using the regression and the estimated capacity of the canal (300 cfs). The Acequia Madre diversions were also limited to an irrigation season of March to November. A water balance calculation was conducted to check that the estimated combined diversions at Franklin Canal and Acequia Madre did not exceed the total Rio Grande flow at El Paso gage.

The Sewage Flow from 1926 – 1937 was estimated to be 49 percent of the Cuidad Juarez (“JMAS”) pumping using methodology described in the report. There are no data for JMAS pumping prior to 1926, although the annual JMAS pumping was less than 500 af in the late 1920s. Because of the lack of data and the small magnitude of the JMAS pumping, no Sewage Flows were computed to include in the surface water supply to Juarez prior to 1926. Sewage Flow available to the farms from 1926 – 1937 was limited to the irrigation season of March – October.

Annual estimates of River Diversions from 1930 – 1936 from the 1938 Rio Grande Joint Investigation (“RGJI”) were used in the CFB Models (USNRC, 1938). Due to similar hydrological conditions, annual data for 1937 was assumed to be equal to 1936. The extent of the River Diversions prior to 1930 is unknown and there are little flow data to estimate these diversions. The River Diversions prior to 1930 were not included in the surface water supply to Juarez.

The total JID water supplies from 1903 – 1937 were distributed to the JID units based on the irrigated area in each unit. This distribution of water is consistent with the water distribution used during this period in Carreno (1957), except in the drought years 1903 – 1906 in which water was assumed to only be available to JID Unit 1.

2.2 Irrigated Area

Available irrigated area data from 1903 – 1937 were compiled for use in the CFB Models of the Hueco area irrigation units. There are no data on primary acres in Texas and Mexico and all irrigated lands for these areas are assumed to be supplemental acres.

Irrigated area in Texas (El Paso Valley and HCCRD) from 1903 – 1937 are from the 1938 RGJI. The 1938 RGJI records are not complete from 1903 – 1937, and missing irrigated area data were estimated using interpolation/extrapolation of the years with data. The reported and estimated irrigated acreage data used in the CFB Models are shown in the table below.

The irrigated area data for JID was obtained from various reports for use in the Hueco GW Model (USNRC, 1938 and IBWC, 1989). Similar to El Paso Valley and HCCRD, the irrigated acreage for years of no data were interpolated between the available reported acreage. The total acreage was distributed into the three JID units primarily using the reported distribution from Carreno (1957), except from 1903 – 1906, it was assumed that during low flows all diversions would go to JID Unit 1. In 1904, it was assumed that there were zero irrigated acres since there were no flows at the Rio Grande at El Paso gage that year from March – July.

The irrigated area used in the annual Hueco CFB Models is summarized in the table below.

District	**Supplemental Acres 1903 – 1937**
El Paso Valley (EPCWID)	1903 – 1906: Set equal to 1907 acreage from RGJI (USNRC, 1938) 1907, 1914, and 1920 – 1937: Acreage from RGJI (USNRC, 1938) 1915 – 1916: Set equal to 1914 acreage from RGJI (USNRC, 1938) 1918 – 1919 and 1936 – 1937: Reclamation Water Distribution Reports (Accounting DataSet) 1908 – 1913: Linear interpolation between 1907 and 1914 acreage from RGJI (USNRC, 1938)
HCCRD	1903 – 1914: Assumed zero irrigated acres (MMA) 1915 – 1919: Linear interpolation between zero acres in 1914 to 1920 acreage from RGJI (USNRC, 1938) 1920 – 1937: Acreage from RGJI (USNRC, 1938)
JID	1903, 1905, 1908 – 1914, 1916 – 1922, 1927 – 1929, and 1931 – 1937: Acreage interpolated from IBWC (1989) and RGJI (USNRC, 1938), data provided by MMA 1904, 1906, 1915, and 1930 – 1949: Acreage from IBWC (1989) 1907 and 1923 – 1926: Acreage from RGJII (USNRC, 1938)

2.3 Crop Irrigation Requirement and Excess Effective Precipitation

For the 1903 – 1937 annual Hueco CFB Models, the CIR is the average annual 1936 – 1937 CIR from DE reduced by 5 percent. There is no assumed excess effective precipitation simulated in the 1903 – 1937 annual CFB Models.

2.4 Conveyance and Other Losses

The total canal loss and wasteway flows loss is a user-specified percent of the total diversions for each annual CFB Model. These percentages do not vary from year-to-year. The total canal loss is set to 40% for all irrigation units from 1903 – 1937. The wasteway flow percentage is set to 10% for the El Paso Valley irrigation unit and 0% for the other irrigation units.

2.4.1 Incidental Canal Loss and Canal Seepage

The incidental canal loss is computed based on a user specified a percentage of the total canal loss and is set at 6%.

2.5 Maximum On-Farm Irrigation Efficiency ("MFE")

The MFE is a user-specified percent for each annual CFB Model. The MFE does not vary from year-to year. The MFE is currently set at 68% for all irrigation units.

2.6 On-Farm Loss Split

The surface runoff percentage is a user-specified percent for each annual CFB Model that does not vary from year-to year. The surface runoff percentage is currently set at the 6%for all irrigation units. The deep percolation percent is computed as one minus the surface runoff percent (94%).

2.7 Soil Moisture Reservoir

The soil moisture reservoir (inches) for the annual Hueco CFB Models are set equal to the values used in the monthly CFB Models.

2.8 Ground Water Pumping

There is no ground water pumping for irrigation supply on the Hueco lands from 1903 – 1937. However, the structure to simulate the supplemental and primary pumping has been added to the annual Hueco CFB Models.

USGS	United States Geological Survey
US-IBWC	United States section of the International Boundary and Water Commission
WDR	Water Distribution Report
WTP	Water Treatment Plant
WWTP	Wastewater Treatment Plant

17.0 SUMMARY OF OPINIONS

17.1 Introduction

The Case Management Order in Texas v. New Mexico and Colorado set forth a schedule for alternating the exchange of expert reports by parties to the case and the following reports have been submitted to date:

- Opening expert reports for Texas and the United States were submitted on May 31, 2019.
- Expert reports for New Mexico supporting the New Mexico counterclaims and responding to the original reports of Texas and the United States were submitted on October 31, 2019.
- Rebuttal expert reports for Texas and the United States responding to the New Mexico reports were submitted on December 30, 2019.
- Supplemental expert reports were submitted by several of the experts for Texas and United States after the deadlines in the case management orders. These included a May 2020 Coors Supplemental Report, a September 2019 Moran Supplemental Report, and a May 2020 Moran Second Supplemental Report. In addition, updated information and analysis was provided by certain of the Texas experts that was not documented in any expert reports.
- Rebuttal expert reports for New Mexico were originally scheduled for submittal on March 27, 2020, but this deadline was postponed to June 15, 2020 for non-modeling experts and July 15, 2020 for modeling experts as a result of the Covid-19 situation and other factors, including allowance of time to respond to the late-disclosed supplemental reports from Texas and the Unites States.
- Also, on July 15, 2020, the New Mexico experts submitted revised or second editions of their opening expert reports.

Among the opening New Mexico reports submitted on October 31, 2019 was the Expert Report of Gregory K. Sullivan, P.E., and Adelheid (Heidi) M. Welsh ("SWE Report"). The topics covered in the SWE Report generally consisted of the following:

- Hydrologic and Rio Grande Project data,
- Summaries of historical water supply and water uses,
- Canal and farm budget modeling,
- Review of the New Mexico Integrated LRG Model ("ILRG Model"),

- Results from ILRG Model simulations, and
- Responses to certain of the Texas expert reports.

This Rebuttal Expert Report by Gregory K. Sullivan, P.E. and Heidi M. Welsh was prepared to respond to certain of the rebuttal expert reports and supplemental expert reports submitted by the Texas and United States experts ("SWE Rebuttal Report").

Due to changes in the analyses performed by the Texas experts and updates to the ILRG Model runs, certain of the results that were reported in the text, tables, figures, and appendices in the SWE Report have changed. Revised figures and tables from the SWE Report are provided with this report. **Appendix 18** contains updates of the figures and tables for which the presentation format did not change. The format for certain of the figures, tables, and appendices that presented results of the ILRG Model have been updated. For these, rather than updating the original attachments in their original format, revised figures, tables, and appendices in the new format are attached to this rebuttal report and are described in Sections 28.0 – 30.0.

To avoid confusion with the numbering of the sections and attachments in the SWE Report, the section numbering in this rebuttal report picks up where the prior report left off with Section 17. All figures, tables, and appendices are identified with a prefix of the section number followed by numbers that are sequenced in the order described in the report text.

A second edition of the SWE Rebuttal Report was prepared to describe corrections and improvements that have been made to the ILRG Model, to report the results of the model re-tuning, and to present the results of the updated Base Run (Run 1) and alternative scenario runs (Runs 2 – 18). This second edition report also corrects typographical errors in the original SWE Rebuttal Report. A new Appendix 17 is attached that contains an errata list for Sections 17-29 and 31, a redline depiction of the changes to Section 30, and a list of the figures, tables, and appendices revised for this second edition.

17.2 Assignments

Our assignments for this rebuttal report were developed in discussions with legal counsel for the State of New Mexico. We were asked by legal counsel to develop analyses and expert opinions in the following areas:

- Review of rebuttal reports and supplemental report and supporting data, analyses, and modeling submitted by experts for the Texas and the United States,
- Updates to the CFB Models of the major irrigation users between Elephant Butte Reservoir and Fort Quitman Texas,

- Coordination of the updates to and use of the ILRG Model,
- Analysis of the effects of changes in Project operations and accounting in the El Paso Valley portion of EPCWID compared to those that existed in the past, and
- Evaluation of conjunctive use of ground water and surface water under alternative conditions, including limiting pumping to D1/D2 amounts, limiting M&I pumping to pre-compact levels, and/or limiting pumping to crop demands on authorized Project acres.

Summaries of the opinions that were developed by Ms. Welsh and Mr. Sullivan for this case follow. The numbering of the opinions picks up where the numbering in the SWE Report left off.

17.3 Summary of Opinions of Heidi M. Welsh

Ms. Welsh updated the SWDataSet as described in Section 26.0 and prepared an update to the annual CFB Model of the Hueco Bolson area that is described in Section 27.0. and summarized below. In addition, she continued to be involved in disseminating data for use in the New Mexico models, and in post-processing the model output files into summary tables and graphs.

Section 26.0 – Lower Rio Grande Data

47. Additional data for the Socorro WWTP and monthly drain water diverted at Fabens were added to the SWDataSet. The updated SWDataSet was used to supply data inputs to the revised ILRG Model.

Section 27.0 – Lower Rio Grande Canal and Farm Budget Models

48. The annual CFB Models that simulate irrigation operations in the portions of the Texas and Mexico irrigation districts that overlie the Hueco Bolson during 1903 - 1937 were revised to incorporate new FHG delivery data and to include a switch to turn off Juarez sewage discharge to canals when Mexico pumping is turned off. The revised CFB Model was used to prepare certain input data used in the early 1903 – 1939 annual warm-up simulation in the Hueco Model.

17.4 Summary of Opinions of Gregory K. Sullivan

Mr. Sullivan prepared Sections 18.0 – 25.0, and Sections 28.0 – 31.0 and is responsible for the opinions presented in those sections, which are summarized below.

Section 18.0 – Response to Revised Texas Analyses Submitted Without a Rebuttal Report

Based on review of the revised Texas analyses that were submitted without a rebuttal report, I developed the responses and opinions that are presented in Section 18.0, some of which are summarized below.

49. Corrections to the M&A Farm Budget analysis of EPCWID reduced the magnitude of the differences in results compared to the SWE CFB analysis, however substantial differences remain, including M&A's unrealistically high estimates of crop evapotranspiration and supplemental pumping.

50. Dr. Dorrance updated her analysis that translates impacts on Rio Grande at El Paso flow from New Mexico pumping computed by the Texas Model into estimated impacts on deliveries to Texas water users. The revised analysis remains flawed and inappropriate for the reasons described in the original SWE Report.

Section 19.0 – Response to Ferguson Rebuttal Report

Based on review of the rebuttal report by Dr. Ian Ferguson (U.S. expert), his backup files and references, and attending his deposition, I developed the responses and opinions that are presented in Section 19.0, some of which are summarized below.

51. Annual Texas Mesilla pumping occasionally exceeded 20% of the total pumping in the Rincon and Mesilla Valleys. (Figure 19-1). Simulated depletions of El Paso flow caused by Texas Mesilla pumping, on the other hand, were often much greater than 20% of the total depletions from all pumping in the Rincon and Mesilla Valleys. (Figure 19-2).

52. Pumping from the Hueco Bolson, including pumping by wells in Texas, depletes river flows, canal and lateral flows, and drain flows in and around the EPCWID service area. These depletions increase EPCWID calls for Project releases, reduce farm headgate deliveries of Project water, and reduce the surface flows leaving EPCWID that supply HCCRD. The impacts of Texas Hueco pumping on Project operations impact diversions and FHG deliveries of Project water to EBID. These impacts are reflected in the ILRG Model Runs that are discussed in Section 30.0.

53. The effects of Texas Hueco pumping have been partially offset by Texas WWTP discharges and urban deep percolation return flows. In order to minimize the impacts of Texas Hueco pumping, EPW WWTP discharges must continue to be a part of the irrigation supply used by EPCWID farmers. If EPW WWTP discharges were to become unavailable, the effects of Texas Hueco pumping on EBID would increase.

54. Total New Mexico pumping during 1979-2005, when the D1/D2 accounting was in use, averaged 109,600 AF/y, which is less than the total New Mexico pumping during the D1/D2 source data period of 1951-1978, when it averaged 179,100 AF/y. (Figure 19-5).

55. New Mexico Irrigation pumping since the 2008 OA has been in effect (2006-2017) is marginally greater than the average irrigation pumping during the 1951-1978 D1/D2 period. The increased recent pumping is due to severe drought conditions and the effect of the 2008 OA that has substantially reduced the allocation of Project water to EBID. (Figure 19-7).

56. New Mexico M&I pumping has increased by approximately 20,000 AF since the end of the D1/D2 period (1978), but a portion of the impacts of the increased pumping has been offset by urban return flows. (Figure 19-7).

57. Total beneficial consumptive use for irrigation and non-irrigation uses in New Mexico has increased relatively little over the last 60 years, with the 10-year average ending in 2017 only 20,000 AF greater than it was in 1960. (Figure 19-9).

58. EPCWID's unused allocation has exceeded 50,000 AF in 20 years since 1978, more than half of all the years, and these years tend to correspond with years of little or no irrigation pumping to meet unmet demand, thus confirming that EPCWID's unused allocation generally occurs in years when EPCWID irrigation demands are met (Figure 19-12).

59. Historical records show that annual EPWCID use of drain flows for irrigation declined from almost 30,000 AF in the late 1940s to zero in the early 1980s. Use of drain flows throughout the Project has been an integral part of Project operation throughout the history of the Project and the cessation of use of return flows arising within the EPCWID service area has impacted Project operations to the detriment of EBID. (Figure 19-16).

60. Analysis of historical records confirms that the increase in reported EPCWID waste that occurred after EPWCID took over distribution of water within its service area from the BOR in about 1980 was unreasonable compared to the more efficient operation that occurred prior to that time. (Figures 19-17 – Figure 19-20).

61. Analysis of historical records of Project operation clearly shows that releases from Project storage vary inversely with the amount of net gains between the Caballo Reservoir outlet and American Dam in order to meet Project water demands. Reservoir releases are higher in dry years with more losses and lower in years with

more gains. Since pumping affects Rio Grande gains and losses, changes in pumping result in changes in reservoir releases (Figure 19-23).

Section 20.0 - Response to George Rebuttal Report

Based on review of the rebuttal report by Mr. Jonathan D. George (Texas expert), his backup files and references, and reviewing his deposition transcript, I developed the responses and opinions that are presented in Section 20.0 and summarized below.

62. Increases in average crop evapotranspiration in the Rincon and Mesilla Valleys during 1985-2016 compared to 1938-1950 can be explained mostly by differences in weather and crop selection as opposed to well pumping. (Figure 20-1).

Section 21.0 - Response to Hornberger Rebuttal Report

Based on review of the rebuttal report by Dr. George M. Hornberger (Texas expert), his backup files and references, and viewing his deposition, I developed the responses and opinions that are presented in Section 21.0, some of which are summarized below.

63. The Texas Model fails to meet the stated Texas objective of showing how New Mexico pumping affects Rio Grande at El Paso flows because the Texas model (a) does not simulate the dynamic response of Project operations to changes in flows that would occur without pumping, (b) does not simulate the area downstream of the El Paso gage and thus cannot simulate the feedback response from those areas to changes in Project operations, and (c) uses annual stress periods that prevent distinguishing impacts that occur during the irrigation season from impacts that occur during the non-irrigation season.

64. The effects of pumping from the Hueco Bolson can propagate upstream of El Paso through Project operation mechanisms. Because the Project is operated as a unit, depletions of surface flows that affect deliveries to EPCWID users can result in increased releases of Project water to meet EPCWID demands, which in turn reduces the supply available for allocation to EBID. The impacts to EBID from Hueco Bolson pumping are magnified under the D3 accounting in the 2008 OA.

65. Simulation of Project operations is essential in modeling impacts of pumping on deliveries to LRG water users. The key aspects of Project operation are well understood and amenable to simulation, and there is a rich trove of historical data to validate the model simulation processes.

Section 22.0 - Response to Coors Rebuttal Report

Based on review of the rebuttal report by Mr. Adolph (Shane) Coors V (Texas expert), his backup files and references, and attending his deposition, I developed the responses and opinions that are presented in Section 22.0, one of which is summarized below.

66. Average deviations between simulated and observed data in the historical run of the ILRG Model do not represent uncertainty of the ILRG Model in simulating impacts of pumping or changes in operating practices. These impacts are quantified based on differences between model runs, and any model imperfections tend to cancel out when computing these differences.

Section 23.0 - Response to Coors Supplemental Report

Based on review of the supplemental report by Mr. Coors, his backup files and references, and viewing his deposition, I developed the responses and opinions that are presented in Section 23.0, some of which are summarized below.

67. Development and refinement of the ILRG Model by the New Mexico experts occurred over many years based on extensive discussion, testing, and evaluation of the simulated processes and model outputs. Additional simulation capabilities were added incrementally when they were shown to improve the functionality of the model and improve its performance. The result is a model that captures the essential elements of the reservoir and irrigation system operations in the LRG Basin. The robust and sophisticated operation of the ILRG Model is supported by the rich and extensive record of historical Project operation.

68. The complexity and detail included in the ILRG Model is consistent with the complexity of the Rio Grande Project and the LRG irrigation systems, and this complexity and detail is needed to answer and address the complex questions and issues raised in this case.

69. Project operation responses to impacts from pumping vary depending on several factors including the allocation procedure that is in effect (D1/D2 vs. D3+Carryover) and whether there is a full or partial allocation to the Districts. The Project operation responses that are simulated in the ILRG Model reflect the real-world responses to changes in surface water supply resulting from variations in pumping and other factors.

70. The monthly timestep of the ILRG Model is consistent with the monthly scale of the generally extensive historical data that document the historical Project operation,

and allow the model to importantly distinguish impacts on surface flows that occur within the irrigation season from those that occur during the non-irrigation season.

71. While there are numerous statistics and graphical methods that can be used to evaluate model calibration, there are no universally accepted guidelines for calibration assessment in the scientific community. Assessment of model calibration should be focused on how the model is being used.

72. The calibration statistics proposed by Mr. Coors for evaluation of model calibration are partially consistent with the statistics that were used by the New Mexico experts to evaluate performance of the ILRG Model. However, these statistics were computed using irrigation season or annual flows consistent with the temporal scale of the questions that the ILRG Model is being used to answer.

73. The statistics and graphical methods used to evaluate the calibration of the ILRG Model are based, in part, on performance measures and performance evaluation criteria recommended by Moriasi et.al. (2015) on behalf of the American Society of Agricultural and Biological Engineers ("ASABE").

74. The Log NSE statistic proposed by Mr. Coors is inappropriate for use in evaluating the ILRG Model because of its emphasis on differences in low flows. The claims and counterclaims by the states implicate Project operations and deliveries at all levels of flows. In addition, the highly regulated nature of the Rio Grande Project insulates it from the extreme flow variations and extreme low flows that are typical of unregulated river basins that may be more suited to evaluation using the Log NSE statistic.

75. The locations selected by Mr. Coors for evaluation of the calibration of the ILRG Model reflect an indiscriminate selection based on available data rather than locations that are important to the essential model functions and intended uses of the model. The individual and aggregated locations selected by the New Mexico experts for evaluating model calibration reflect thoughtful consideration of the interaction of the simulated model components and the questions that the model is being used to answer in this case.

76. Calibration of the ILRG Model should not be assessed using statistics computed from monthly data for several reasons. First, Project water is allocated to the Districts and to farmers as irrigation season volumes that they can take delivery of at their discretion. Second, releases from Project storage can buffer the monthly variability of stream depletions caused by pumping. Third, the availability of wells to

supplement surface supplies can smooth out monthly water supply variations caused by the pumping of others.

77. There is no widespread consensus in the scientific community for excluding a portion of the historical data period for use in validating a simulation model calibrated using data from a different period. In this case, since the ILRG Model is being used mostly to analyze the past, it is logical to use the entire simulation period for calibration.

78. It is common in modeling alternative irrigation scenarios using historical data to leave the irrigated acreage and cropping pattern at the historical values. This is reasonable because when the water supply to a farm is reduced in the absence of supplemental pumping, consumptive use will be limited by the available surface water supply and the maximum irrigation efficiency rather than crop water demand.

79. The dynamics of the Rio Grande Project operation and management are evident in the extensive historical records that have been analyzed and used in developing and calibrating the ILRG Model. The remarkable calibration performance of the ILRG Model is clear evidence that the system can be reasonably simulated.

80. Quantification of impacts on streamflows, diversions, and deliveries is not dependent on precise replication of historical conditions in calibration. Indeed, no simulation models of heterogeneous real-world systems could meet such an impossible standard. Rather, good model simulations are ensured using a model with reasonable and rational simulation processes that is calibrated to reasonably match the magnitude and patterns of the historical data. In this case, since model results are largely being evaluated based on differences between model runs, the cancelling of errors that occurs when differencing model results further enhances the reliability of model results.

81. It is illogical and inappropriate to use the results of the All Pumping Off (Run 2) scenario of the ILRG Model to evaluate the impacts of New Mexico pumping on Project operations, surface water flows, and ground water storage because pumping in the Texas portion of the Mesilla Valley and all pumping from the Hueco Bolson is turned off. There is no way to distinguish the impacts of New Mexico pumping from the impacts caused by the other pumping.

82. Due to non-linearities in the ILRG Model, differences between results of the All Pumping Off (Run 2) and Rincon-Mesilla Pumping Off (Run 6) should not be used to assess the impacts of Hueco Bolson pumping on Project operations. These impacts can be assessed by turning off the Hueco pumping and the associated return flows

in isolation and simulating the results as was done in Run 14 and several variants that are described in Section 30.0.

Section 24.0 - Response to Moran Supplemental Report

Based on review of the supplemental report by Ms. Jean Moran (U.S. expert), her backup files and references, and reviewing her deposition transcript, I developed the responses and opinions that are presented in Section 24.0, some of which are summarized below.

83. The results of the simulations of impacts of New Mexico pumping performed by Ms. Moran using the Texas Model are unreliable because of the serious flaws in that model which include the lack of simulation of the dynamic response of Project facilities and irrigation systems to changes in supply, the coarse annual stress periods, and the limited model domain that ends at the El Paso gage.

84. The crude redistribution of simulated increases in flow at the El Paso gage that result from turning off New Mexico pumping performed through iterative post-processing by Ms. Moran fail to incorporate many essential processes that affect Project operations and deliveries and therefore the results of these analyses are unreliable. Notwithstanding, the redistribution that was attempted by Ms. Moran recognizes the crucial point that Project operations, including reservoir releases, diversions, and deliveries, would have been different if pumping had been reduced.

85. In addition to the limitations of the Texas Model and the crudeness of her redistribution attempt, the estimates of the impacts of New Mexico pumping that were simulated by Ms. Moran are inflated because (a) all pumping in the Rincon and Mesilla Valleys was turned off, including the irrigation and M&I pumping in the Texas portion of the Mesilla Valley, and (b) WWTP discharges were not turned off which precluded simulation of the offset these discharges provide to depletions from pumping.

Section 25.0 - Response to Moran Second Supplemental Report

Based on review of the second supplemental report by Ms. Moran, her backup files and references, and reviewing her deposition transcript, I developed the responses and opinions that are presented in Section 25.0, some of which are summarized below.

86. The differences in ILRG Model performance before and after 1985 are insignificant and have not been shown to affect the results of the ILRG Model simulations. The average percent differences between modeled and measured values of Caballo releases and Rio Grande at El Paso flows fall within the "Very Good" evaluation

criteria proposed by Moriasi et. al, (2015). The performance of the updated ILRG Model is improved compared to the version of the model evaluated by Ms. Moran.

87. The other criticisms of ILRG Model performance made by Ms. Moran are not significant in the context of the overall calibration performance that is described in detail in Section 28.0. Moreover, Ms. Moran has not analyzed whether the alleged imperfections in the ILRG Model simulation of the Historical Base Run would affect the differences in the simulated results of alternative scenarios, given the cancelling of errors that occurs with such comparisons.

88. The calibration of the Rio Grande at El Paso flow in the ILRG Model is very good. The purportedly perfect calibration of the Texas Model at El Paso is achieved through inappropriate overparameterizing of conductance values and canal spills to drains in every stress period.

89. The comparisons of ILRG Model results of Run 2 (All Pumping Off) with Run 6 (R-M Pumping Off) are not reliable indications for the effect of Hueco pumping for the same reasons described in the opinions for Section 23.0.

90. When evaluating the effects of New Mexico pumping, WWTP returns from use of Las Cruces' Jornada Wells should be turned off to compute an appropriate credit for water imported to the basin.

91. Differences between simulated impacts of Rincon-Mesilla pumping computed by the Texas Model compared to the ILRG Model have not been demonstrated by Ms. Moran to be within the range of uncertainty of the models. Moreover, as described at length in this report and the SWE Report, the ILRG Model is far superior to the Texas Model due to its more sophisticated and robust processes and first-rate calibration.

Section 28.0 - Overview and Assessment of Updated ILRG Model

92. Changes to the RiverWare operating rules along with updated tuning have improved the ILRG Model simulation of historical Project operations. Substantive changes included modifications to reservoir operations to improve model performance when Project storage is near full or spilling. In addition, refinements were made to EPCWID operations to more evenly distribute water within the EPCWID service area and to make the simulated RHG demands more responsive to changes in irrigation use of WWTP discharges and local drain flows.

93. The improvements to the ILRG Model are reflected in the updated and expanded calibration summaries that demonstrate the outstanding performance of the ILRG Model in replicating historical operation of the Project and the associated LRG irrigation systems.

94. A wide range of statistical performance measures were employed to characterize the statistical performance of the ILRG Model in simulating the reservoir operations, streamflows, RHG diversions, FHG deliveries, supplemental pumping, and drain flows in the study area. These included a standard regression measure (R^2), dimensionless statistics (NSE, d), and error indices (BIAS, PBIAS, MAE, PMAE, RMSE, RSR).

95. The statistical performance measures were evaluated in comparison to performance evaluation criteria recommended by the ASABE and contained in a peer-reviewed journal article by Moriasi et. al. (2015) based on synthesis and meta-data analysis of numerous published articles describing calibration performance of various watershed models.

96. In addition, graphical performance measures were utilized to visually assess the goodness of fit of ILRG Model results, including monthly and annual time series graphs, cumulative residual graphs, scatter plots, and flow duration curves.

97. All statistical performance measures and graphical performance depictions were applied to a set of individual and aggregated locations that were thoughtfully selected as representative of model performance in relation to the intended uses of the ILRG Model results to answer the questions posed in this case.

98. The results of the application of the statistical performance measures to the ILRG Model Historical Base Run (Run 1) are summarized in Table 28-1. The results demonstrate acceptable to remarkable performance of the ILRG model in simulating Project operations, diversions and deliveries to LRG water users, and Rio Grande streamflows.

99. Graphical depictions of the ILRG Model performance are presented in Figure 28-1 through Figure 28-21. The graphs confirm and illustrate the ability of the ILRG Model to reasonably replicate the monthly, seasonal, annual, and decadal variations in streamflows, RHG diversions, FHG deliveries, supplemental pumping and drain flows throughout the LRG Basin.

100. The calibration performance of the ILRG Model is generally excellent considering the complexity and scale of the Rio Grande Project, the associated irrigation systems,

and the M&I water uses in the LRG Basin. The model achieves this excellent performance by reasonable and rational simulation of the physical and management processes that control the movement and interaction of surface water and ground water throughout the study area.

Section 29.0 – Historical Base Run of ILRG Model

101. The revised ILRG Model (v116) was used to prepare a new Historical Base Run (Run 1) generally according to the procedures described in the original SWE Report. Project water allocations were simulated using the D1/D2 allocation procedure from 1950-2005, the D3 allocation procedure without carryover in 2006 and 2007, and the D3+Carryover procedure in the 2008 OA from 2008-2017. Irrigation pumping coverage in EBID, EPCWID, HCCRD, and JID Units 2 and 3 was specified to increase linearly from 0% in 1947 to 100% in 1955, and in JID Unit 1 from 0% in 1939 to 100% in 1954. Non-irrigation pumping and return flows were specified and simulated based on historical records and estimates.

102. In addition to the statistics and graphs illustrating the calibration of the Historical Base Run in Section 28.0, numerous graphs were prepared to illustrate Project reservoir water budgets, canal and farm water budgets, river water budgets, and river point flows over the 1940-2017 simulation period. These results demonstrate that the ILRG Model reasonably and sensibly simulates the operation of the Rio Grande Project over the range of hydrologic conditions that occurred during the historical study period.

103. The excellent calibration of the ILRG Model achieved using rules that facilitate dynamic response of the essential Project and irrigation system functions make the model the best available tool and a reliable tool for answering the complex questions presented in this case through simulation of alternative scenarios and computing the differences between model runs.

Section 30.0 - Alternative Runs of ILRG Model

104. The revised ILRG Model was used to simulate "what-if" scenarios over the historical period to assess the impacts on reservoir operations, reservoir releases, RHG diversions, FHG deliveries, and Rio Grande flows resulting from cessation or reduction in historical pumping and/or changes in operating practices. Changes in model inputs cause dynamic responses of all simulated processes as the changed conditions ripple spatially and temporally through the model, just as they would in the real world. For the most part, the results from the what-if scenarios were compared to the Historical Base Run (Run 1) and changes in model outputs were

computed and summarized using a consistent set of tables and graphs that facilitate comparison of results between the various model runs.

105. The thirteen original runs described in the original SWE Report were repeated using the revised ILRG Model. These include the previously described Historical Base Run (Run 1), nine no-pumping runs (Runs 2 - 10), and three alternative operations scenarios (Runs 11 - 13) (Table 30-1).

106. Fourteen new runs were made in response to issues raised by experts for Texas and United States in rebuttal and supplemental expert reports, and in response to issues raised by legal counsel for Texas and the United States in their questioning of the New Mexico experts in depositions. These included five scenarios of reduced pumping from the Hueco Bolson in Texas and Mexico (Runs 14 – 14d), four scenarios with EPCWID operations modified to be consistent with earlier practices (Runs 15 – 15c), and five alternative conjunctive use scenarios (Runs 16, 16a, 17, 17a, and 18) (Table 30-2).

107. In the no-pumping runs, all pumping or just non-irrigation pumping was turned off in all areas (Run 2) or in certain geographic areas (Runs 3 – 10, 14, 14a, 14b, 14d, 15c). When non-irrigation pumping was turned off or reduced, so were the associated wastewater treatment plant discharges and urban deep percolation (except 14d). Because the Project is operated as a single system, any effects of pumping on surface water supplies that occur upstream of points of water delivery affect Project operations. The model results show that pumping in Texas and Mexico affects Project water deliveries to EBID water users in New Mexico.

108. The updated results for the original no pumping scenarios (Runs 2-10) are generally similar to the results for these scenarios that were presented and described in the original SWE Report. Keep in mind that the updated results for Runs 2-10 report differences in net RHG diversions as opposed to the differences in gross RHG diversions that were presented in the results for the original simulations of these scenarios.

109. Several runs were made to analyze the effects of Hueco Bolson pumping on Project operations and water supplies. These included turning off all Hueco pumping (Run 14), Texas Hueco pumping (Run 14a), and Mexico Hueco pumping (Run 14b). To further analyze the effect of Texas Hueco pumping, two additional runs were made. A run was made in which the Texas Hueco pumping was turned off, but the return flows from Texas M&I pumping were left on (Run 14d), to show the effect of Texas Hueco pumping without M&I return flow offsets. Another run was made in which all discharges from Texas WWTPs were turned off (Run 14c). The results from these

simulations show that pumping from the Hueco Bolson affects Project operations including deliveries to EBID and EPCWID as well as the total supply of water available to HCCRD. The results also show that without the offsetting effects of Texas WWTP discharges, impacts from Hueco pumping would be greater.

110. The updated results for the original runs that were made to evaluate the effect of the 2008 OA on Project operations (Runs 11 and 12) are similar to the results presented in the original SWE Report. The updated results show that since the new Project water allocation procedures in the 2008 OA were enacted beginning in 2006, the new procedures have caused a profoundly negative impact on the allocation and delivery of Project water to EBID that far outweighs the impacts of New Mexico pumping. Comparison of Runs 11 and 12 over the 1951-2017 period show that the negative impacts of the 2008 OA on EBID allocations and deliveries during average and dry years when water is most needed far outweigh the increased allocations and deliveries in wet years when water supplies are more plentiful.

111. The updated simulation of Project operations in which operational waste in EBID and EPCWID is limited to no more than 10 percent of the simulated diversions (Run 13) results that are similar to the original run described in the original SWE expert report. Limiting Project operational waste would substantially increase allocations and deliveries of Project water to both EBID and EPCWID.

112. Four runs of the ILRG Model were made to evaluate the effects on Project operations that would result from a return to EPCWID operations that are consistent with how the Project operated in the past (Runs 15, 15a, 15b, and 15c). The simulated changes in EPCWID operations generally consisted of increased use of drain flows for irrigation and charging EPCWID for all of the water that it uses. The results of these runs show that EBID allocations and deliveries would increase in average and dry years.

113. Based on discussion with New Mexico representatives and legal counsel, several ILRG Model runs were made to simulate various conjunctive use scenarios (Runs 16, 16a, 17, 17a, and 18). The results for Runs 16 and 16a are described in detail in the supplemental rebuttal expert report of Ms. Barroll (2020b), and the results for Runs 17, 17a, and 18 are detailed in the supplemental rebuttal expert report of Mr. Lopez (2020b).

Section 31.0 - Sensitivity Analyses of ILRG Model

114. Alternative runs of the updated ILRG Model were made to test the sensitivity of the model results to changes in certain input parameters and input data. The

sensitivities of model results were evaluated based on differences in alternative simulations of Run 3 (No New Mexico Pumping) and Run 1 (Historical Base Run). The results of the sensitivity analyses showed the simulated effects of pumping were most sensitive to changes in crop irrigation requirements. The results showed moderate sensitivity to changes in canal bed conductance, and minor sensitivity to changes in river bed conductance, drain bed conductance, and alluvial aquifer hydraulic conductivity.

18.0 RESPONSE TO REVISED TEXAS ANALYSES SUBMITTED WITHOUT A REBUTTAL REPORT

Certain of the analyses prepared by Texas experts, M&A and Dr. Dorrance, were updated to address some of the criticisms of the New Mexico experts. Neither M&A nor Dr. Dorrance submitted a rebuttal report or a supplemental report describing their updated analyses. Rather, the revised analyses were submitted as part of the materials relied upon by Texas expert Dr. Sunding for his rebuttal report. Upon learning of these revised analyses, legal counsel requested backup for the analyses and provided this information to SWE.

The SWE Report contained comparisons of results from simulations of the ILRG Model performed by the New Mexico experts to runs of the Texas Model performed by Dr. Hutchison. While Dr. Hutchison did not submit any new runs of the Texas Model, it was necessary to revise the comparisons of the model results to incorporate the results of the simulations made using the updated ILRG Model that are described in Section 30.0.

Discussion of the revised M&A Farm Budget analysis for EPCWID (El Paso Valley), the revised Dorrance analysis, and the updates to the comparisons of the ILRG Model and Texas Model results is provided below, and updated figures and tables relevant to these topics are included in **Appendix 18**.

18.1 Revised M&A Farm Budget Analysis

The May 31, 2019 expert report from M&A included a water budget analysis of irrigation operations by EPCWID and HCCRD in the El Paso Valley that was used in analysis of alleged damages to Texas from water quality impacts caused by New Mexico pumping during the period from 1985 – 2016. A revision to the M&A water budget analysis of EPCWID (El Paso Valley) was used in the updated damages analysis by Dr. Sunding.

The Goldsim Model input and output files and associated Excel spreadsheets that comprised the revised M&A Farm Budget Model and output for the revised analysis of EPCWID operations in the El Paso Valley were provided to SWE for review. The following is a summary of the changes to the M&A farm budget analysis of EPCWID (El Paso Valley) and our responses.

- <u>On-Farm Conveyance Efficiency</u> – The on-farm conveyance loss in the revised M&A Farm Budget Model of EPCWID (El Paso Valley) was changed from 10% to 2%. The basis for the revised on-farm conveyance loss was not provided in the Texas rebuttal materials. Nor was any basis provided as to why it is appropriate to change the on-farm conveyance loss for EPCWID (El Paso Valley), but leave the on-farm conveyance loss in the other M&A Farm Budget Models of the Rincon basin, the Mesilla basin, and HCCRD at 10%. As a sensitivity analysis, the M&A Farm Budget Models for Rincon basin and Mesilla basin were rerun by adjusting the on-farm conveyance loss (FCE) in the M&A input file from 10% to 2%, and the average annual simulated supplemental pumping in the Rincon and Mesilla basins declined by a combined total of 12,500 AF during 1985 - 2016.

- 2010 FHG Delivery Data – As described in the SWE Report, it appeared that the BOR FHG delivery data used by M&A for EPCWID (El Paso Valley) in 2010 were in error. While this error was corrected in the revised M&A farm budget analysis, disagreement with the method that M&A used to estimate EPCWID (El Paso Valley) FHG deliveries after 2008 remains.

- EPCWID Irrigated Area – The New Mexico experts criticized the irrigated area data used in the original M&A Farm Budget Model of EPCWID (El Paso Valley) because prior to 2011 it appeared to include the irrigated area for the Texas portion of the Mesilla Valley. The pre-2011 irrigated area values in the revised M&A farm budget analysis for EPCWID (El Paso Valley) were reduced, but the basis for the reduced values was not described in the rebuttal materials provided by Texas, and it was not clear if the reduction was to correct for the apparent error or for other reasons.

The results for the M&A Farm Budget Model of EPCWID (El Paso Valley) were compared to the results from the SWE CFB Model in **Figure 12-12** – **Figure 12-14** of the SWE Report. Updated versions of these figures with the results from the revised M&A Farm Budget Model are provided in **Appendix 18**. The following are comparisons of the 1985-2016 annual averages from the SWE CFB Model to the outputs from original and revised M&A Farm Budget Models.

Comparison of 1985-2016 Annual Averages
SWE CFB Model vs. M&A Farm Budget Model
EPCWID (El Paso Valley)

Quantity	SWE	M&A Original	M&A Revised	M&A Rev minus SWE	% Diff
Irrigated Area (ac)	37,900	43,200	38,800	+900	+2.3%
FHG Deliveries (AF)	116,800	104,400	100,100	-16,700	-14.3%
Unit ET (ft)	2.48	3.18	3.17	+0.69	+28.0%
ET Volume (AF)	93,400	137,200	122,700	+29,300	+31.4%
Irrigation Pumping (AF)	14,300	78,900	58,000	+43,800	+306.9%

The corrections to the irrigated area closed the gap in average annual irrigated area, but the revised M&A value remains 2.3% greater than the SWE value.

The correction to the 2010 FHG deliveries further increased the difference in average annual FHG deliveries, with the M&A value being 14.3% less than the SWE value. As described in the SWE Report, the difference between the M&A and SWE FHG deliveries appears to be due to differences in how the reported total EPCWID FHG deliveries were disaggregated between the Texas Mesilla and the El Paso Valley, with the M&A method providing unrealistically low results for the El Paso Valley FHG deliveries in many years.

The change to the M&A weighted average unit ET was minimal, and it remains 28% greater than the weighted average value in the SWE farm budget during the 1985-2016 period. This difference is due to differences in ET values for individual crops and differences in the annual crop mix.

The difference in ET Volume has decreased, but the average in the M&A Farm Budget Model is 31.4% greater than in the SWE CFB Model of EPCWID (El Paso Valley).

The revisions to the irrigated area, FHG deliveries, and the on-farm loss narrowed the difference in the computed pumping in EPCWID (El Paso Valley). However, the average annual pumping in the M&A Farm Budget analysis of 58,000 AF is still much greater than the 14,300 AF average in the SWE CFB Model.

While the revisions to the M&A farm budget analysis have reduced the differences between the pumping for EPCWID (El Paso Valley) computed by M&A and SWE, the opinions and criticisms of the M&A farm budget analysis that were originally presented in the SWE Report remain valid, most notably the unrealistically high M&A estimates of consumptive use and pumping.

18.2 Revised Comparisons to Texas Model Results

Dr. Hutchison has not submitted additional or revised runs of the Texas Model. However, because of the updates to the ILRG Model and the revised ILRG Model runs described in Section 30.0, it was necessary to update **Figure 13-1** and **Figure 13-2** from the SWE Report to reflect the revised ILRG Model results. These updated figures are included **Appendix 18**. The revisions to these figures did not change the overall conclusions and opinions regarding the Hutchison Report that were presented in the SWE Report.

18.3 Revised Dorrance Analyses

The May 31, 2019 expert report from Dr. Dorrance included analyses that translated simulated changes in the annual flows for the Rio Grande at El Paso computed using the Texas Model into estimated changes in monthly surface water deliveries to EPCWID farmers, HCCRD farmers, and EPW municipal water users. The Dorrance Report also describes the effect that changes in the monthly surface water deliveries would have on the salinity of the mixed surface water and ground water supplies of farmers and municipal water users.

While Dr. Dorrance did not submit a rebuttal report on behalf of Texas, she did prepare a revised analysis to translate the depletions of the Rio Grande at El Paso caused by New Mexico pumping from the Texas Model into effects on deliveries to Texas farmers, HCCRD farmers, and to EPW for M&I use. The analysis was revised to incorporate the results of the updated farm budget analysis of EPCWID (El Paso Valley) that was prepared by M&A as described Section 18.1. An Excel spreadsheet containing the revised Dorrance analysis was provided to SWE for review.

The additional available flow from the simulated reduction in New Mexico pumping used by Dorrance did not change because there were no new runs of the Texas Model submitted with the Texas rebuttal reports. However, the increases in deliveries to Texas water users and reductions in simulated pumping computed by Dorrance did change as a result of the corrected 2010 FHG deliveries and the reduced pumping provided as part of the revised M&A farm budget analysis of EPCWID (El Paso Valley). Updated versions of

Figure 14-1 – **Figure 14-3** from the SWE Report reflecting the updated Dorrance analysis are provided in **Appendix 18**.

The results from the updated Dorrance analysis were also used to prepare revised comparisons between her estimates of the increased deliveries to Texas water users that would occur with a reduction in New Mexico pumping to the increased deliveries to Texas users in the ILRG Model simulation of no New Mexico pumping (Run 3). These updated comparisons are provided in the revised **Figure 14-4** – **Figure 14-7** that are included in **Appendix 18**.

The revisions to the Dorrance analysis described above do not change the overall conclusions and opinions regarding the Dorrance Report that were originally presented in the SWE Report.

18.4 Revised Sunding Analyses

The May 31, 2019 expert report from Dr. Sunding computed alleged damages to Texas resulting from the increased Texas pumping for irrigation and M&I uses due to the effects of pumping by New Mexico computed by the Texas experts. According to Dr. Sunding, the increased pumping in Texas caused by New Mexico pumping increased the salinity of the mixed surface water and ground water supply used in Texas for irrigation (in EPCWID and HCCRD) and M&I uses resulting in economic damages that were quantified during 1985 – 2016.

Dr. Sunding used the revised Dorrance analysis described above to recompute the damages to Texas generally in accordance with the procedures set forth in the original Sunding Report.

The responses to the Sunding Report contained in the SWE Report did not rely on ILRG Model runs or any other analyses by the New Mexico experts that were updated since the original expert reports were prepared. As a result, it was unnecessary to update any of the responses to the Sunding opinions, and all responses and associated data, information, summaries contained in Section 15.0 of the SWE Report remain valid.

19.0 RESPONSE TO FERGUSON REBUTTAL REPORT

Ian M. Ferguson, Ph.D., P.E. prepared a December 30, 2019 rebuttal expert report on behalf of the United States ("Ferguson Rebuttal Report") that describes his rebuttal opinions to expert reports prepared on behalf of New Mexico by Margaret Barroll, Estevan Lopez, Gregory K. Sullivan and Heidi M. Welsh (SWE Report), and John C. Carron and Steven T. Setzer.

SWE was asked by legal counsel for New Mexico to review the Ferguson Rebuttal Report and to prepare expert opinions to respond the opinions of Dr. Ferguson. A lack of response regarding a particular issue should not be interpreted as tacit agreement with the Ferguson opinions on that issue.

Ferguson Opinion 1 – *Estimates of groundwater pumping provided in the expert report of Sullivan and Welsh indicate that more than 80% of the total groundwater pumping in the Rincon and Mesilla Valleys occurs in New Mexico and less than 20% occurs in Texas; similar estimates are provided in the expert report of Hutchinson. While the relative amount of annual pumping in each state varies from year to year, these studies indicates that the relative amount of cumulative pumping has remained consistent since the late 1960s. (page 3).*

Response:

Contrary to Dr. Ferguson's assertion, the relative amounts of New Mexico and Texas annual pumping in the Rincon and Mesilla Valleys have not remained constant since the late 1960s. The upper chart in **Figure 19-1** shows that total annual New Mexico pumping (sum of irrigation and M&I pumping) as blue bars and the total annual Texas Mesilla pumping as orange bars from 1940 – 2017. The annual New Mexico and Texas pumping as percentages of the total pumping in the Rincon and Mesilla Valleys are shown as blue and orange lines, respectively in the lower chart in **Figure 19-1**. The graph shows that the Texas pumping percentage exceeded 20% in 16 years between 1974 and 2000.

As shown in **Figure 19-1**, the Texas pumping as a percentage of the total pumping in the Rincon and Mesilla Valleys has declined in recent years due to the increase in New Mexico pumping that has occurred in large part due to the effect of the 2008 OA that significantly reduced New Mexico's allocation of Project water, resulting in a significant increase in unmet irrigation demand that was met by pumping.

Ferguson Opinion 2 – *Model simulation results presented in the expert report of Sullivan and Welsh and the expert report of Hutchinson further suggest that the depletion of Project surface water supplies is roughly proportional to the cumulative amount of* *pumping, with approximately 80% of the total depletion of Project supplies in the Rincon and Mesilla Valleys resulting from groundwater pumping in New Mexico and approximately 20% resulting from groundwater pumping in Texas. (page 3).*

Response:

The relative impact of New Mexico pumping and Texas Mesilla pumping on Rio Grande at El Paso flows was computed using results from the ILRG Model runs described in Section 30.0. Annual depletions to El Paso flow were computed based on differences in simulated El Paso flow between no pumping runs and the Historical Base Run (Run 1). Annual depletions from 1950 - 2017 for New Mexico pumping (Run 3 minus Run 1), Texas Mesilla pumping (Run 7 minus Run 1), and all Rincon-Mesilla pumping (Run 6 minus Run 1) are shown in the upper chart in **Figure 19-2**.

Annual depletions from New Mexico pumping and Texas Mesilla pumping as percentages of the depletions from all Rincon-Mesilla pumping are shown in the lower chart in **Figure 19-2**. The relative effects of Texas Mesilla pumping on Rio Grande at El Paso flows are often much greater 20%.

Ferguson Opinion 3 – *With respect to groundwater pumping in the El Paso Valley (Hueco Bolson aquifer), model simulation results presented in the expert report of Sullivan and Welsh indicate that the effects of groundwater pumping in the El Paso Valley on historical Project diversions and deliveries to Elephant Butte Irrigation District ("EBID") are negligible. Groundwater pumping in El Paso Valley no longer impacts Project deliveries in El Paso Valley due to the construction of the American Canal Extension ("ACE"), which eliminates the effects of groundwater/surface-water interactions on Project deliveries in the El Paso Valley. (page 3).*

Response:

Prior to construction of the ACE, depletions of the Rio Grande upstream of Riverside Dam affected Project deliveries to the Riverside Canal, requiring more releases from Project storage to the Riverside Canal than would be necessary without pumping from the Hueco Bolson in the El Paso Valley ("Hueco").

Depletions to the Rio Grande downstream of American Dam affect deliveries of 1906 Treaty water to Mexico at the Acequia Madre. In addition, depletions to river flows downstream of American Dam would affect downstream diversions from the river (if any) by HCCRD at the structure that can supply the Hudspeth Feeder Canal.

Hueco pumping also increases seepage from EPCWID canals and laterals (MMA, 2019). The increased seepage losses in the EPCWID service area require additional Project releases to deliver orders for Project water to EPCWID farmers. The increased seepage losses also reduce the amount of waste and drain flows from EPCWID that can be delivered to the headgates of HCCRD farmers.

Finally, Hueco pumping also depletes EPCWID drain flows that accumulate in the Fabens Waste Drain and the Tornillo Drain. Historical BOR records show EPCWID diverted water from the Fabens Waste Drain until the early 1980s for irrigation in the Tornillo area. Therefore, Hueco pumping reduced the drain supply that comprised a portion of the irrigation supply delivered to Tornillo area farmers until the early 1980s, and would still be depleting that supply if EPCWID had not ceased diverting from the Fabens Waste Drain.

Depletions of drain flows that reach the Fabens Waste Drain as well as depletions of Tornillo Drain flows reduce the supply leaving the EPCWID service area that is the primary source of supply to HCCRD farmers. The effect of Texas Hueco irrigation pumping on drain flows is illustrated in **Figure 19-3** which compares the monthly net recharge from the SWE CFB Model (orange line; defined as canal seepage plus deep percolation minus irrigation pumping) to the sum of the Fabens Waste Drain and the Tornillo Drain (blue line). Comparison of the lines in **Figure 19-3** shows that the simulated drain flows fluctuate up and down with the fluctuation in net recharge. During extended drought periods such as the mid-1950s, the net recharge declined due in large part to pumping, becoming negative at times (pumping exceeded the sum of canal seepage and deep percolation), and this resulted in the drain flows declining substantially and even drying up. The accumulated effect of the negative recharge during the 1950s drought is seen in the slow recovery of the drains after the drought, when it took two or three years for the drains to recover.

The impacts of Hueco pumping on surface water flows are ongoing and are reflected in the ILRG Model results for Runs 4, 5, 8, 10, 14, 14a, and 15c that are discussed in Section 30.0.

While Hueco pumping has impacted and continues to impact EPCWID and HCCRD water supplies, these impacts have been partially offset by increases in EPW WWTP discharges from pumping. The offsetting effects of the EPW WWTP discharges from pumping are immediate and concentrated in the EPCWID service area as opposed to the depletive effects of Hueco pumping, particularly the M&I pumping by EPW and Juarez, that are significantly lagged in time and distributed geographically throughout the El Paso Valley.

The combined effect of Texas Hueco pumping and Texas WWTP offsets is reflected in Run 14a of the ILRG Model that is described in Section 30.0. In this run, all Texas Hueco irrigation and non-irrigation pumping was turned off as well as the WWTP returns and urban deep percolation returns from the non-irrigation pumping. Differencing the results from Run 14a and Run 1 (Historical Base Run) reflects the net effect of Texas Hueco pumping and Texas Hueco returns. The following is a summary of the differences in EBID diversions and FHG deliveries averaged over two periods of time:

Average Annual Change in EBID Supply
from Turning Off Texas Hueco Pumping and Return Flows
(Run 14a minus Run 1)
(acre-feet)

Output	1951-1978	2006-2017
Diversions	-600	-7,800
FHG Deliveries	-300	-4,000

The impacts of Texas Hueco pumping are relatively small due in part to the offsetting effect of the Texas WWTP discharges (although there are some years with larger impacts). To illustrate this, a Run of the ILRG Model was made in which all Texas Hueco pumping was turned off, but leaving on the Texas WWTP returns at the historical levels (Run 14d). Comparison of Run 14d to Run 1 shows the effect of Texas Hueco pumping without the Texas WWTP offset. The following is a summary of the average changes in EBID diversions and FHG deliveries that would be caused by Texas Hueco pumping without the Texas WWTP offset:

Average Annual Change in EBID Supply
from Turning Off Texas Hueco Pumping without WWTP Offset
(Run 14d minus Run 1)
(acre-feet)

Output	1951-1978	2006-2017
Diversions	8,200	3,400
FHG Deliveries	5,000	2,000

Another run of the ILRG Model was made to isolate the effect of the Texas WWTP offsets. In this run, all Texas WWTP discharges were turned off, but all of the Texas pumping (irrigation and EPW pumping) was left on (Run 14c). The results show that without the Texas WWTP offsets, EBID diversions and FHG deliveries would decrease by the following average volumes:

Average Annual Change in EBID Supply from Turning Off Texas WWTP Discharges (Run 14c minus Run 1) (acre-feet)

Output	1951-1978	2006-2017
Diversions	-15,200	-25,000
FHG Deliveries	-8,200	-11,700

The above comparisons clearly show that Texas Hueco pumping would have a greater impact on deliveries to EBID without the offsetting effect of the Texas WWTP discharges. In order to minimize the effect of Texas Hueco pumping on Project operations going forward it is essential that the Texas WWTP offsets continue and are a part of a future EPCWID compliance requirement. This means that the EPW WWTP discharges to the EPCWID canal system must continue to be part of the irrigation supply that is used by EPCWID farmers. If EPW found another use for its WWTP discharges (e.g., nonpotable reuse or sale to others), the effects of Texas Hueco pumping on EBID would increase.

Ferguson Opinion 4 *– Estimates of groundwater pumping in the Rincon Valley and the New Mexico portion of the Mesilla Valley provided in the expert report of Sullivan and Welsh show that groundwater pumping in New Mexico increased from 1985 to 2002, despite full diversion allocations to EBID through this period. Pumping in New Mexico continued to increase from 2003 to 2005, prior to the implementation of the "D3 Method" allocation procedure. (page 5).*

Response:

Dr. Ferguson's observation about increases in EBID ground water pumping during the full allocation years of 1985 – 2002 ignores that pumping during this period was generally lower than the EBID pumping in the full allocation years of 1979 – 1984. The upper chart in **Figure 19-4** shows the simulated annual EBID supplemental irrigation pumping from 1948 – 2017. The lower chart in **Figure 19-4** shows the annual EBID supplemental irrigation pumping during 1979 – 2017 along with the reported annual EBID allocations and delivery charges.

The simulated annual volume of EBID supplemental ground water pumping varies based on the unmet demand which is a function of the irrigation demand and the surface water supply. The irrigation demand is affected by the irrigated area, crop mix, weather conditions, and irrigation efficiency. Surface water supply is affected by the Project water allocation and how much Project water is called for and delivered to the farms. Given all of the factors that contribute to variations in pumping to meet unmet demand, the simulated variability in supplemental pumping during the full supply years from 1979 – 2005 is not surprising, and it has not been shown to be indicative of any upward or downward trend in supplemental pumping. As described in the Barroll Rebuttal Report (2020a), over the long term, to the extent there has been a shift to higher water consuming crops in EBID, this has been offset by overall reductions in irrigated area.

Ferguson Opinion 5 *– Increases in groundwater pumping in New Mexico occurred prior to the OA due to increases in water demands for supplemental irrigation within EBID, increases in water demands for irrigation of groundwater-only lands outside of EBID, and increases in water demands for domestic, municipal, industrial, and commercial uses. Current demands within EBID exceed the historical full-supply delivery of 3.024 AF per acre. (page 5).*

Response:

Dr. Ferguson appears to assert that EBID pumping increased during the time that the D1/D2 allocation procedure was in effect from 1979 – 2005 before it was replaced by the 2008 OA accounting that commenced in 2006. **Figure 19-5** is a stacked bar chart showing the annual pumping in New Mexico comprised of supplemental pumping in EBID, primary ground water pumping outside of EBID, and total M&I pumping. **Figure 19-5** shows that the total pumping in New Mexico actually decreased from an average of 179,100 AF/y during 1951 – 1978 (period used to develop the D1 and D2 Curves) to an average of 109,600 AF/y in 1979 – 2005 (period of D1/D2 accounting).

The normal or full supply delivery of 3.024 AF/ac was computed by the BOR based on analysis of actual Project water deliveries during 1946 – 1950 (Friedkin and Resch 1956). This represents the water supply that the BOR determined was sufficient in the late 1940s to meet average annual irrigation water demands. This unit full supply delivery was multiplied by the authorized Project acres in EBID (90,640 acres) and EPCWID (69,010 acres) to compute the average annual full supply delivery volume for the authorized Project acres. The actual annual FHG delivery demands for EBID and EPCWID were computed as the crop-weighted CIR multiplied by the reported annual irrigated acres divided by the estimated farm irrigation efficiency used in the CFB Models (increased from 65% before 1950 to 75% after 1984). The historical EPW diversions were added to the computed EPCWID FHG demands.

Figure 19-6 compares the average annual full supply delivery determined by the BOR for the authorized Project acres (dashed lines) to the computed annual FHG delivery demands in EBID and EPCWID (solid lines) for the period from 1940 – 2017. This comparison shows that the EBID FHG delivery demand consistently exceeded the BOR estimate during most years from 1951-1978. Since that time, the demand has remained above the BOR estimate in most years, but as shown in the inset table in **Figure 19-6**, the average FHG demand has declined since the D1/D2 period by an average of 27,900 AF. The annual EPCWID FHG demand (plus EPW Project water deliveries) was above the BOR estimate in the 1940s and 1950s, fluctuated above and below the estimate during the 1960s and 1970s, and has been generally less than the BOR estimate since then.

Ferguson Opinion 6 *– Increased groundwater pumping to meet these demands, and the corresponding impacts on Project surface-water supplies, was a major driver in negotiation of the OA. The reduction in EBID's annual diversion allocation under the "D3 Method" was negotiated as a means to offset these impacts. Under the "D3 Method," EBID foregoes a portion of its annual diversion allocation to offset the impacts of groundwater pumping in New Mexico on Project allocations and deliveries to EPCWID. (page 5).*

Response:

As discussed in Section 11.0 of the SWE Report, the D1 and D2 curves implicitly grandfathered in the effects of pumping during 1951 – 1978 by New Mexico, Texas, and Mexico on Project performance and Project deliveries. Contrary to Dr. Ferguson's assertion, the 2008 OA does not include any explicit statements that its purpose was to address only increases in pumping impacts after the D1/D2 period.

Historical pumping data and information from the SWE CFB Models were compiled to characterize and compare surface water and ground water use during and after the 1951 – 1978 D1/D2 period. The results are presented in **Figure 19-7** through **Figure 19-11** which are described below.

<u>Pumping</u>

Figure 19-7 shows the annual New Mexico pumping from 1940 – 2017. The upper chart shows the EBID irrigation pumping (blue bars). The maximum annual pumping during the D1/D2 period is shown as a horizontal black line and the average annual pumping during

that period is shown as a horizontal blue line. Since the D1/D2 period there has been only one year (2011) with irrigation pumping that exceeded the D1/D2 period maximum. The running 10-year average pumping (red line) has only exceeded the D1/D2 average during the dry years from 2012 – 2017 when the 2008 OA was in effect. Therefore, Dr. Ferguson is wrong to imply that implementation of the 2008 OA was to address increased irrigation pumping in New Mexico after the D1/D2 period.

The lower chart in **Figure 19-7** shows the New Mexico M&I pumping from 1940 – 2017. The maximum annual pumping during the D1/D2 period is shown as a horizontal black line and the average annual pumping during that period is shown as a horizontal blue line. The New Mexico M&I pumping steadily increased after the D1/D2 period through about 2000 and has since leveled off. The annual New Mexico M&I pumping following the D1/D2 period has been above the D1/D2 maximum during most years. However, a portion of the impacts of the New Mexico M&I pumping is offset by WWTP discharges and urban deep percolation return flows. As is shown in the results for Run 9 described in Section 30.0, the impacts of New Mexico M&I pumping on EPCWID FHG deliveries averaged less than 1,500 AF/y during 1985-2017.

Figure 19-8 shows the annual Texas pumping from 1940 – 2017. The upper chart shows the sum of EPCWID and HCCRD irrigation pumping from 1940 – 2017 in the same format as **Figure 19-7**. Since the D1/D2 period there have not been any years that the irrigation pumping exceeded the D1/D2 maximum. The running 10-year average pumping (red line) exceeded the D1/D2 average during 1979 and 1980.

The lower chart in **Figure 19-8** shows the Texas M&I pumping from 1940 – 2017 in the same format as **Figure 19-7**. The Texas M&I pumping increased steadily throughout the D1/D2 period, leveled out during the 1980s, and then declined through the 1990s and 2000s. The annual M&I pumping then rose during the 2010s and has declined again during recent years. The annual Texas M&I pumping since 1978 has not exceeded the maximum during the D1/D2 period, however the running 10-year average pumping exceeded the D1/D2 average until the 2008 and since that time it has hovered near the D1/D2 average.

<u>Consumptive Use</u>

Figure 19-9 shows the annual New Mexico consumptive use comprised of surface water (grey bars) and pumping (irrigation and M&I) (light blue bars). The annual average total consumptive use during the D1/D2 period is plotted as a horizontal blue line and the 10-year running average total consumptive use is plotted as a red line. The running 10-year average consumptive use has remained slightly above the D1/D2 average since until the mid-1990s, and is currently about 21,000 AF above the D1/D2 average.

Figure 19-10 shows the annual Texas consumptive use of surface water (orange bars) and pumping (irrigation and M&I) (yellow bars). The annual average total consumptive use during the D1/D2 period is plotted as a horizontal blue line and the 10-year running average total consumptive use is plotted as a red line. The running 10-year average consumptive use remained slightly above the D1/D2 average until the early 2000s, after which it declined and is currently about 30,000 AF below the D1/D2 average.

Figure 19-11 shows the annual Texas plus Mexico consumptive use comprised of Texas surface water (orange bars), Texas pumping (irrigation and M&I) (yellow bars), Mexico surface water (dark green bars), and Mexico pumping (irrigation and M&I) (light green bars). The annual average total consumptive use during the D1/D2 period is plotted as a horizontal blue line and the 10-year running average total consumptive use is plotted as a red line. The running 10-year average consumptive use rose steadily above the D1/D2 average until the early 2000s. Since that time, the 10-year average consumptive has declined, but currently remains about 44,000 AF above the D1/D2 average.

Ferguson Opinion 7 *– Model simulation results presented in the expert report of Sullivan and Welsh indicate that the effects of groundwater pumping in El Paso Valley, including pumping in Texas and Mexico, on historical Project deliveries is negligible. (page 11).*

Response:

See response to Ferguson Opinion 2.

Ferguson Opinion 8 *– Reclamation ensures that diversion allocations do not exceed the amount of water that can be physically delivered to Project diversion points and accounted for under Project water accounting procedures. Allocations are constrained by the available Project supply, including return flows, as accounted for under Project water accounting procedures. Water orders by EBID, EPCWID, and US-IBWC on behalf of Mexico are subsequently constrained by each entity's allocation. Reclamation will not allocate water that cannot be delivered, and will not accept a delivery order that cannot be met. Therefore, the fact that all delivery orders were met cannot be interpreted as all demands being met. (page 12).*

Response:

Figure 19-12 was prepared to summarize EPCWID's historical use of Project water, irrigation pumping to meet unmet demand determined in the CFB Model, and unused allocation from 1940 – 2017. The annual EPCWID FHG demand is shown as a black line and was computed as the EPCWID FHG deliveries plus EPCWID irrigation pumping plus the historical deliveries of Project water to EPW. The historical FHG deliveries of Project water for irrigation are depicted as grey bars, the historical deliveries of Project water to EPW are shown as light blue bars, and the pumping to meeting unmet irrigation demand is shown as dark blue bars. The unused allocation for EPCWID was computed for the period 1979 – 2017 as the final allocation minus the reported delivery charges and is shown as orange bars.

The summary in **Figure 19-12** shows that there was substantial unused allocation in many years during 1979 – 2017. The unused allocation exceeded 30,000 AF in 26 years (67%), 50,000 AF in 20 years (51%), and 70,000 AF in 14 years (36%). The years with substantial unused allocation generally coincide with years of little or no supplemental irrigation pumping, thus confirming that the unused EPCWID allocation generally occurs in years when the EPCWID irrigation demands are met.

Ferguson Opinion 9 *– Increased operational waste from EPCWID in El Paso Valley from 1979-2002 was primarily the result of extremely wet hydrologic conditions throughout this period. As shown in the expert report of Sullivan and Welsh, operational waste from El Paso Valley was generally greater than 15% of total diversions from 1938-1950, generally less than 10% from 1951-1978, and generally greater than 15% from 1979-2002. Fluctuation in operational waste are consistent with fluctuations in hydrologic conditions: the period 1938-1950 was dominated by extremely wet hydrologic conditions; the period from 1951-1978 was dominated by dry and normal conditions; and the period from 1979-2002 was again dominated by extremely wet conditions. Operational waste increased during wet hydrologic conditions due to increases in storm runoff and greater than anticipated bypass and return flows from the Rincon and Mesilla Valleys. In addition, operational waste during the 1980s and 1990s included large amounts of water ordered by EBID but not diverted. Increased operational waste during this period did not result from negligence or improper operations by EPCWID or Reclamation. (page 19).*

Response:

While operational waste can fluctuate based on water supply conditions with more waste in wet years and less waste in dry years, Project records show that there was an increase in EPCWID waste after EPCWID took over operation from the BOR in 1979 that cannot be attributed solely to changes in water supply conditions. Additional analysis of the available water supply in the El Paso Valley was performed to further assess the reported increases in operational waste that occurred in EPCWID after the BOR relinquished operation of the EPCWID system.

The Rio Grande Project was conceived and initially operated to use all available water supplies to meet Project water deliveries. This included use of all available return flows between the Caballo Reservoir outlet and the last diversion from the river at Tornillo that supplied the Tornillo Canal.

The Rio Grande Rectification project in the late 1930s changed the surface water plumbing in the El Paso Valley so that most of the flows were conveyed through the EPCWID service area to EPCWID farmers using the canal system (including the part of the Rio Grande that was converted to an extension of the Riverside Canal), and from EPWCID to the HCCRD more in drains and less in the relocated Rio Grande channel.

As a result of the replumbing of the system in the Fabens area, return flows that previously were conveyed in the river and diverted to supply the lower portion of the EPCWID service area in the river instead were conveyed using canals and drains. Regardless of the conveyance mechanism, WWTP discharges and drain flows in the Fabens area have always been a portion of the supply available for use within the EPCWID service area.

Consistent with the Project planning described in the RGJI, it is reasonable to expect that WWTP discharges and drain flows that arise within the EPCWID system should be efficiently used by EPCWID farmers in order to reduce unnecessary releases from Project storage that could be saved and conserved for subsequent allocation and use.

Historical records of flows available for use in the El Paso Valley portion of EPCWID were tabulated and analyzed to determine how efficiently the available flows have been used and whether the records provide additional information as to the reasons for the increases in reported EPCWID operational waste that were described in the SWE Report.

A schematic diagram prepared by MMA that illustrates the EPCWID water distribution and drainage system is provided in **Figure 19-13**. Canals and laterals are shown as blue lines, wasteways as black lines, and drains as red lines. Long-term flow measurement locations are depicted as triangles.

The surface water supply available for use in the El Paso Valley portion of EPCWID has historically been comprised of (a) Rio Grande diversions at American Canal, (b) drain flows, and (c) discharges from EPW WWTPs.

Discharges from EPW WWTPs have long been a part of the supply used by EPCWID farmers. These include discharges to the Riverside Canal from the Socorro WWTP (1967-1992) and later from the Bustamante WWTP (1991 – present), discharges to the Rio Grande upstream of the Riverside Canal heading from the Haskell WWTP (until 1999), and discharges to the ACE from the Haskell WWTP (1999-2017). A chart illustrating the WWTP discharges to EPCWID canals from 1967 – 2017 is shown in **Figure 19-14**. Total irrigation season discharges to the EPCWID canal system have increased from about 5,000 AF/y in the mid-1960s to approximately 30,000 AF/y in recent years. These WWTP discharges comingle with other supplies in the EPCWID distribution system and comprise a portion of the available irrigation supply.

Drain flows collected in the Fabens area are another supply that is available and has historically been used for irrigation by EPCWID farmers. There are daily records of diversions from the River Drain to the Riverside Canal Extension from 1945 – 1983. This is labeled as "Drain to Canal" in **Figure 19-13**. A chart summarizing the historical drain diversion data is provided in **Figure 19-15**. The blue line depicts the monthly average diverted flow and the orange line presents the daily maximum diversion in each month. The chart shows that monthly average drain flow diversions often exceeded 50 cfs in the 1940s and early 1950s while maximum diversions often exceeded 100 cfs. The maximum reported monthly diversion volume was 5,700 AF in July 1946.

Historical records of Fabens area irrigation season drain flows from 1940 – 2017 are summarized in **Figure 19-16**. Until 1983 the drain flow records include measurements at five drains that collected in the Fabens Waste Drain. The blue bars depict the flows of the River Drain and Middle Drain that flow into the River Drain upstream of the point where the diversions to the Riverside Canal Extension occurred until 1983. These are referred to as the "Usable Drains." The other three bars represent flows in the Fabens Intercepting Drain, the Mesa Drain, and the Cuadrilla Drain that accrue to the Fabens Waste Drain downstream of where drain flows were diverted into the Riverside Canal Extension. These are referred to as the "Other Drains."

Beginning in 1984, the Fabens area drain records are limited to measurements of the Fabens Waste Drain upstream of where it discharges into the Fabens Waste Channel. These records are plotted as the green bars in **Figure 19-16**. The drain flows measured at this location represent the accumulation of the flows contributed by all five drains that were separately measured until 1983. Therefore, the irrigation season totals depicted by the green bars from 1984 – 2017 are comparable to the sum of the flows of the five drains that were separately measured prior to 1984. On average during 1945 – 1983 when there are records of diversions from the River Drain to the Riverside Canal Extension, the average flow of the Usable Drains comprised approximately 70% of the total Fabens Drain flows during the irrigation season.

Figure 19-17 shows the total supply available to EPCWID users in the El Paso Valley from 1940 – 2017. The blue bars represent the historical EPCWID diversions[1] less the reported and estimated conveyance losses from the CFB Model, the yellow bars represent the total EPW discharges to the canal system, and the grey bars represent the usable Fabens drain flows[2]. The black line represents the total Project water deliveries to EPCWID users including deliveries to irrigation users and deliveries to EPW. The reported total supply to HCCRD is shown for comparison as the negative light blue bars. EPCWID flows in excess of EPCWID deliveries are represented by the portion of the stacked bars that project above the black line. These excess flows generally correspond to the total flows to HCCRD. The data presented in **Figure 19-17** shows that the EPCWID system was generally operated efficiently during most years from 1951 – 1979 with modest amounts of excess flow going to HCCRD.

Figure 19-18 presents a more detailed analysis of the excess flows (portion of bars above the black line) in **Figure 19-17**. Superimposed on the excess flow bars are lines depicting the unadjusted reported EPCWID waste in the WDR's (black line) and EPCWID waste adjusted to fill in missing data and to make other mass balance adjustments (red line). The data plotted in **Figure 19-18** show that the reported EPCWID waste generally corresponds with the sum of the excess EPCWID diversions and EPW WWTP discharges, but does not include the unused Fabens drain flows.

Additional insight on the flow exiting the EPCWID service is gained by analysis of the historical water supply for HCCRD. **Figure 19-19** is a stacked bar chart illustrating the historical irrigation season flows to HCCRD that are comprised of water tailing out of the Tornillo Canal at Alamo Alto (dark blue bars), the Tornillo Drain (grey bars) and the Hudspeth Feeder Canal (yellow bars). Also shown in **Figure 19-19** is a red line computed as 10% of the EPCWID diversions, which represents a reasonable upper limit of the waste that should be exiting the EPCWID service area. Comparison of the sum of the Tornillo Canal at Alamo Alto and non-drain flows in the Hudspeth Feeder Canal shows this sum is similar to the red line until 1980.

Table 19-1 contains a summary of the irrigation season totals depicted in **Figure 19-19**. The total waste exceeding a reasonable upper limit of 10% of the EPCWID supply is summarized in column 12. During 1980 – 2002, the waste to HCCRD in excess of 10% of the EPCWID supply averaged approximately 16,700 AF. Had the deliveries to EPCWID

[1] Franklin Canal plus Riverside Canal minus Ascarate Wasteway plus EPW diversions.

[2] Sum of reported Middle Drain and River Drain flows from 1940 – 1983 and 70% of the reported Fabens Waste Drain flows from 1984 – 2017.

been managed more carefully to reduce the excess waste that flowed to HCCRD, additional water would have been conserved in Project storage that would have increased allocations to EBID and EPCWID in later years with less than full allocations.

The dramatic increase in supply to HCCRD that occurred after EPCWID took over operation is remarked upon in a report by Dr. Phillip King (2003) containing analyses of irrigation operations in the LRG Basin:

> *In his evaluation of the District Kirby (1978) presented a rather gloomy outlook for the District, understandable considering the 28 years of drought that preceded his investigation: "It would appear that the Hudspeth (sic) District may continue marginal agricultural operations at about current levels for perhaps another twenty years. At the end of that time, the district most probably will begin dissolution with only those few water users blessed with good soil drainage and reasonably good groundwater surviving as independent farmers."*
>
> *Ironically, the water supply began its wet cycle the very next year, and HCCRD has enjoyed three to nine feet of inflow per water righted acre ever since. If the current drought proves to be anything like the period of 1951-1978, Kirby (1978) may prove to be prophetic, but ahead of his time.*

***Ferguson Opinion 10** – Sullivan's and Welsh's use of correlation or regression analysis to fill missing data does not account for the effects of hydrologic conditions on Project operations. For example, operational waste from EPCWID in El Paso Valley was estimated based on correlations over the period 1951-2002. The early part of this period (1951-1978) is characterized by normal to extremely dry hydrologic conditions; the latter part of this period (1979-2002) is characterized by extremely wet hydrologic conditions. These conditions affect Project operations, including operational waste. Use of correlations based in part on extremely wet conditions (1979-2002) to estimate operational waste during recent years characterized by normal to extremely dry hydrologic conditions (2003-2018) results in a significant over estimation of recent operational waste. (page 21).*

Response:

Contrary to Dr. Ferguson's statement, the regression analyses that were used to fill missing data in the SWDataSet did account for variations in hydrologic conditions. The regression relationships were developed using the available historical data which typically included wet, average, and dry years. Note that there was significant missing data that needed to be estimated for the pre-1940 period for use in the Hueco ground water model. Considering the data needs and time period, these pre-1940 regressions were largely performed using data from the 1930s and 1940s that would have been more representative of the looser operational practices that existed before the BOR tightened up operations with the onset of the drought in the early 1950s.

Dr. Ferguson goes on to complain that estimates of operational waste from EPCWID in the El Paso Valley for 2003 – 2017 are too high because they were based on a regression analysis of historical data from 1951 – 2002 that included a wet period from 1979 – 2002. His comments imply that the 1979 – 2002 historical data should have been excluded from the regression analysis.

EPCWID operational waste estimates from 2003 – 2017 were computed using a correlation with the total flows to HCCRD using historical data from 1951 – 2002 (excluding spill years) that included dry, average, and wet years. The data from this period generally show that EPCWID operational waste and HCCRD total diversions are lower in dry years and higher in wet years.

In order to assess Dr. Ferguson's contention that the 1979 – 2002 data influenced the regression relationship, the historical irrigation season (March – October) EPCWID waste data from 1951 – 2002 that were used in the regression analysis were plotted against irrigation season Caballo Reservoir releases in the scatter diagram in **Figure 19-20**. The blue dots in represent data for 1951 – 1978 and the orange dots show data for 1979 – 2002. While comparison of the blue dots and the orange dots indicates that reservoir releases were generally lower during 1951 – 1978 than during 1979 – 2002, the data also show that EPCWID waste was significantly greater after 1978 for similar reservoir releases. Therefore, it would be inappropriate to exclude the 1979 – 2002 data from the regression relationship because only using the blue dots would result in a regression relationship that would ignore the apparent change in operational practices that resulted in increases in operational waste for similar hydrologic conditions. If anything, it may be more appropriate to use only the data after 1978 since it would reflect the change in operational practices that is apparent in the data.

Ferguson Opinion 11 *– As shown in Figures 5-10, 5-12, and 5-14, FHG deliveries of Project water were not "relatively steady from the 1950s-1970s." Rather, FHG deliveries during this period varied from less than 0.5 acre-feet per acre to more than 2.5 acre-feet per acre (Figures 5-12 and 5-14). In addition, it should be clarified that FHG deliveries declined in the early 2000s relative to the wet period during the 1980s and 1990s, not relative to the 1950s-1970s. Recent FHG deliveries since 2003 are comparable to FHG deliveries during the 1950s-1970s; FHG deliveries during both of these periods reflect severe drought conditions. (page 22).*

Response:

Dr. Ferguson implies that the SWE report mischaracterized the changes in EBID FHG deliveries. However, the partially quoted language from the SWE Report accurately stated that "average annual farm headgate deliveries remained relatively steady from the 1950s – 1970s." This is indicated by the running 10-year average line in Figure 5-10. Further, the decline in FHG deliveries during the recent drought is described as a decline "since then" with "then" referring to the "1980s and 1990s."

Ferguson Opinion 12 *– Figure 5-15 indicates that the total applied water in EBID during the period 2008-2016 is slightly greater than the total applied water during the period 1984-1993. Figure 5-19 indicates that the total applied water in EPCWID, including deliveries to EPW, declined slightly during the 1980s, increased during the 1990s, and has generally declined since 2003. (page 22).*

Response:

As shown in Figure 5-15 of the SWE Report, the 10-year average total applied water for EBID declined from approximately 300,000 AF in the early 1980s to about 270,000 AF in recent years

Ferguson Opinion 13 *– Operational waste in during the period 1979-2002 is greater than during the period 1951-1978 due to extremely wet hydrologic conditions during this period. Operational waste during this period includes large amounts of water diverted in excess of district water orders, including storm runoff, greater than anticipated bypass and return flows from the Rincon and Mesilla Valleys, and water ordered by EBID and not diverted. Operational waste during this period is consistent with operational waste during the 1940s, which were also characterized by extremely wet hydrologic conditions. (page 22).*

Response:

As described in the response to Ferguson Opinion 9 and as shown in **Figure 19-20**, the reported EPCWID waste is greater after 1978 than before that time for years of similar releases from Project storage.

Irrigation season operational waste during the 1940s (excluding the 1942 spill year) averaged 87,400 AF which is much greater than the average of 67,400 AF during 1979 – 2002 (excluding spill years 1986, 1987, and 1995).

Ferguson Opinion 14 *– In addition, as noted above, the correlation analysis used to estimate operational waste for the period 2003-2016 incorrectly over-estimates* *operational waste. Lack of accounting for hydrologic conditions in estimating recent operational waste contributes to the incorrect conclusion that operational waste from 2003-2016 is excessive compared to operational waste from 1951-1978. (page 23).*

Response:

See the response to Ferguson Opinion 9.

Ferguson Opinion 15 *– This conclusion incorrectly implies or assumes that metering of pumping results in reduction of pumping, or that lack of metering of pumping results in an increase in pumping. The fact that groundwater pumping in New Mexico is metered has no bearing on the fact that groundwater pumping in New Mexico depletes Project water supplies. In addition, this conclusion incorrectly implies that recent increases in groundwater pumping in New Mexico are the result of reduced allocations to EBID under the OA; to the contrary, increased groundwater pumping in New Mexico and corresponding impacts on Project water supplies began decades before the Operating Agreement was adopted. Lastly, this conclusion fails to acknowledge that increased groundwater pumping in New Mexico, and the corresponding impacts on Project surface-water supplies, was a major driver in negotiation of the OA and that the reduction in EBID's annual diversion allocation under the "D3 Method" was negotiated as a means to offset these impacts. (page 23).*

Response:

Dr. Ferguson's statement that metering has no effect on pumping is contrary to statements in a report by Texas expert, Dr. Phillip King (2003) that analyzed irrigation water use in the Rio Grande Project. In a section of that report describing Farm Delivery Metering, Dr. King states the following:

> *It has been noted by several researchers that the very act of metering reduces the amount of water people use, though it is difficult to prove because there is no pre-metering baseline to which metered water usage can be compared. Newly installed meters often show an initial drop in use with time as water users adjust their management practices in response to the new information provided by the meters. Fipps (1999) suggested that metering is a necessary part of a water conservation program. The fact that farmers have quantitative metrics to guide their management can, in itself, significantly reduce water use by as much as 20 percent. (p. 108).*

While Dr. King's report was referring to metering of farm deliveries of surface water, the same logic would apply to ground water pumping. It costs money to pump ground water. If farmers have knowledge of how much water their crops require and how much their surface water and ground water sources supply, they can employ management practices such as irrigation scheduling to optimize their water use, minimize their operational costs, and maximize their profits.

Dr. Ferguson's assertion that increased New Mexico pumping is not the result of reduced allocations to EBID under the 2008 OA is illogical. **Figure 19-21** is a scatter plot of annual EBID supplemental pumping from the SWE CFB Model versus the annual EBID Project water allocation for 1979 – 2017. The blue dots represent data for the years that EBID's allocation was determined using the D1/D2 procedure (1979 – 2005) and the orange dots are data for the years that the D3 procedure under the 2008 OA was in effect (2006 – 2017). The chart shows clearly that as the EBID allocation declines, EBID supplemental pumping increases. Since 1979, the lowest annual EBID allocations have occurred under the 2008 OA resulting in the greatest annual supplemental pumping in 2011.

Simulations of the ILRG Model demonstrate that EBID supplemental pumping is greater under the 2008 OA than under D1/D2 accounting. Annual EBID pumping under Run 11 with D1/D2 allocation simulated in all years starting in 1950 averages 129,600 AF during 1951 – 2017. This compares to an average of 154,200 AF during the same period under the D3 + Carryover accounting of the 2008 OA. The results for these ILRG Model runs are presented and discussed in Section 30.0.

Ferguson Opinion 16 *– This conclusion incorrectly implies that the impact of groundwater pumping on the Project is proportionate to the volume of pumping, without consideration as to the location where pumping occurs. Modeling results provided with the expert report of Sullivan and Welsh demonstrate that groundwater pumping in New Mexico results in significant depletion of Project deliveries to EBID and EPCWID. These modeling results also demonstrate that groundwater pumping in the Texas portion of the Mesilla Valley results in much smaller depletions of Project deliveries to EBID and EPCWID (less than 25% of the depletion caused by pumping in New Mexico). In addition, these modeling results demonstrate that groundwater pumping in the Conejos-Médanos Basin (i.e., the Mexican portion of the Mesilla Valley aquifer) and in the Hueco Bolson have negligible impact on Project deliveries to EBID and EPCWID. (page 24).*

Response:

The Rio Grande Project is operated as an integrated system. Releases from storage are made to deliver orders for Project water, and the release amounts are varied in consideration of the gains and losses in the river system and the canal system. For any particular aggregate Project water demand, when net downstream gains increase, storage releases are reduced to meet that demand. Conversely, when downstream gains decrease, storage releases must be increased to meet the same demand.

Historical monthly records of reservoir releases, diversions, and Rio Grande flows were analyzed to assess the relationship between reservoir releases and downstream gains. These records included the following:

- Caballo Reservoir releases
- Arrey Dam diversions (Rincon)
- Leasburg Dam diversions
- Mesilla Dam diversions
- American Dam diversions
- Rio Grande Below American Dam flows
- Acequia Madre diversions

Except during periods of high flow and spills, the flow past American Dam is generally limited to the flow necessary to deliver the Mexico order at the Acequia Madre including river conveyance losses. This is illustrated in the scatter plot in **Figure 19-22** that shows the monthly Rio Grande below American Dam flow vs. the monthly Acequia Madre diversions from 1940 – 2017.

The total gain/loss between the Caballo outlet and American Dam was computed as the sum of the Rio Grande below American Dam plus diversions at American Dam plus all upstream river diversions minus the Caballo releases. **Figure 19-23** shows the historical monthly releases from Project storage, the gains and losses, and the total diversions between the Caballo Dam and American Dam. The graphs on the left side of **Figure 19-23** show the monthly Caballo Dam to American Dam diversions (black line), the monthly release (blue bars) and the monthly gain (+) or loss (-) (orange bars).

On the right side of **Figure 19-23** is a plot of the normalized monthly gain (+) or loss (-) against the normalized monthly Caballo release (both values normalized by the sum of the monthly Caballo to American Dam diversions). The results, which all plot along a straight line, show empirically that as monthly gain increases the reservoir release needed to meet the diversion decreases, and as the monthly gain decreases the reservoir release increases.

There is no disagreement that pumping in the Rincon and Mesilla Valleys affects the gains and losses between the Caballo Outlet and American Dam. Therefore, by logical extension to the gain/loss – reservoir release relationship shown in **Figure 19-23**, pumping affects reservoir releases. When more water needs to be released from storage to meet demands, this leaves less water in storage for subsequent use, and thus creates or exacerbates shortages in non-full supply years. Return flows from irrigation pumping and M&I pumping within the Rincon and Mesilla Valleys offset a portion of the impacts of pumping.

As with the impacts of pumping in the Rincon and Mesilla Valleys, there is a similar relationship among pumping, gains/losses, and reservoir releases within EPCWID. The BOR should be operating the Project to release only enough water from storage to meet the EPWICD demands with a minimum of waste, and net of the gain/loss within the EPCWID system. Since Hueco pumping increases the losses between American Dam and Riverside Dam (before 1999), increases conveyances losses through the EPCWID distribution system, and reduces the drain flows available for irrigation use, this requires increased releases from Project storage to meet EPCWID demands. This is how Hueco pumping affects upstream Project operations.

Under current Project operation and accounting, discharges from EPW WWTPs to EPCWID canals provide an offset to the negative effects on Project operations caused by Hueco pumping. Just as Hueco pumping increases the reservoir releases needed to meet EPCWID demands, WWTP discharges to the EPCWID canal system that are used by EPCWID farmers reduce the reservoir releases needed to meet demands.

What is dissimilar between the WWTP offsets in the Rincon and Mesilla Valley versus the WWTP offsets in the El Paso Valley is that EPCWID either receives a credit or is not charged for its use of EPW WWTP discharges while EBID is charged for all water that it uses and receives no credit for New Mexico WWTP discharges.

20.0 RESPONSE TO GEORGE REBUTTAL REPORT

Jonathan D. George, P.E. prepared a December 30, 2019 rebuttal expert report on behalf of Texas ("George Rebuttal Report") that describes his rebuttal to opinions of the New Mexico experts related to crop consumptive use in the LRG Basin.

SWE was asked by legal counsel for New Mexico to review certain opinions in the George Rebuttal Report and to prepare expert opinions to respond those opinions of Mr. George.

George Opinion 1 *– [Based] on the October 2019 NM SWE Report, the SWE Farm Budget average actual evapotranspiration in the Rincon and Mesilla valleys increased from a pre-well development average of 188,830 acre-feet per year during the 1938 through 1950 period to a post-well development average of 236,916 acre-feet per year during the 1985-2016 period, an increase in average actual evapotranspiration of 48,085 acre-feet per year or 25.5%, and the M&A Farm Budget average actual evapotranspiration in the Rincon and Mesilla valleys increased from a pre-well development average of 201,183 acre-feet per year during the 1938 through 1950 period to a post-well development average of 257,364 acre-feet per year during the 1985-2016 period, an increase in average actual evapotranspiration of 56,181 acre-feet per year or 27.9%. The percentage increase in average actual evapotranspiration between the SWE Farm Budget and M&A Farm Budget (25.5% vs. 27.9%, respectively), as reported in the October 2019 NM SWE Report, are very similar and the increase can largely be attributed to use of wells. (p. 10).*

Response:

While it is true that a portion of the increase in consumptive use in the SWE Farm Budget analysis of the Rincon and Mesilla Valleys is due to the development of ground water pumping for irrigation, differences in weather conditions and changes in crops also are reasons that the consumptive use during 1985-2016 is greater than the consumptive use during 1938-1950.

The effect of weather and crop selection on consumptive use are integrated in the crop-weighted average CIR input to the SWE CFB Model. Therefore, differences in crop-weighted CIR between one period and another reflect differences in weather effects on Reference ET, difference in effective precipitation, and differences in crop selection between the two periods. Based on inputs to the SWE CFB Model, the crop-weighted average CIR in the Rincon and Mesilla Valleys was 2.74 and 2.78 inches per year ("in/yr") during 1985-2016, which is 116% and 117% greater than the average of 2.35 and 2.36 in/yr during 1938-1950.

In order to test the effect of differences in weather and crop selection on differences in the consumptive use in the Rincon and Mesilla Valleys between 1938-1950 and 1985-2016, a test run of the SWE CFB Model was made in which the crop-weighted average inputs to the model during 1985-2016 were scaled by the ratio of the 1938-1950 average CIR to the 1985-2016 average CIR (i.e., ratio for Rincon = 0.86). The results of this analysis showed that the annual consumptive use in the Rincon and Mesilla Valleys during 1985-2016 computed using the adjusted CIR values averaged 203,763 AF. This is an average of 33,153 AF/y less than the average of 236,916 AF/y computed with the original unadjusted CIR values. These results show that 69% of the 48,095 AF/y difference in average consumptive use in the SWE CFB Model for the Rincon and Mesilla Valleys between 1985-2016 and 1938-1950 can be explained by differences in weather and crop selection between the two periods.

The upper graph in **Figure 20-1** shows annual crop-weighted average CIR from 1938-2017, and averages for 1938-1950 and 1985-2016. The lower graph in **Figure 20-1** shows the annual consumptive use of applied water for the same period with annual average for 1938-1950 and 1985-2016. The 1985-2016 adjusted CIR and consumptive use volumes are also shown in the two graphs. This analysis shows that Mr. George is incorrect in his assertion that differences in average annual consumptive use in the Rincon and Mesilla Valleys between 1938-1950 and 1985-2016 "can largely be attributed to wells."

21.0 RESPONSE TO HORNBERGER REBUTTAL REPORT

George M. Hornberger, Ph.D. prepared a December 30, 2019 rebuttal expert report on behalf of Texas ("Hornberger Rebuttal Report") that describes his rebuttal to opinions of the New Mexico modeling experts regarding the Texas Model.

SWE was asked by legal counsel for New Mexico to review the Hornberger Rebuttal Report and to prepare expert opinions to respond the opinions of Dr. Hornberger. A lack of response regarding a particular issue should not be interpreted as tacit agreement with the Hornberger opinions on that issue.

Hornberger Opinion 1 *- The critiques of the groundwater modeling approach (hereinafter Texas model") taken by Hutchison (2019) from experts for New Mexico lack specificity. The Texas groundwater model focuses on modeling the impact of pumping groundwater in the Rincon and Mesilla Valleys on flow in the Rio Grande at El Paso using annual stress periods. In contrast, the models produced by New Mexico include a river flow routing model using RiverWare, include groundwater models of the Hueco Bolson in addition to the Rincon-Mesilla Valleys, use monthly stress periods, and use hypothetical reservoir releases in place of historical observations. The argument that these "improvements" to the model are necessary without presentation of any justification of what purpose is served by adding complexity, is completely opaque. Without justification in terms of the specific objectives stated for the model, such criticism is meaningless.*

Response:

The assertion by Dr. Hornberger that so-called "improvements" were made to the ILRG Model by the New Mexico experts without presentation of any justification for the purpose of the improvements is blatantly false, and confirms Dr. Hornberger's statement in the Introduction section of his report that "he only scanned the reports produced by the experts for New Mexico." During his deposition, Dr. Hornberger admitted to only spending two hours reviewing the New Mexico expert reports.

The New Mexico experts provided ample description and support for the monthly stress periods, spatial scale, and rule-based processes for simulating Project operations that are essential bedrock elements of the ILRG Model. This is discussed at length in the SWE Report, and in the responses to the Coors Supplemental Report in Section 23.0.

By comparison, the coarse annual stress periods, limited geographic scope, and absence of dynamic processes for simulating Project operations render the Texas Model woefully inadequate for analyzing the claims and counterclaims in this case.

Hornberger Opinion 2 *- The objectives set forth for the Texas model by Hutchison (2019) are stated clearly and are straightforward. The goal is to show how groundwater pumping in the Rincon and Mesilla Valleys affects the amount of water that flows to Texas at the gage at El Paso. This is the key issue that needs to be addressed both to demonstrate the impact of pumping in New Mexico on water deliveries to Texas and to provide a simple and straightforward method to explore counterfactuals related to what deliveries would have been if pumping had been curtailed over the period of record.*

Response:

The Texas Model fails to meet the stated Texas objective "to show how groundwater pumping in the Rincon and Mesilla Valleys affects the amount of water that flows to Texas at El Paso" for several reasons.

- The Texas Model lacks simulation of the dynamic responses of Project operations to changes in surface water flows that would occur under no pumping or reduced pumping scenarios.
- The limited geographic scope of the Texas Model from the Caballo Reservoir outlet to the Rio Grande at El Paso gage precludes simulation and analysis of the response of upstream reservoir operations to changes in pumping, and the effects of irrigation and non-irrigation pumping in the Hueco Bolson on deliveries to EBID, EPCWID, and HCCRD.
- The annual stress periods of the Texas Model are too coarse to distinguish the effects of pumping on surface water supplies and Project deliveries that occur within the irrigation season versus the effects on surface flows during the non-irrigation season.

In addition, the stated Texas objective is an incomplete statement of the questions that need to be answered to fully analyze the claims and counterclaims in this case. Other questions that need to be answered include how pumping throughout the Project affects Project deliveries to New Mexico and Texas water users, and how changes in Project operations (e.g., enactment of the 2008 OA) have affected deliveries.

Hornberger Opinion 3 *- The vast majority of Project deliveries to Texas are diverted at the American Dam, a short distance downstream from the El Paso gage. Because the clearly stated objective of the Texas model is to determine the impact of groundwater pumping on deliveries to Texas, the only possible reason to include the use of water between El Paso and Ft. Quitman in the model would be if pumping from the Hueco Bolson significantly influenced flow in the Rio Grande above El Paso. The only groundwater links between the*

Mesilla and the Hueco are at Fillmore Pass and at the Narrows. The connecting strata are thin, however, so the underflows from the Mesilla to the Hueco are quite limited (Slichter 1905). Hutchison's estimates of about 400 to 1200 AF/year (Hutchison 2019) are somewhat higher than other estimates (e.g., Heywood and Yager 2003) but nevertheless a small fraction of annual groundwater pumping by New Mexico above El Paso. Pumping from the Hueco aquifer can have very little effect on the Rio Grande flows at the El Paso gage and thus on deliveries to Texas; therefore, adding complexity to the Texas model on this account is unnecessary to address the objectives stated. The criticism leveled at the Texas model has no merit.

Response:

Due to an apparent lack of understanding of Project operations, Dr. Hornberger mistakenly assumes that the only way for impacts of Hueco pumping to propagate upstream is through changes in ground water flow either at Fillmore Pass or at the El Paso Narrows. Rather than through ground water flow changes, Hueco pumping impacts propagate upstream through changes in Project operations caused by such pumping.

The mechanism for Hueco pumping impacts to propagate upstream is rooted in the long-standing practice of operating the Rio Grande Project as a single unit, and that changes in flows anywhere within the system have the potential to affect deliveries to all Project water users, including users located upstream of where the pumping occurs. Upstream impacts from Hueco pumping occur when the pumping depletes delivery of Project water to EPCWID water users, thus necessitating increased releases of Project water to meet EPCWID demands. Depletions of Project water deliveries by Hueco pumping occur through mechanisms that vary based on the location:

- Prior to construction of the ACE, depletions of the Rio Grande upstream of Riverside Dam caused by Hueco pumping required increased releases from Project storage to meet demands for Riverside Canal users.

- Depletions to the Rio Grande downstream of American Dam caused by Hueco pumping increase the reservoir releases needed to deliver 1906 Treaty water to Mexico at the Acequia Madre.

- Hueco pumping also increases seepage from EPCWID canals and laterals (MMA, 2019). The increased seepage losses in the EPCWID service area require additional Project storage releases to deliver orders for Project water to EPCWID farmers.

Any of the above effects of Hueco pumping that require increases in Project storage releases reduce the unused supply of water left in Project storage at the end of the year.

Under the accounting that existed prior to the 2008 OA, these reductions in unused supply would have reduced the supply available for allocation to the Districts in the following year.

Under the 2008 OA, the above effects of Hueco pumping reduce the computed Diversion Ratio, and this negatively impacts deliveries of Project water to EBID in the current year in accordance with the D3 allocation procedure. In addition, the increased reservoir releases to deliver EPCWID orders for Project water increase the amount of "paper water" in EPCWID's carryover storage account that must be filled by inflows in the next year, thus reducing the supply available for allocation to EBID in the next year.

In addition to the effects on Project water deliveries described above, Hueco pumping also affects the supply of water to HCCRD through the following mechanisms:

- Hueco pumping depletes the Tornillo Canal at Alamo Alto and the flows of the Tornillo Drain and Fabens Waste Channel that comprise the HCCRD supply.

- Hueco pumping increases seepage losses in the HCCRD canals and laterals, reducing the supply available for delivery to the headgates of HCCRD farmers.

The ILRG Model is the only model in this case that is capable of analyzing and quantifying the effects of Hueco pumping on EBID, EPCWID, and HCCRD.

Hornberger Opinion 4 *- Hutchison (2019) stated no objective about exploring how management decisions in the future might affect Project deliveries. Rather, he focused on the physical response because that is the central question related to the Compact. Any institutional or management changes would involve several stakeholders to determine how much of a given flow increase would be retained in storage and how much would flow to the Narrows. Information about such management is unknowable before any negotiations are completed so any such simulation would be highly speculative and counterproductive given the objectives stated by Hutchison.*

Response:

It is naïve to state that impacts in this case would somehow be limited to impacts that manifest solely through physical processes. Given the dominant effect that Project operations have on the water supply of the LRG area, both directly and indirectly, virtually all impacts from pumping or other actions that affect the available water supply are likely to be filtered through the Project water allocation and delivery mechanisms. The key elements of the allocation and delivery processes are well established and well understood. For example, the water available for allocation in the current year is generally based on the water available in storage, and releases from storage are based on the aggregation of downstream demands adjusted for gains and losses between the reservoir outlet and the points of delivery.

The effects of pumping are implicit in the gains and losses to surface flows throughout the LRG area. During periods of high pumping, net surface water gains (gains minus losses) decrease and more water must be released to meet certain demands. Conversely, during periods of low pumping, net surface water gains increase and less water needs to be released to meet the same demands. The specific effects of pumping generally cannot be discerned by observation or measurement from other processes that affect the gains and losses. Nor do such pumping impacts need to be specifically discerned in order to determine reservoir releases that are needed to meet demands. Reservoir releases are made in consideration of the downstream gains and losses regardless of what causes those gains and losses.

It is not necessary to speculate how the Project would operate with reduced pumping because the records of operations during the 1940s, 1980s, and 1990s already provide ample empirical evidence.

Hornberger Opinion 5 *- The intent of the Hutchison report was to determine to what extent groundwater pumping by New Mexico depletes deliveries to Texas from the Rio Grande Project. This is the key question and the answer does not depend on a distinction between the irrigation and non- irrigation seasons. Changes in pumping over time influence short-term conditions near the well being pumped but impacts on river flow are manifested in the long term. The point is that at some distance from the river the effects of an intermittent or cyclic pumping pattern "become indistinguishable from a constant pumping pattern at a cycle (or long-term) average pumping rate" (Barlow and Leake 2012). The long-term impact of pumping and associated consumptive use of the water through irrigation on the regional water budget is captured by use of an annual stress period in calculations. The important question is not about potential monthly fluctuations but about long-term average impacts.*

Response:

As discussed in the response to the Coors Supplemental Report, responses of surface water flows (canals, drains, and Rio Grande) to irrigation pumping typically occur within months but can persist for longer durations during extended drought periods. See the response to Coors Opinion 6 for a detailed discussion of this subject.

The annual stress periods of the Texas Model are too coarse to evaluate the monthly and seasonal effects of pumping on LRG surface water supplies. Quantification of the portion of the surface water depletions caused by pumping is of significant importance because of the seasonal nature of Project operations and deliveries. Depletions to surface water flows during the non-irrigation season from pumping are less significant in this case than depletions during the irrigation season. Uses of surface water during the non-irrigation season are minimal, and none of the impacts claimed by Texas are due to depletions of non-irrigation season surface water flows caused by New Mexico pumping.

22.0 RESPONSE TO COORS REBUTTAL REPORT

Mr. Coors prepared a December 30, 2019 rebuttal expert report on behalf of Texas ("Coors Rebuttal Report") that describes his rebuttal opinions and criticisms of New Mexico's ILRG Model.

SWE was asked by legal counsel for New Mexico to review the Coors Rebuttal Report and to prepare expert opinions to respond to the opinions of Mr. Coors. A lack of response regarding a particular issue should not be interpreted as tacit agreement with the Coors opinions on that issue.

Although the deadline for Mr. Coors to submit his report was in December 2019, he much later substantially expanded on his initial rebuttal opinions and added new rebuttal opinions in a supplemental report that was submitted on May 5, 2020. In some instances, my responses to Mr. Coors' initial and supplemental opinions are consolidated in the responses to his supplemental report in Section 23.0. The opinion numbering system in the following discussion is independent of the opinion numbering in the Coors Rebuttal Report.

Coors Opinion 1 *- The Lower Rio Grande (LRG) system itself is complex and the data used to develop the models comprising the ILRG is limited, so determining if the model produces meaningful results is something that warrants further analysis. A sensitivity analysis of the ILRG system is in order to determine the reliability of the model results and the level of uncertainty present in them. There is no indication in the NM experts' reports that a sensitivity analysis of the ILRG was performed. (page 4).*

Response:

Sensitivity analyses of the ILRG Model were performed to test the sensitivity of the model results (differences between runs) to changes in selected input parameters and input data. The results of the sensitivity analyses are reported in Section 31.0.

Coors Opinion 2 *- The impacts on flows in the river at El Paso are determined by longer time scale effects that may not warrant the shorter timestep and highly uncertain modeling that has been performed by the NM experts on a monthly timestep. (page 5).*

Response:

See the responses to Mr. Coors' supplemental report.

Coors Opinion 3 *- The uncertainty present in the ILRG model due to insufficient data, unknowable historical practices in irrigation and Project operations may make the model results unreliable or require that the modeled domain be further aggregated either spatially or temporally in order to reduce the uncertainty present in the results to an acceptable level for quantifying impacts. (page 5).*

Response:

See the responses to Mr. Coors' supplemental report.

Coors Opinion 4 *- I also generated a timeseries of annual differences between the Run 1 and Run 0 variables. If the model was a perfect replica of the LRG system, each of the 78 annual difference values (1940-2017) for each variable would be zero acre-feet. The average deviation of each of these timeseries provides a simple measure of the level of uncertainty in values produced by the model for each variable. It is important to note that five of the six calculated impacts of pumping in New Mexico and Texas are smaller than this uncertainty metric in the model as indicated by the Run 1 to Run 0 comparison across the three modeled variables. This is further indication that a sensitivity analysis of the model is needed to determine if the level of uncertainty in the ILRG model results is problematic for answering the questions it is being used to answer.*

> *12.1 For Project water storage the average deviation of the Run 1 – Run 0 values is 152,156 acre-ft. The differences in the no New Mexico and no Texas pumping run combinations are 104,802 acre-ft and 9,386 acre-ft respectively.*
>
> *12.2 For the annual volume of flow at El Paso the average deviation of the Run 1 – Run 0 values is 121,572 acre-ft. The differences in the no New Mexico and no Texas pumping runs are 121,939 acre-ft and 30,850 acre-ft respectively.*
>
> *12.3 For the annual diversion at the American Canal, the average deviation of the Run 1 – Run 0 values is 110,040 acre-ft. The differences in the no New Mexico and no Texas pumping runs are 56,375 acre-ft and 20,419 acre-ft respectively. (page 6).*

Response:

Like all simulation models, the ILRG Model does not perfectly replicate historical observed flows in the Historical Base Run (Run 1). However, as is described in Section 28.0, the ILRG Model is well calibrated to give reliable results, and is the best model available for analyzing the claims and counterclaims in this case.

The analyses of the ILRG Model presented by Mr. Coors are not useful measures of the uncertainty of the ILRG Model in analysis of the impacts of pumping or other actions in this case. This is because such impacts are analyzed by differences between model runs. For example, the effects of New Mexico pumping can be assessed by comparing the result of Run 3 (No New Mexico Pumping) and Run 1 (Historical Base Run). When computing the differences between model runs, the model imperfections that are present in both runs cancel out. Therefore, differences between model runs can be more accurate than simulated values in a single model run. See additional discussion of canceling of errors in the responses to Coors' supplemental report and in Section 28.0.

Coors Opinion 5 *- It is my opinion that characterizing the results [based on differences between runs] is not necessarily accurate and that a more thorough model validation process would need to be conducted in order to make this claim. If the Run 1 model is not a sufficiently accurate representation of the basin and all of the water dynamics, then the differences between any of the Scenario Runs and Run 1 do not give a reliable approximation of what would have happened historically if pumping in any particular region of the basin did not occur. (page 7).*

Response:

See the response to Coors Opinion 4.

23.0 RESPONSE TO COORS SUPPLEMENTAL REPORT

Mr. Coors prepared a May 5, 2020 supplemental rebuttal expert report on behalf of Texas ("Coors Supplemental Report") that greatly expanded on and added to the rebuttal opinions provided in the Coors Rebuttal Report. The topic of both Coors reports is criticism of New Mexico's ILRG Model.

SWE was asked by legal counsel for New Mexico to review the Coors Supplemental Report and to prepare expert opinions to respond to the opinions of Mr. Coors. A lack of response regarding a particular issue should not be interpreted as tacit agreement with the Coors opinions on that issue.

The opinion numbering in this section picks up where the opinion numbering in the responses to the Coors Rebuttal Report left off.

Coors Opinion 6 *- So, the Compact was intended to fix the existing apportionment of the LRG water supply among the two states and Mexico at the time of the Compact, which included a recognition of the influence of groundwater on surface water. With this as one of the fundamental objectives of the Compact, in order to substantiate its Complaint, Texas developed the Texas Model to simply demonstrate that New Mexico's ongoing use of groundwater throughout the years since the signing of the Compact represents an inappropriate overuse of the original apportionment of the limited water supply to the Project. The Texas model was designed specifically to substantiate this claim and as was concluded by Dr. Hornberger in his report:*

> *"These questions supplied a clear purpose for developing a parsimonious model…I conclude that Hutchison (2019) indeed followed appropriate modeling guidelines and produced a model that meets the stated objectives, clearly showing the impacts of groundwater pumping by New Mexico on Rio Grande water deliveries to Texas." (Hornberger Rebuttal at p. 10.)*

New Mexico experts, Spronk Water Engineers (Spronk) and Hydros Consulting (Hydros) state repeatedly in their expert reports that the LRG system is highly complex and includes many dynamics that occur on a monthly scale, namely Project operations. While this is true it does not ipso facto justify a model that attempts to model all known dynamics in the system. A justification tied specifically to the Texas Complaint that drives the decision to include a very ambitious level of detail in on-farm processes throughout the project, a monthly timestep, and an attempt to capture in rules historical Project operations is not clearly given. (page 4).

Response:

The Supreme Court has essentially stated that the Rio Grande Project has been the mechanism for effecting the allocation of water under the Rio Grande Compact between New Mexico and Texas downstream of Elephant Butte Reservoir, and implicit in this recognition was the necessity to ensure successful operation of the Rio Grande Project (Lopez, 2019). Consistent with this, the BOR, New Mexico, and Texas encouraged the development of ground water pumping to supplement Project water deliveries in dry years when it became evident that the Project supply was inadequate to provide a full irrigation water supply (Barroll, 2019). Conjunctive use of surface water and ground water ensured the continued successful operation of the Rio Grande Project in all hydrologic conditions, including during extended drought periods, which had not been experienced in the LRG Basin between 1915, when Elephant Butte Reservoir began delivering Project water, and 1939, when the Compact was enacted.

Notwithstanding the encouragement and embrace of ground water pumping by the BOR, New Mexico, and Texas, Mr. Coors and Dr. Hornberger continue to support the overly simplistic Texas objective of the of the Texas Model to answer the question, "Did New Mexico's pumping deplete streamflows at El Paso on an annual basis?" The scope of this case is not limited to this very simplistic question. Rather, to determine impacts to Project deliveries it is necessary to develop a simulation model that includes simulation of Project operations to answer the correct questions.

New Mexico and its experts understood from the outset that the issues in this case were more complex than portrayed by Mr. Coors and Dr. Hornberger. This case involves <u>quantifying</u> the amount and timing of impacts from pumping and changes in Project operations on deliveries to water users in New Mexico and Texas. Quantification of these impacts needs to consider how pumping and other actions affect the Project operations that dominate how the highly variable Rio Grande inflows to Project storage are managed and delivered to New Mexico and Texas water users.

As was described at length in the opening expert reports of the New Mexico experts and further expounded upon in their rebuttal reports, the Texas Model, with its limited geographic scope, coarse annual stress periods, and lack of dynamic simulation of Project operations, is woefully inadequate and inappropriate for answering the complex technical questions posed in this case, including the quantification of impacts from pumping and other actions.

The level of detail included in the ILRG Model developed by the New Mexico experts was developed over many years of model testing, evaluation, and refinement. The simulations of Project operations and on-farm processes were developed and refined to capture essential elements of these processes. Additional simulation capabilities were added when detailed review of model output revealed that simulation of historical conditions could be improved. Potential model improvements were identified, discussed, and tested in the model. Proposed model changes were implemented if (a) they reasonably reflected physical processes or rational operating procedures and (b) resulted in significant improvement in model performance. Proposed changes were not implemented and if they did not meet these criteria. The following are examples of improvements that were made to the ILRG Model through the years:

- Extension of the model south to Fort Quitman and incorporation of full simulations of irrigation operations in the El Paso Valley and Juarez Valley as well as M&I pumping and returns.
- Development of the Hueco Ground Water Model as a component of the ILRG.
- Subdivision of the spatial scale of the simulated water user and ground water components in the RiverWare Model into smaller subareas,
- Linking of the ground water models to the RiverWare Model to provide a dynamic exchange of data between the models, including the RiverWare inputs for canal seepage, riparian ET, and flux between the shallow and deep aquifers,
- Simulation of WWTP discharges and urban deep percolation from M&I pumping,
- Implementation of a soil moisture simulation algorithm in the farm budget kernel of the RiverWare model,
- Refinement of rules for allocating Project water under D1/D2 accounting and D3+Carryover accounting, and
- Refinement of operational rules for simulating farm headgate and river headgate demands considering crop water demands, conveyance losses, and other irrigation supplies (i.e., WWTP flows and drain flows).

Development of the ILRG Model employed the principle of parsimony in the sense that additional detail was added to the simulation processes only as necessary to capture essential elements of the system operation. The robust and sophisticated functionality of the ILRG Model is supported by the rich and extensive record of historical Project operations.

Coors Opinion 7 *- The ILRG model became a monumental undertaking that is not appropriate for, or successful in, refuting the Texas Complaint or supporting New Mexico's criticisms of the Texas Model for reasons surveyed in the remainder of this report. What is most interesting is that once the ILRG model was completed and a set of runs were made* *by New Mexico experts, the results support Texas's claims, confirm the Texas experts' findings both from modeling and historical analysis, and refute New Mexico's Counterclaim 1. (page 5).*

Response:

What Mr. Coors' portrays as a monumental undertaking was instead incremental and rational development of a model appropriate for simulating the complex Project operations, irrigation system operations, and ground water and surface interactions in the LRG Basin. The effort and care in developing the ILRG Model reflect the necessary attention that New Mexico and its experts are giving to this case.

The objectives for developing the ILRG Model were not limited to refuting the Texas complaint. Rather, the ILRG Model was also developed to gain insight into and understanding of the effects of various actions on Project operations and deliveries to the U.S. Districts and Mexico, and to analyze New Mexico's counterclaims. This includes identifying and quantifying how past or proposed changes in Project operations and water use practices have affected surface flows, reservoir storage, ground water storage, Project water allocations and deliveries, and consumptive use since the Compact became effective in 1939.

The Texas Model is wholly inadequate to meet the foregoing objectives because it does not extend downstream beyond the El Paso gage, it employs annual stress periods that cannot distinguish between Project operations during the irrigation season and non-Project operations during the non-irrigation season, and it does not simulate the Project operation and accounting that determine deliveries of surface water for irrigation and non-irrigation uses in the Project area.

Coors Opinion 8 *- The nature of Texas's Complaint against New Mexico is that groundwater pumping in New Mexico has resulted in New Mexico consistently using more than its share of water annually as defined by the Compact to the injury of the Texas water users. The effects of groundwater pumping are slow and are not realized within a single year. As Dr. Hornberger stated in his rebuttal report:*

"The long-term impact of pumping and associated consumptive use of the water through irrigation on the regional water budget is captured by use of an annual stress period in calculations. The important question is not about potential monthly fluctuations but about long-term average impacts." (Hornberger Rebuttal, Criticism 3 at p. 9.)

New Mexico experts describe the complexity of the effects of GW pumping within a given year. (See Spronk Report at pp. 71-72) The sequence of effects given in this section *qualitatively describe how the system would be affected by a reduction in pumping in the Project. While effects in this sequence might be accurate, this is put forth as one of the justifications for the ILRG model and its complex representation of the system. This sequence of effects generally takes place within a single year and does not describe the sequence of events (mechanism) that gives rise to the Texas Complaint. (page 5).*

Response:

The Compact has no explicit definition of how water delivered into Elephant Butte Reservoir is divided among downstream water users in New Mexico and Texas. Instead, the inflows are allocated and delivered to downstream water users in accordance with the operating practices of the Rio Grande Project, which have long incorporated the conjunctive use of ground water and surface water to ensure successful operation during drought periods.

Mr. Coors and Dr. Hornberger are wrong in their assertions that the effects of ground water pumping are slow and not realized within a single year. Irrigation wells in the LRG area are generally less than 250 feet deep and less than one-half mile from the drains that control the alluvial ground water levels. This results in a relatively rapid response (within months) of surface flows to pumping during non-drought periods when the ground water table is hydraulically connected to surface water flows (canals, drains, and the Rio Grande). During drought periods, the combination of a lack of recharge from surface water use and increased ground water pumping can cause the ground water table to become disconnected from the surface water flows in some areas. When this happens, the drains can cease flowing, and seepage from rivers and canals will stabilize and not be affected by short-term variation in pumping. Therefore, the effects of pumping during drought periods can persist for longer periods than during non-drought periods.

The rapid response of the LRG area drains is illustrated in **Figure 23-1** for the Rincon Valley and **Figure 23-2** for the Mesilla Valley for 1938 - 2005[3]. Each graph compares the monthly net recharge (orange line; defined as canal seepage plus deep percolation minus irrigation pumping) to the aggregate recorded monthly drain flows (blue line). Close inspection of the Rincon Valley and Mesilla Valley graphs shows that the drain flows respond rapidly and typically lag the net recharge by only one to three months.

During drought periods such as the mid-1950s, net recharge declined, becoming negative at times (pumping exceeded the sum of canal seepage and deep percolation), and this

[3] Some drain data are not available from 1984-2005, and limited drain data are available after 2005.

resulted in the drain flows declining substantially and even drying up. The accumulated effect of the negative recharge during the drought is seen in the slow recovery of the drains after the drought, when it took two or three years for the drains to recover.

The ILRG Model, with its monthly stress periods, is capable of simulating the monthly, seasonal, and long-term responses of surface water flows to pumping as well as the Project operation responses to the changing surface flows. While the ILRG Model results reported by New Mexico generally rely on seasonal stress periods, the granularity of monthly stress periods is helpful in simulation of the following processes:

- Monthly inflows to Project storage and the resulting increases in Project water allocations through the early portions of the irrigation season (typically through July) and reserving later inflows for carryover to the next year.
- Characteristic monthly variability in LRG irrigation operations including planting dates, crop irrigation demands, diversions and deliveries, soil moisture carryover, and irrigation pumping,
- Monthly or sub-seasonal lagged impacts from recharge and pumping on surface flows (e.g., canal, drain, and river flows),
- Monthly M&I pumping volumes and WWTP returns based on historical monthly data, and associated estimates of monthly urban deep percolation,
- Bunching of reservoir releases into shorter delivery periods during non-full supply years.

The Texas Model, with its annual stress periods and lack of Project operating rules, is incapable of simulating many of the real-world responses described in Section 7.0 of the SWE Report (2019), including their monthly and seasonal variability.

Coors Opinion 9 *- When there is not a full allocation, Project operations do not provide a mechanism to compensate for the reduced flows that occur at El Paso due to pumping in New Mexico. Then, in subsequent years of full allocation, the groundwater elevation remains lower than it would have been without New Mexico pumping. So even if Texas receives a full allocation in a full allocation year, the depleted groundwater condition in New Mexico continues depleting additional water from the river and the injury to Texas continues. (page 6).*

Response:

The description of the Project response to the impacts of pumping described by Mr. Coors is overly simplistic and incomplete. Under D1/D2 accounting, pumping impacts during a year with less than a full allocation can potentially result in (a) more water having to be released from storage to deliver the allocations or (b) insufficient water being available to deliver the allocations. In the latter case, pumping can reduce deliveries in the current year. In both cases, the supply available for allocation in the next year can be reduced. In a full supply year, the effects of pumping can result in more water needing to be released to deliver the orders for irrigation water, which can result in less water available for allocation in the next year.

Under the D3 accounting in the 2008 OA, mechanisms for pumping to impact deliveries to EPCWID are generally similar to the mechanisms described above for the D1/D2 accounting. However, pumping (or other actions) can also affect EBID in the current year due to changes in the diversion ratio.

The ILRG Model, with its dynamic rules for simulating Project operations, is capable of reasonably simulating the foregoing real-world responses to changes in surface water supply caused by pumping in New Mexico and Texas in full supply and non-full supply years as well as the effects on future Project water allocations and deliveries.

Coors Opinion 10 *- The ILRG runs on a monthly timestep. For the questions raised by the Texas Complaint and New Mexico's Counterclaim, the most appropriate timestep is an annual one. By selecting a monthly timestep, simulating Project operations, including on-farm processes, reservoir operations, and canal operations and drain flows becomes significantly more complex and uncertain. Data needs to support modeling at this time scale also become greater. Due to a lack of much important historical data, a significant data development effort needed to be undertaken that introduces significant uncertainty to the model. Just because there are dynamics in the Project that occur on a monthly or seasonal level, does not mean that a monthly timestep is the appropriate one. The objective of the model is better served by an annual timestep which reduces the uncertainty present in the model results and more effectively captures the effects of a depleted groundwater condition on the surface water in the Rio Grande and in the Project over the course of years. (page 7).*

Response:

Contrary to Mr. Coors' statements, simulating the monthly operations of the Rio Grande Project and the LRG irrigation systems is not significantly more complex than simulating these operations using an annual timestep. Most of the LRG data needed for modeling are recorded and tabulated as monthly if not daily values. There is no significant "lack of important historical data" that limits the monthly simulation of the ILRG Model as asserted by Mr. Coors, and he did not specifically identify any data alleged to be lacking.

The monthly time-step of the ILRG Model allows it to simulate and distinguish the effects of pumping and other actions on Project water deliveries during the irrigation season from less important impacts on surface flows during the non-irrigation season. This capability is extremely important for analysis of the issues in this case.

Coors Opinion 11 *- Hydros applied three statistical metrics to quantify the effectiveness of the calibration of the Historical Base Run. For a short list of locations, they analyzed all the differences between the Run 1 simulated values and the observed values. The difference between an observed value and a modeled value is called the residual. Residuals from the Historical Base Run were analyzed by the following three statistics:*

1. *Monthly Mean Error*
2. *Mean Error as Percentage of Monthly Average*
3. *Nash-Sutcliffe Efficiency.*

The statistical methods selected are inadequate and inappropriate, and the locations at which they were applied are inadequate for determining the quality of the calibration of the Historical Base Run. (page 8).

Response:

While use of calibration statistics to evaluate the calibration of hydrologic models is commonplace, there are no universally accepted guidelines for calibration assessment in the scientific community (Moriasi et al., 2012). There are numerous statistical performance measures that have been developed to assess the goodness of fit of modeled values to measured values, and the choice of statistics is generally left in the hands of the modeler based on professional judgment. In addition, there are numerous graphical performance measures to evaluate model calibration, and most modelers use some combination of statistical and graphical performance measures to assess calibration of hydrologic models.

Coors Opinion 12 *- The third statistical parameter reported in the New Mexico experts' reports is the Nash Sutcliffe Efficiency (NSE) parameter, Eq (2). This parameter characterizes the goodness-of-fit between a modeled quantity and the observed. The value ranges from - ∞ to 1.0. A value of 1.0 represents a perfect fit. Negative values indicate the observed mean is a better representation of the timeseries than the model results. "Performance Evaluation of Hydrological Models: Statistical Significance for Reducing Subjectivity in Goodness-of-Fit Assessments" by Ritter, Axel, and Rafael Muñoz-Carpena (2013) provides performance ratings for NSE values. This performance rating system is given in Table 1. (page 9).*

NSE Category	*Value Range*
Unsatisfactory	*< 0.65*
Acceptable	*0.65 – 0.80*
Good	*0.80 – 0.90*
Very Good	*0.90 – 1.00*

Response:

The NSE has become a widely used statistic for evaluating the calibration of hydrologic models because it more appropriately measures the goodness of fit than does the coefficient of determination (R^2) statistic that previously was the standard regression statistic used to evaluate model performance (Harmel et al., 2010; Legates, 1999; Moriasi et al., 2007). However, there are no universally accepted performance criteria in the scientific community for evaluating NSE scores, and performance criteria used by Mr. Coors are proposed criteria included in Ritter (2013).

A widely cited journal article by Moriasi et al. (2007) included performance evaluation criteria for the NSE statistic that are less stringent than the criteria advocated by Mr. Coors. A subsequent article by Moriasi et al. (2015) describes an in-depth review and analysis of statistical and graphical performance measures and performance evaluation criteria in the hydrologic modeling literature. The following criteria were recommended for the NSE, coefficient of determination (R^2), Index of Agreement (d), and the Percent Bias (PBIAS) by Moriasi et al. (2015) on behalf of the American Society of Agricultural and Biological Engineers ("ASABE"):

Recommended Performance Evaluation Criteria
ASABE (2015)

Performance Evaluation Criteria	Nash-Sutcliff Efficiency (NSE)	Coefficient of Determination (R^2)	Index of Agreement (d)	Percent Bias (PBIAS)
Very Good	> 0.80	> 0.85	> 0.90	< 5%
Good	0.70 – 0.80	0.75 – 0.85	0.85 – 0.90	±5% – ±10%
Satisfactory	0.50 – 0.70	0.60 – 0.75	0.75 – 0.85	±10% – ±15%
Unsatisfactory	0.0 - 0.50	0.18 - 0.60	0.60 - 0.75	±15% - ±30%
Unacceptable	≤ 0.0	≤ 0.18	≤ 0.60	≥ ±30%

Note also that the NSE equation presented in the Coors Report on page 9 is incorrect. The opening parentheses in the numerator and denominator should be placed after, rather than before, the summation character.

Coors Opinion 13 *– [T]he NSE methodology fails to accurately evaluate model calibration across the whole range of values in the dataset. Krause, et al. (2005) asserts,*

> *"the Nash-Sutcliffe is not very sensitive to systematic model over- or underprediction especially during low flow periods."*

The NSE metric overemphasizes a model's ability to match higher values and underemphasizes the ability to match lower values. For model output intended to represent the surface water conditions of the Rio Grande Project, matching low flows is particularly important as it is during the low flow times when surface water is limited that the impacts of groundwater pumping are realized. It is more important that the model be effective at capturing the low flow periods to address the issues at hand. The NSE is more a measure of how well a model represents the higher values than the lower ones, which is not appropriate for determining the effectiveness of the ILRG model in replicating Project operations. (page 9).

Response:

The criticism by Mr. Coors of use of the NSE methodology for evaluating calibration of the ILRG Model because it underemphasizes low flows is misplaced for several reasons. First, the LRG system is different from more typical unregulated flow systems. Except for rare spills from Project storage, the irrigation season surface water flows in the LRG area are highly regulated by Project operations, resulting in streamflow and diversion rates that generally fall within a relatively narrow range of flows. This is much different than unregulated basins in the West in which streamflows may routinely vary widely between snowmelt or rainfall runoff in the spring and baseflows in the fall.

Second, reported monthly flow volumes (streamflows and diversions) in the LRG area are often very low in shoulder season months because the Caballo Reservoir releases commence late in a spring month or cease early in a fall month. These low flow volumes should not be treated in the statistics as if they are significant extreme values when they represent typical regulated flow rates occurring over a limited number of days in the month. Zero flows are typically rare in unregulated watersheds and of great interest to engineers and planners. However, zero flows in the LRG Basin are routine because of reservoir and canal operations.

Finally, the claims and counterclaims in this case need to be evaluated at all levels of flow conditions and not just in low flow years.

Coors Opinion 14 *- There are three additional metrics that are needed for a more complete assessment of the quality of the Run 1 calibration (tuning). The first is the Mean Absolute Error (MAE), shown in Eq (3). By taking the absolute value of the residual before applying the average, positive and negative residuals do not cancel each other out and the formula produces a statistic that meaningfully quantifies the predictive capability of a model. Note this metric does not have a "squared" term in its formulation which prevents large deviations from dominating the calculation. In hydrology, large flows generally exhibit larger deviations and so, unlike the NSE, this metric characterizes the model's ability to represent a full range of flows, not just high flows which are not nearly as important for the questions being addressed in this case. Additionally, this metric has units of flow and provides an intuitive value that simply represents the average absolute size of the model residual. (page 10).*

Response:

The MAE is a commonly used statistic for evaluating the range of the differences between simulated and observed values without the cancelation of positive and negative differences that occurs in the mean error statistic. The New Mexico experts informally reviewed the MAE in calibrating their models but did not publish this statistic in their prior reports. The MAE statistic is included in the calibration and tuning results for the ILRG Model that are presented in Section 28.0.

Mr. Coors again misplaces his criticism of the NSE statistic. Unlike other hydrologic models that may be focused more exclusively on drought periods, the modeling required for the LRG area needs to more equally consider and weigh conditions in dry, wet, and average periods because the claims and counterclaims in this case have the potential to affect Project operations in all types of hydrologic conditions.

Coors Opinion 15 *- The second is simply the MAE divided by the observed monthly mean. This calculates the relative size of the MAE to the mean of the observed quantity through the run period. (page 10).*

Response:

The MAE divided by the observed mean ("PMAE") statistic is included in the calibration and tuning results for the ILRG Model that are presented in Section 28.0. As with any relative statistic, care must be given in reviewing the computed values of the PMAE and PBIAS statistics because a simulated output with small mean can result in deceivingly high computed values for these statistics (i.e., a large percentage of a small value).

Coors Opinion 16 *- The third additional metric to apply is the Log NSE. Applying a log transformation to values in the NSE formula, shown in Eq (4), reduces parameter sensitivity to extreme high values and increases sensitivity to low flow conditions. (page10).*

Response:

As discussed in the response to Coors Opinions 13 and 14, the LRG modeling in this case should not be focused on drought conditions or low flow conditions because the claims and counterclaims by the states implicate Project operations and deliveries at all levels of supply, and in any event, the low monthly streamflows and diversions are typically the result of (a) normal partial month operations rather than dry conditions, or (b) months with no reservoir releases, typically in the non-irrigation season. In addition, the highly regulated nature of the Rio Grande Project insulates it from the more extreme flow variations that typically characterize unregulated river basins in the west. While the Log NSE can be useful in emphasizing the match of low flows, this is not necessary and indeed is undesirable in evaluating the LRG modeling for the aforementioned reasons.

In reviewing the implementation of the Log NSE statistic in the backup spreadsheets disclosed by Mr. Coors, it was discovered that he did not adjust his computations to consider a common issue associated with log transforming very small numbers. The equation for computing the Log NSE is shown below.

$$Log\ NSE = 1 - \frac{\sum_{i=1}^{n}(logx_{io} - logx_i)^2}{\sum_{i=1}^{n}(logx_{io} - log\bar{x}_o)^2}$$

n = number of stress periods
$x_i = modeled\ value$
$x_{io} = observed\ value$
$\bar{x}_o = mean\ of\ observed\ values$

The numerator of the above equation computes the sum of the squared differences between the log of the observed value and the log of the modeled value. The log of zero is negative infinity and the log of a small number approaching zero becomes a very large negative number. Therefore, the computed value of the numerator in the Log NSE equation can become inappropriately dominated by a few very small flows. This is what happens in Mr. Coors' application of the Log NSE equation to the simulated results of Run 1 of the ILRG Model. The RiverWare Model, like other computer models, sometimes computes a very small number for what is effectively a zero flow. When the log of that very small number is computed in the Coors spreadsheet, the result is a relatively large negative number that dominates the numerator in the Log NSE equation when squared[4]. In order to avoid this issue, it is typical in computing log transformed values to either (a) exclude flows lower than a certain threshold from the computations, or (b) to add a nominal amount to all flows (e.g., 100 AF) to avoid the computational issues described above. As described above, Mr. Coors did not make this important adjustment when computing the Log NSE statistics that he presented in his report.

It was also noted that the Log NSE equation presented in the Coors Report is incorrect. As shown in the above equation, the opening parentheses in the numerator and denominator should be placed after, rather than before, the summation character.

Coors Opinion 17 *- The three metrics used by the New Mexico experts and the three additional metrics described above are applied at 26 locations in the model. These provide*

[4] For example, the flow computed by the RiverWare Model in Run 1 (v106) for the Acequia Madre in October 1956 is 2.095 x 10^{-29}. The log of this value is approximately -29 and when squared, the result is 841.

a much more robust and representative set of locations to assess how well the model represents Project operations throughout the basin on a monthly basis. (page 11).

Response:

An important consideration for determining the locations for evaluating model calibration is whether the simulated flows at those distinct locations are important to the functioning and proposed uses of the model. In reviewing the locations selected by Mr. Coors for evaluating the calibration of the ILRG Model, it appears that many of the locations were selected just because there were historical data available to compare to the modeled values. In particular, eleven of the locations selected by Mr. Coors are drain flow sites. Drains are important features in the ILRG Model because they are significant areas for the interaction of ground water and surface water. The effects of surface water irrigation and ground water pumping are realized, in part, in the model by impacts on drain flows that in turn affect Rio Grande flows. However, when evaluating the drain flows from a particular area (for example the Mesilla Valley) it is more important to assess the combined flow of all drains rather than the flow of the individual drains. As long as the combined drain flow is reasonably simulated, it is not so important that one drain is simulated too high and another is simulated too low. By evaluating the calibration of flows at individual drains, Mr. Coors' calibration statistics give the appearance of very poor drain flow calibration. The calibration performance improves when the drain flows are reasonably aggregated.

In addition, the flows at several of the Rio Grande gages evaluated by Mr. Coors are relatively unimportant to the model functioning and uses. These include the flows at the gages below Leasburg Dam and below Mesilla Dam. The streamflows at these two gages typically are not a limitation on diversions because of the additional flows that are being delivered past the gages downstream to Texas and Mexico. Also, the Rio Grande at Island Station gage is not of great importance because the flow at this gage does not limit any of the simulated water uses. Most of the surface water in this area is moving through the irrigation systems of EPCWID and JID and not in the Rio Grande.

Finally, the spatial scale of the data for use in modeling the LRG Basin is also important. **Table 23-1** summarizes the spatial scale of the major input data for the ILRG Model.

After reviewing the list of 26 locations evaluated by Mr. Coors and considering the model processes and intended model uses, the following individual and combined locations for evaluating the calibration and tuning of the updated ILRG Model were used:

River Gages
Caballo Reservoir Outflow
Rio Grande at El Paso
Rio Grande at Fort Quitman

Drains
Rincon Valley Drains
Mesilla Valley Drains
El Paso Valley Drains

FHG Deliveries and Pumping
EBID
EPCWID
HCCRD

Diversions
Rincon Dam
Leasburg Dam
Eastside Canal
Westside Canal
American Canal
Riverside Canal
Franklin Canal
Acequia Madre
Total HCCRD Supply

The above individual and aggregated locations represent thoughtful consideration of the extent to which historical and simulated flows are effectively aggregated in their simulated interactions, as summarized below:

- Rio Grande Flows – Releases from Caballo Reservoir and the flows at the El Paso and Fort Quitman gages are most important. The flows at the Rio Grande gages between the Caballo outlet and El Paso are less important because the river typically does not dry up at these locations, and therefore the simulated flow at these gages does not limit diversions of Project water. The flow at the Rio Grande gages between El Paso and Ft. Quitman is of less significance because most of the surface water is delivered through EPCWID and JID irrigation systems rather than the Rio Grande in this area.
- Diversions – Diversions are assessed at each of the major river headgates in the study area and at the Franklin and Riverside Canal gages in EPCWID.
- FHG Deliveries and Pumping – FHG deliveries are assessed for each District, consistent with the scale that the historical FHG delivery data are available. Because pumping is simulated to meet unmet demands after the FHG deliveries, pumping is also evaluated on a consistent District-wide basis. Note that irrigation pumping data is not available in the LRG Basin except for pumping in New Mexico starting in 2009. As result, simulated pumping in the Historical Base Run (Run 1) was compared to the simulated pumping in the Historical Calibration Run (Run 0).
- Drains – The flow of individual drains is generally less important than the aggregate flow of drains that collect flow from the major valleys. It is the aggregate total drain flow that contributes flow to the downstream users, and the

particular drain in which the flow arises is of little importance to the model simulation. Aggregated drain flows were assessed for the Rincon Valley, the Mesilla Valley, and the El Paso Valley.

The claim by Mr. Coors that the ILRG Model is poorly calibrated is based on his assessment of calibration using statistics that compare monthly modeled and observed data. This assessment does not consider whether matching of monthly flows is necessary given how the Project operates and how the results from ILRG Model will be used in this case.

Project water is allocated to the Districts and allotted to the farmers as irrigation season volumes that they can take delivery at their discretion. In general, it is reasonable to assume that water users took delivery of water to meet the needs of their crops, but they also likely considered bunching releases to minimize transit losses, prioritizing irrigation of certain crops at the expense of other crops, whether late season reservoir inflows were better saved for use in the next year, and other factors. It is generally not possible to develop simulation rules that exactly match the variable water ordering and reservoir release practices that existed during the simulation period. Fortunately, accurate matching of historical monthly releases and deliveries is not necessary in the ILRG Model because simulating too much delivery early and not enough delivery late, or vice-versa, just redistributes a similar seasonal volume of deliveries and similarly redistributes a similar seasonal volume of pumping to meet unmet demand.

The existence of stored Project water in Elephant Butte and Caballo Reservoirs is another important consideration in assessing the need for close matching of modeled and observed values on a monthly basis in the ILRG Model. This stored water is by far the largest source of surface water supply in the LRG Basin. The availability of stored water to the Project users has a buffering effect on the impacts of pumping and other actions on Project water supplies. This means, for example, that monthly depletions to surface flows from pumping can be buffered in the short-term by greater releases from storage to meet delivery demands until the available storage supply is exhausted (either the physical supply or the annual allocations). It would be unreasonable to use the model to compute injurious impacts on a monthly basis without consideration of whether water remained in the water user's account. The availability of supplemental wells can buffer the effect of monthly variations in Project supply

The foregoing considerations invite use of the ILRG Model to evaluate impacts on a seasonal basis rather than a monthly basis. This recognizes the important fungible nature of the timing of Project water use within the irrigation season. While aggregation of monthly model results to irrigation season totals is appropriate for analysis of impacts from pumping or other actions, aggregating model results into annual totals is generally not appropriate for evaluating diversions and deliveries of irrigation water supplies. Less usable flows occurring during the non-irrigation season are not a substitute for more useable flows during the irrigation season. This is consistent with Project accounting that is based on irrigation season allocations and deliveries, and water used outside of the irrigation season when the reservoir is not releasing is not considered or charged as Project water.

Given how the Project operates based on seasonal allocations, allotments, and releases as described above, it is appropriate to evaluate the ILRG Model calibration of diversions, FHG deliveries, and pumping using irrigation season totals. Reasonable matching of diversions goes hand in hand with reasonable simulation of river flows during the irrigation season. If there is not enough water is in the river, then the diversions can't be met, and if there is too much water in the river, then there will be too much water passing the American and International Dams. Therefore, the calibration of river flows was evaluated using annual totals to verify the model was reasonably matching the entire volume of the simulated flows that typically includes both reservoir releases and return flows in the irrigation season and return flows only during the non-irrigation season. Drain flows were also evaluated using annual totals.

Coors Opinion 18 *- It would be ideal to include model locations that were not used as calibration targets to assess the quality of the calibration process, but all of the locations that have observation data were used as calibration targets. It would have been more appropriate for the New Mexico experts to either leave some portion of every location's data for validation or some portion of the locations for validation, but this does not appear to have been done. (page 11).*

Response:

There is no broad consensus in the scientific community for excluding a portion of the historical study period from the model calibration, and to use the excluded data to validate the calibration. Some advocate that validation is useful and a good test of a model. Others argue that using all available information for calibration produces a better model (Konikow and Bredehoeft, 1992).

In this case, the ILRG Model is being used mostly to analyze the past, so it makes sense to use all available historical data to calibrate the model. Further, the historical data contain a representative variety of hydrologic conditions ranging from full supply years with relatively little pumping demand to low supply drought periods requiring large pumping volumes. The range of conditions during the historical calibration period generally encompasses the range of conditions that would be expected to occur in any of the conditions that are simulated in alternative scenarios. Therefore, it is reasonable to use all available data to calibrate the ILRG Model.

Coors Opinion 19 *- The results from the statistical analysis demonstrate that the Historical Base Run fails to accurately model historic Rio Grande Project conditions throughout the basin. The more robust and appropriate statistical parameters and list of locations introduced in this report provide a more accurate assessment of the quality of the Run 1 calibration process, and how well Run 1 simulates historical Project operations. (page 12).*

Response:

For the reasons described above, including the use of monthly calibration statistics applied to needlessly disaggregated locations, the calibration assessment presented by Mr. Coors is not appropriate for evaluating the utility of the ILRG Model for assessing the claims and counterclaims in this case.

The calibration and tuning assessment presented in Section 28.0, which includes calibration statistics computed using irrigation season and annual flows, and visual comparisons of simulated and observed values, is more representative of the capabilities of the ILRG Model in simulating conditions during the historical study period than the assessment presented by Mr. Coors. The calibration evaluation described in Section 28.0 provides confidence that the ILRG Model simulations of alternative scenarios are reasonable and can be relied upon in analyzing the claims and counterclaims in this case.

Coors Opinion 20 *- The ME parameter and the ME as Percent of Monthly Mean values reported by New Mexico experts give the appearance of a good fit. However, this metric only characterizes bias in modeled values at calibration target locations. When this metric is applied to a more comprehensive and representative set of locations, a significant bias in modeled values is shown. The average absolute value for the ME as Percent of Monthly Mean is 19% with values for four drains being nearly 50% and higher. The Rio Grande at Island Station gage shows a 55.1% value. This indicates an unacceptable level of bias throughout the model. (page 12).*

Response:

As discussed in more detail in Section 28.0 and shown in **Table 28-1**, the Mean Error and PBIAS statistics applied to a more representative set of locations or aggregated locations using irrigation season and annual totals demonstrate much better performance of the ILRG Model than indicated by the assessment presented by Mr. Coors. The PBIAS is less than 5% at the Caballo outlet and the Rio Grande at El Paso (very good), less than 10% at the canal gages (good to very good), and 16% or less for the aggregated drains (not satisfactory to very good).

***Coors Opinion 21** - The MAE parameter indicates significant uncertainty in the modeled values. The MAE as Percent of Monthly Mean values range from 28% to 121% of the observed monthly mean at the analyzed locations. The average value of this quantity for all 26 locations is 52.7%. This means that on average across all of these locations in the model, the monthly modeled values are over 50% off from observed values at these locations. This indicates an unacceptably high level of uncertainty in the monthly values across the whole model. (page 12).*

Response:

The MAE and PMAE statistics for locations selected by the New Mexico experts show better model performance when computed using irrigation season and annual totals rather than the monthly values used by Mr. Coors. The PMAE for most locations ranges from 6% to 36% with most values less than approximately 20%. This represents reasonable model performance given the size and complexity of the Rio Grande Project and irrigation systems in the LRG Basin. In addition, the graphs in **Figure 28-1** through **Figure 28-21** that are discussed in Section 28.0, demonstrate satisfactory to excellent performance in reproducing the monthly, seasonal, and long-term patterns of the historical data.

***Coors Opinion 22** - According to the NSE rating criteria created by Ritter, Axel, and Rafael Muñoz-Carpena (2013) three of the 26 locations analyzed perform at a satisfactory level. The average NSE value across all locations is 0.41 which is unsatisfactory. There is one location that has a NSE value that is negative. This means that the historical mean value is a better representation than what the model simulates. This also indicates an unacceptably high level of uncertainty in the monthly values across the whole model. (page 12).*

Response:

As discussed in the response to Coors Opinion 12, there is no consensus in the scientific community for what for what constitutes a satisfactory NSE value. However, according to the criteria proposed by the ASABE contained in Moriasi et al. (2015), an NSE greater than 0.50 is considered satisfactory. All but one of the 21 seasonal or annual NSE values shown in **Table 28-1** for the ILRG Model exceed 0.50, and all but seven exceed the 0.65 threshold advocated by Mr. Coors.

The only NSE value less than 0.50 is for the aggregated Rincon Valley drain flows which on average after 1950 flowed less than 15,000 AF/y.

Coors Opinion 23 *- Applying the same performance criteria to the Log NSE parameters only three of the 26 locations perform satisfactorily. Because the Rio Grande at El Paso is one of the calibration targets used during the operational tuning, this location and its associated calibration metrics have limited value in characterizing the quality of the calibration of the model. There are seven locations that have a Log NSE value that is negative including Caballo Reservoir Outflow which is discussed further in section 6.1.2.1, below. This is a clear indication of an unacceptable amount of uncertainty in the model. The fact that the log NSE indicates worse performance than the NSE says that the model does a particularly poor job of representing lower flow values. (page 13).*

Response:

See the response to Coors Opinion 16. While the Log NSE statistic is generally inappropriate for evaluating the ILRG Model performance because there is no need to emphasize performance at low flows, the Log NSE statistics computed for seasonal and annual values shown in **Table 28-1** show satisfactory to good performance for most locations.

Coors Opinion 24 *- Figures showing the calibration results graphically as scatter plots for all locations are found at the end of the report (see Section 9). (page 13).*

Response:

Mr. Coors included residual plots and scatter plots for the 26 locations that he selected for evaluating the calibration of the ILRG Model in Section 9 of his report. However, Mr. Coors did not offer any opinions regarding these graphs and therefore there are no opinions regarding these charts to rebut.

The presentation of the calibration and tuning results for the updated ILRG Model in Section 28.0 includes numerous graphs comparing modeled results against historical observed data. These charts, which are described in Section 28.0, are further evidence of the overall excellent performance of the updated ILRG Model.

Coors Opinion 25 *- The Caballo Outflow calibration metrics are particularly problematic. Caballo releases are arguably the most important Rio Grande Project operation that the model needs to replicate in the Historical Base Run (page 13).*

Response:

The calibration statistics in **Table 28-1** for the Caballo Outflows in the updated LRG Model show a small PBIAS of 0.1% and an excellent NSE value of 0.93. The monthly and annual graphs of modeled and observed values in **Figure 28-1** demonstrate that the simulated releases reasonably match the amounts and patterns in the historical data. This is evidence of excellent functioning of the RiverWare Model rules that simulate historical Project allocations and releases.

Coors Opinion 26 *- For New Mexico's claim that Project operations are reasonably simulated in the model to be true, the model must demonstrate the ability to, with rules, simulate releases of Project water that are a good representation of how the Project is actually operated. The ability of the ILRG model to meaningfully represent Project operations determines its capability to model hypotheticals, which in turn determines its ability to determine impacts. The Log NSE for this parameter is a problem at -.07. A negative Log NSE value means that the historical (observed) mean for the entire run period would be a better representation of monthly releases from Caballo than what RiverWare produced with its rules (Krause, P., et al). The unacceptable performance of the Caballo Outflow parameter in RiverWare means that the "operationally tuned" RiverWare model is not a reliable simulator of Project operations on a monthly scale and cannot be relied upon to provide accurate what-if analyses of hypothetical scenarios. (page 13).*

Response:

As discussed in the response to Coors Opinion 25, the ILRG Model performance in simulating Caballo Outflows is excellent. While the Log NSE statistic is generally inappropriate for evaluating the ILRG Model for the reasons discussed in the response to Coors Opinion 16, the Log NSE statistic was included among the performance measures presented in **Table 28-1** for comparison to the calibration statistics presented in the Coors Supplemental Report. When computed using simulated and observed annual Caballo releases, the Log NSE performance score for Caballo Outflows is very good at 0.93.

Coors Opinion 27 *- Though this figure (and the others like it) is never referenced by Hydros in the Tech Memo 4, presumably it is being presented to demonstrate that EBID project river diversions are being captured adequately by the rules. This is incomplete. These values have been aggregated significantly, both temporally and spatially. The model is monthly and the New Mexico experts assert that the system must be modeled monthly to be viable. The values in the plot are annual. (page 14).*

Response:

As discussed in the response to Coors Opinion 8, while it is important to model the system using monthly stress periods, the performance of the ILRG Model should be assessed primarily based on the degree that it reasonably simulates Project operations, irrigation operations, and surface water flows using irrigation season or annual totals. Visual comparison of model results on a monthly basis confirms that the simulated flows generally follow the monthly patterns in the observed data, particularly during the irrigation season.

Thoughtful spatial aggregation of ILRG model results for assessment of ILRG calibration is appropriate in consideration of how the Rio Grande Project operates and how water is delivered for use. For example, there is little sense in criticizing the model calibration of individual drains when those drain flows join together before the next downstream diversion.
