OVERVIEW OF THE QUALIFICATIONS OF DR. MARGARET (PEGGY) BARROLL

My name is Margaret ("Peggy") Barroll, Ph.D. I have been retained by the New Mexico Office of the Attorney General by and through the New Mexico Interstate Stream Commission (collectively, the "OAG") to opine on Rio Grande Project operations and accounting over time, including specifically the effects on Project allocation and operations of the 2008 Operating Agreement.

I provide consulting services specializing in hydrogeology focused primarily on my areas of expertise, the Rio Grande and Pecos River basins. Prior to my consulting work, I spent 26 years as a Senior Hydrologist for the State of New Mexico employed by the Office of the State Engineer ("NMOSE").

During my tenure at the NMOSE, I was a principal scientist in the development of MODFLOW groundwater models. Two of the models I have been deeply involved with are the Carlsbad Groundwater Model and the LRG_2007 Groundwater Model ("LRG" is an acronym for "Lower Rio Grande," as that portion of the Rio Grande river basin is known in New Mexico). Each of these models encompass large United Stated Bureau of Reclamation ("Reclamation") surface water irrigation projects: the Carlsbad Project and the Rio Grande Project. Notably, I was one of the developers of the LRG_2007 Groundwater Model, which is the basis for the groundwater model presented by Texas through their expert, Dr. William Hutchison (and as sanctioned by the U.S. through their expert Jean Moran of Stetson Engineers, Inc.).

My professional involvement with Lower Rio Grande issues within the States of New Mexico and Texas began circa 2000 and continues to the present. This work has involved the following:

- Groundwater modeling of the Lower Rio Grande aquifer system in New Mexico,
- Technical support for the development of administrative guidelines for water rights administration,
- Development of Active Water Resource Management ("AWRM") Rules,
- Analysis of groundwater level data both spatially and temporally,
- Trend analyses of groundwater pumping meter data,
- Numerous field visits to the Rio Grande Project in both New Mexico and Texas generally for the purposes of identifying and inspecting critical infrastructure and observing farm management practices,
- In-depth review of Rio Grande Project records relating to Project allocation, accounting, operations, and history,
- Quantitative analysis of Rio Grande Project allocation and accounting, compilation of Project allocation and accounting data from numerous disparate sources, and analysis of that data,
- Simulation of Rio Grande Project allocation through spreadsheet models.

My professional resume and publications from the last 10 years is attached as Section 12 to this report. Over the previous 4 years, I have not been a witness testifying as an expert at trial or by deposition. For the consulting services I am providing to the OAG, my compensation rate is $280 per hour for both expert report preparation and for any testimony I may give. My compensation is not dependent on the outcome of this litigation or the substance of my opinions.

INTRODUCTION TO REPORT

In this Report I explain the origins of the issues that have arisen over the past few decades between Reclamation, the State of New Mexico and the State of Texas over the management of the Rio Grande Project, and the practical results of actions taken by the parties involved that have led to the current litigation. Texas and the United States, through their pleadings and expert reports, make the disputed issues between the parties seem deceptively simple; they claim merely that New Mexico groundwater pumping hurts Texas. This is not the whole story, nor even the primary story of the Rio Grande Project operations and accounting issues between these three parties.

Because the actual issues involved are very complex and technical, I have arranged this Report to first generally educate the reader about how the Rio Grande Project operates, then delve more deeply into the technical issues that drive the Project and that led to dispute between New Mexico and Texas.

In Sections 1 through 5 I give overviews of the primary elements of the Rio Grande Project. Understanding how all these parts work together is necessary to comprehend the technical allocation and accounting issues I explain in Section 6. In Section 7 I describe the fundamental flaw in accounting calculations that contributes in large part to the current disputes. In Section 8 I quantify how current practices by Reclamation and Texas adversely impact New Mexico. Finally, in Section 9 I explain how the actions of Reclamation and Texas harm the Rio Grande Project as a whole, and lead to an unsustainable situation.

I have been involved in investigating and exploring these issues since 2000; I have conducted extensive research and analysis of historic and current data and I am intimately familiar with the history of Rio Grande Project operations. As described above, I was one of the developers of the computer model upon which Texas constructed the model it uses in this litigation.

Since 2000 I have been involved in discussions and negotiations with all the Reclamation, Texas, and New Mexico notable persons involved in management of the Rio Grande Project, both to understand the issues and to try to resolve problems as they arose. Some of the problems we have been able to resolve; for instance, in the early 2000s New Mexico demonstrated to the satisfaction of Reclamation and Texas that the significant salinity problems faced by the El Paso Valley were a natural phenomenon and not the result of any actions by New Mexico. Other problems remain, including problems related to present inequitable allocation of Project Supply between the New Mexico irrigation district ("EBID") and the Texas irrigation district ("EPCWID"), and the negative impacts to the groundwater systems underlying the entire Project and upon which citizens of both states rely.

Conclusions

Based upon my years of direct experience with the issues presented in this case, and the significant research and analysis I have undertaken at the request of the OAG, I have reached the conclusions below and support them with the following Report.

1. The Rio Grande Project 2008 Operating Agreement has greatly reduced the surface water supply to New Mexico farmers, to the detriment of New Mexico. Texas, however, has benefitted by the 2008 Operating Agreement through an increase in the allocation of water to its irrigation district, and because that district can now carry over large amounts of unused allocation from one year to the next.

2. The Rio Grande Project began delivering Project water in 1915. The two water Districts: Elephant Butte Irrigation District ("EBID," in New Mexico) and El Paso County Water Irrigation District No. 1 ("EPCWID," in Texas), were formed in the 1920s. The Rio Grande Compact was signed and took effect in 1938. From the beginning of Project Operations, each Project acre was entitled to the same delivery of water.

3. A 1938 Contract between the Districts sets forth a division of Project water supply between the Districts in accordance with the proportions of Project acreage: 88,000 of 155,000 Project acres (57%) to EBID, and 67,000 of 155,000 Project acres (43%) to EPCWID. From 1938 through 1978, Reclamation operated the Project so that EBID farmers were entitled to 57% of the U.S. share of Project Supply and EPCWID farmers were entitled to 43% of the U.S. share of Project Supply.

4. Starting in 1979, Reclamation explicitly allocated Project Supply to the Districts in the ratio of 57% to EBID and 43% to EPCWID. The total amounts allocated were defined using the D1/D2 Curves. The amounts of water diverted by the Districts and delivered to their farmers were consistent with this 57:43 ratio.

5. In 2008 an Operating Agreement (the "2008 OA") was reached between Reclamation, EBID, and EPCWID without the involvement or approval of New Mexico, Colorado, or the Rio Grande Compact Commission, except for the participation of the Texas Compact Commissioner as a mediator.

6. The 2008 OA adopts the D3 Allocation method which was proposed by EBID in 2006 and implemented in 2006. Under the D3 Allocation, EPCWID and Mexico are allocated Project water based on Project performance during the 1951 – 1978 period (the D1 and D2 Curves), and EBID is allocated whatever Project water is left over.

7. The 2008 OA also adopts "Carryover" (proposed in 2006 by EPCWID and partially implemented that year), so that unused allocation remaining to a District at the end of one year can be carried over intact to that same District the following year.

8. The effect of D3 Allocation, Carryover, and the 2008 OA has been to change the allocation of the U.S. share of Project water so that EPCWID is now allocated an average of 56% (not including Carryover) or 62% (including Carryover). EPCWID's actual charged diversions (that is, water actually called for, received, and charged to the District) during this period (2008-2018) have averaged 55% of total District charged diversions.

9. The D3 Allocation as initiated in 2006, has reduced EBID's full-supply allocation and the amount of water Reclamation has delivered to EBID in full-supply years by approximately one-third (1/3). EBID's full-supply allocation has dropped from 495,000 AF to less than 330,000 AF. Implementation of D3 Allocation in 2006 caused EBID's diversion in full-supply years to decrease from an average of 464,000 AF (in 1996-2002) to an average of 312,000 AF (2007-2009).

10. By contrast, the D3 Allocation and Carryover under the 2008 OA has actually increased EPCWID's full-supply allocation of water to levels not historically contemplated. EPCWID's current-year allocation (that is EPCWID's allocation apart from Carryover) in full-supply years has increased from 377,000 AF to an average of 391,500 AF. EPCWID's total allocation (including Carryover) has exceeded 500,000 AF in some years.

11. EPCWID Charged Diversions (that is, water actually called for, received, and charged to the District) in full-supply years under the 2008 OA have averaged less than 300,000 AF, leaving large amounts of unused, unneeded allocation which is "placed" in its Carryover account. One of the reasons EPCWID's Charged Diversions are as low as they are is because current Project accounting does not charge ECPWID for their diversion and use of municipal treated effluent generated in the El Paso Valley by the City of El Paso.

12. The D3 Allocation as initiated in 2006, and then set forth in the 2008 OA, reduces EBID's allocation to account for all negative departures from historical (1951 – 1978) Project performance. This allocation method is based on the assumption that all of the negative departures from historical performance are caused by New Mexico. However, a significant part of that negative departure in Project performance is caused by changes in Project accounting that have occurred since the 1951 – 1978 historical period. In addition, part of the negative departure in Project performance is caused by the effects of depletions and groundwater pumping in Texas and Mexico.

13. Since the advent of D3 Allocation and the 2008 OA, in many years EPCWID has been allocated amounts of water significantly greater than the amounts that District orders and diverts.

14. The 2008 OA has reduced EBID's share of Project supply during full-supply years below the amount needed to supply EBID's lands. As a result, EBID farmers have increased groundwater pumping.

15. The reduction in EBID's share of Project water has reduced the amount of recharge to the aquifer in the Rincon and Mesilla Valleys through canal seepage.

16. Between the increase in groundwater pumping and the decrease in recharge, the groundwater budget of the Rincon and Mesilla aquifer system has been negatively impacted by more than 100,000 AF/Y in full-supply years. Historically, shallow groundwater levels in the Rincon and Mesilla Valleys responded to surface water supply variation; groundwater levels dropped during times of low supply, and recovered in full supply years. Following implementation of D3 Allocation, shallow groundwater levels have dropped during low supply years, but have not recovered in the full supply years that follow.

17. The Project enjoyed full-supply conditions from 1979 through 2002, and EPCWID was allocated a full supply in each year. EPCWID diverted less than it was allocated in all but two of these years. Available Reclamation records do not suggest that EPCWID ordered water that it did not receive. Therefore, I conclude that EPCWID needed less water than it was allocated during this period.

18. Starting in the year 2003, EPCWID has received an allocation credit for the American Canal Extension ("ACE"). The ACE credit increases EPCWID allocation by up to approximately 20,000 AF. Under the allocation method in the 2008 OA, this same amount (up to ~20,000 AF) is subtracted from EBID's allocation, reducing EBID's total allocation and the amount EBID can order.

19. Because of the decrease in EBID's allocation under D3 Allocation, and because EPCWID is now allocated more water than it diverts in full-supply (or near full-supply) years, EPCWID makes much more use of Carryover than EBID. EPCWID has had a large Carryover account in several years.

20. EPCWID's Carryover account includes the effects of Project credits, some of which do not represent water left in reservoir storage. Carryover accounts are not reduced to account for evaporation. As a result, some amount of water in EPCWID's Carryover account is not associated with actual "wet" water. The amount of allocation carried over, and the extra water needed to deliver the Carryover, is subtracted from Usable Water before any new allocation is made. Therefore, part of the inflow to Elephant Butte is not available for allocation, but instead is used to support and fulfill EPCWID's Carryover account. This has had a significant negative effect on EBID's allocation.

21. Reclamation releases water from Caballo Reservoir in response to orders from the Districts and the Mexican delivery schedule. The amount released from Caballo is determined by combining those orders with current information on river gains and losses and on available drain flow. This calculation determines the amount of release from Caballo Reservoir which, when added to the amount of water already present at diversion headings from other sources, is equal to the District order at each heading. In full-supply years, any increase in drain flows or decrease in river losses would cause Reclamation to release less water from Caballo release in order to meet the existing orders, and there would not be any increase of flow to EPCWID. The assumption that any increase in drain flows would result in an immediate equivalent increase in the flow every year at Courchesne/El Paso is a fallacy. The reduction in Caballo release could, however, have an impact on the available supply in future low-supply years.

RIO GRANDE PROJECT ALLOCATION AND ACCOUNTING

1 OVERVIEW OF THE RIO GRANDE PROJECT

1.1 RIO GRANDE PROJECT BEGINNINGS

In 1905 Congress authorized the Bureau of Reclamation of the U.S. Department of the Interior ("Reclamation") to construct the Rio Grande Project ("Project") to provide irrigation water in southern New Mexico and western Texas, and also to address international water issues with Mexico. The first deliveries of Project water to irrigators were made by Reclamation in 1915.[1] A graphic of important Rio Grande Compact and Project Dates is in Appendix F.

In the 1920s, the Elephant Butte Irrigation District ("EBID") and the El Paso County Water Irrigation District ("EPCWID") (together, the "Districts")[2] were organized to manage water resources in their respective geographic regions and to enter into contracts to repay the United States for costs to construct the Project. In 1938, EBID and EPCWID entered into a contract (the "Inter-district Contract")[3] that allocated the Project's irrigated acreage between the two entities; this contract also assessed the District's proportional cost of repayment to the United States. The contract recognizes EBID authorized Project acreage of 88,000 acres and EPCWID authorized Project acreage of 67,000 acres for a total of 155,000 acres within the United States, and provides for each District to increase its authorized acreage by up to 3%. The Inter-district Contract states:

> *It is further agreed and understood that in the event of a shortage of water for irrigation in any year, the distribution of the available supply in such a year, shall so far as practicable, be made in the proportion of 67/155 thereof to the lands within El Paso County Water Improvement District No. 1, and 88/155 to the lands within the Elephant Butte Irrigation District.*

1.2 OVERVIEW OF GEOGRAPHY AND GROUNDWATER SYSTEM

The Project encompasses an area in southern New Mexico and west Texas that includes Elephant Butte and Caballo Reservoirs, EBID in the Rincon and Mesilla Valleys, and EPCWID in the Mesilla Valley and extending into the El Paso Valley, below Tornillo, Texas (see Figure 1.1). Downstream of EPCWID is the

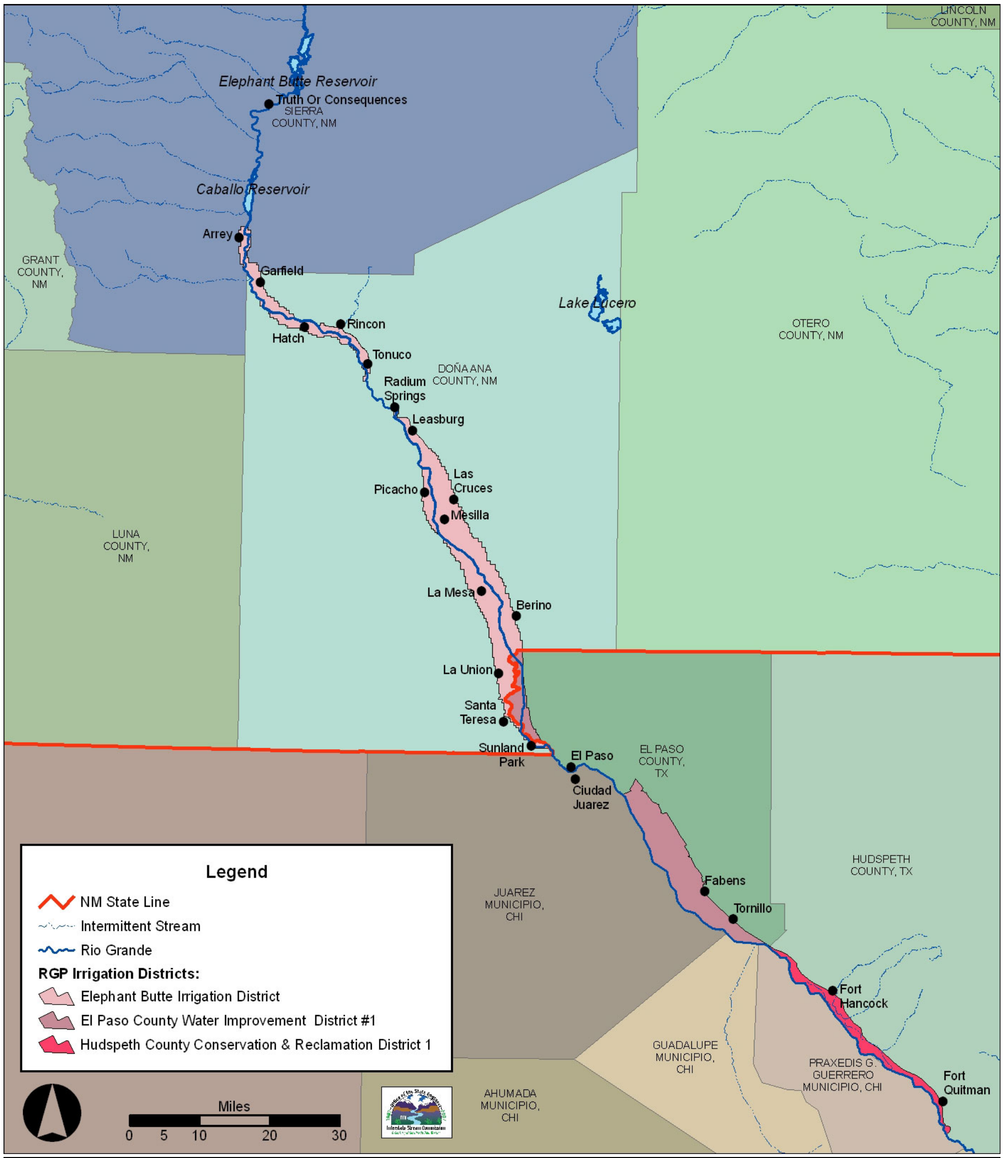
Hudspeth County Conservation and Reclamation District #1 ("HCCRD"), which is not part of the Project. HCCRD receives operational waste from the Project under contract.

Figure 1.1. General location of the Rio Grande Project



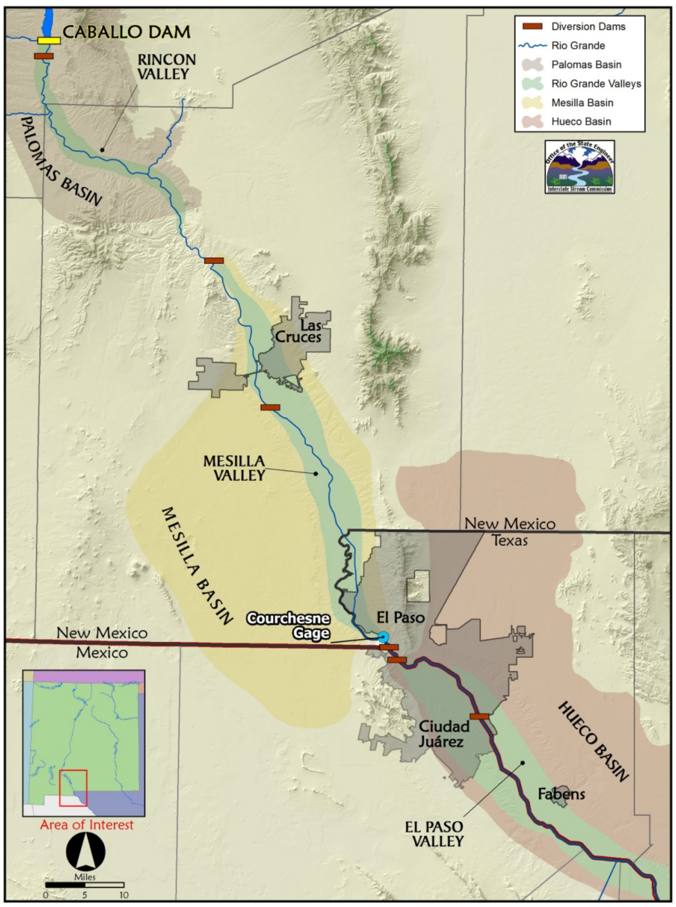
Geographically speaking, the Project area comprises portions of three river valleys along the Rio Grande (Figure 1.2):

1) The Rincon Valley extending from below Caballo Dam to Seldon Canyon,
2) The Mesilla Valley, extending from below Seldon Canyon to the El Paso Narrows, and
3) The El Paso and Juarez Valley (El Paso Valley) extending from below the El Paso Narrows to approximately Fort Quitman, downstream of EPCWID.

These river valleys are relatively narrow, often less than five miles from side to side, and are underlain by approximately 100 feet of river valley alluvial sediments, laid down by the Rio Grande itself over the last million years or so. This river valley alluvium is highly transmissive, which is to say that wells drilled into these sediments can produce large amounts of water. The river valley alluvium composes an important part of the aquifer system that supplies groundwater in the Project area.

Geographically, these river valleys are located within larger sedimentary basins, which were formed and filled with sediments over tens of millions of years. The Rincon Valley is within the much larger Palomas basin, the Mesilla Valley is within the larger Mesilla basin, and the El Paso Valley is within the larger Hueco basin (also known as the Hueco Bolson).

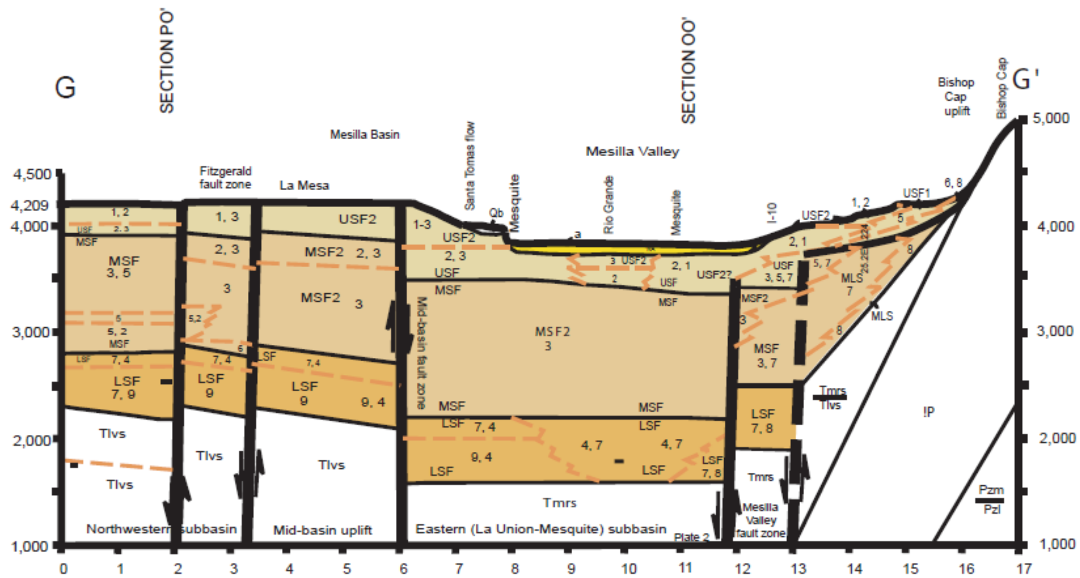
Figure 1.2. River Valleys and Sedimentary Basins within the Project Area



These basins extend over much larger geographic areas than the river valleys, and are very deep, filled with thousands of feet of sediments that are known as the Santa Fe Group. The river valley alluvium overlies the Santa Fe Group sediments within the river valleys. Both the Mesilla basin and Hueco Bolson contain very transmissive Santa Fe Group sediment, and there are deep wells (~1000 feet deep) in these basins that obtain water from the Santa Fe Group. The Santa Fe Group sediments in the Palomas basin are significantly less transmissive, and so wells in the Rincon Valley tend to be relative shallow (on the order of 100 feet deep), since they can only obtain water from the river valley alluvium.

The aquifer system is geologically and hydrologically fairly complex. Figure 1.3 is an example of an east-west cross-section of the alluvial aquifer system in the Mesilla Basin, which shows some of that complexity.

Figure 1.3. Sample East-West Cross Section of LRG alluvial aquifer system in the north-central Mesilla Basin from Hawley and Kennedy, 2004[4]



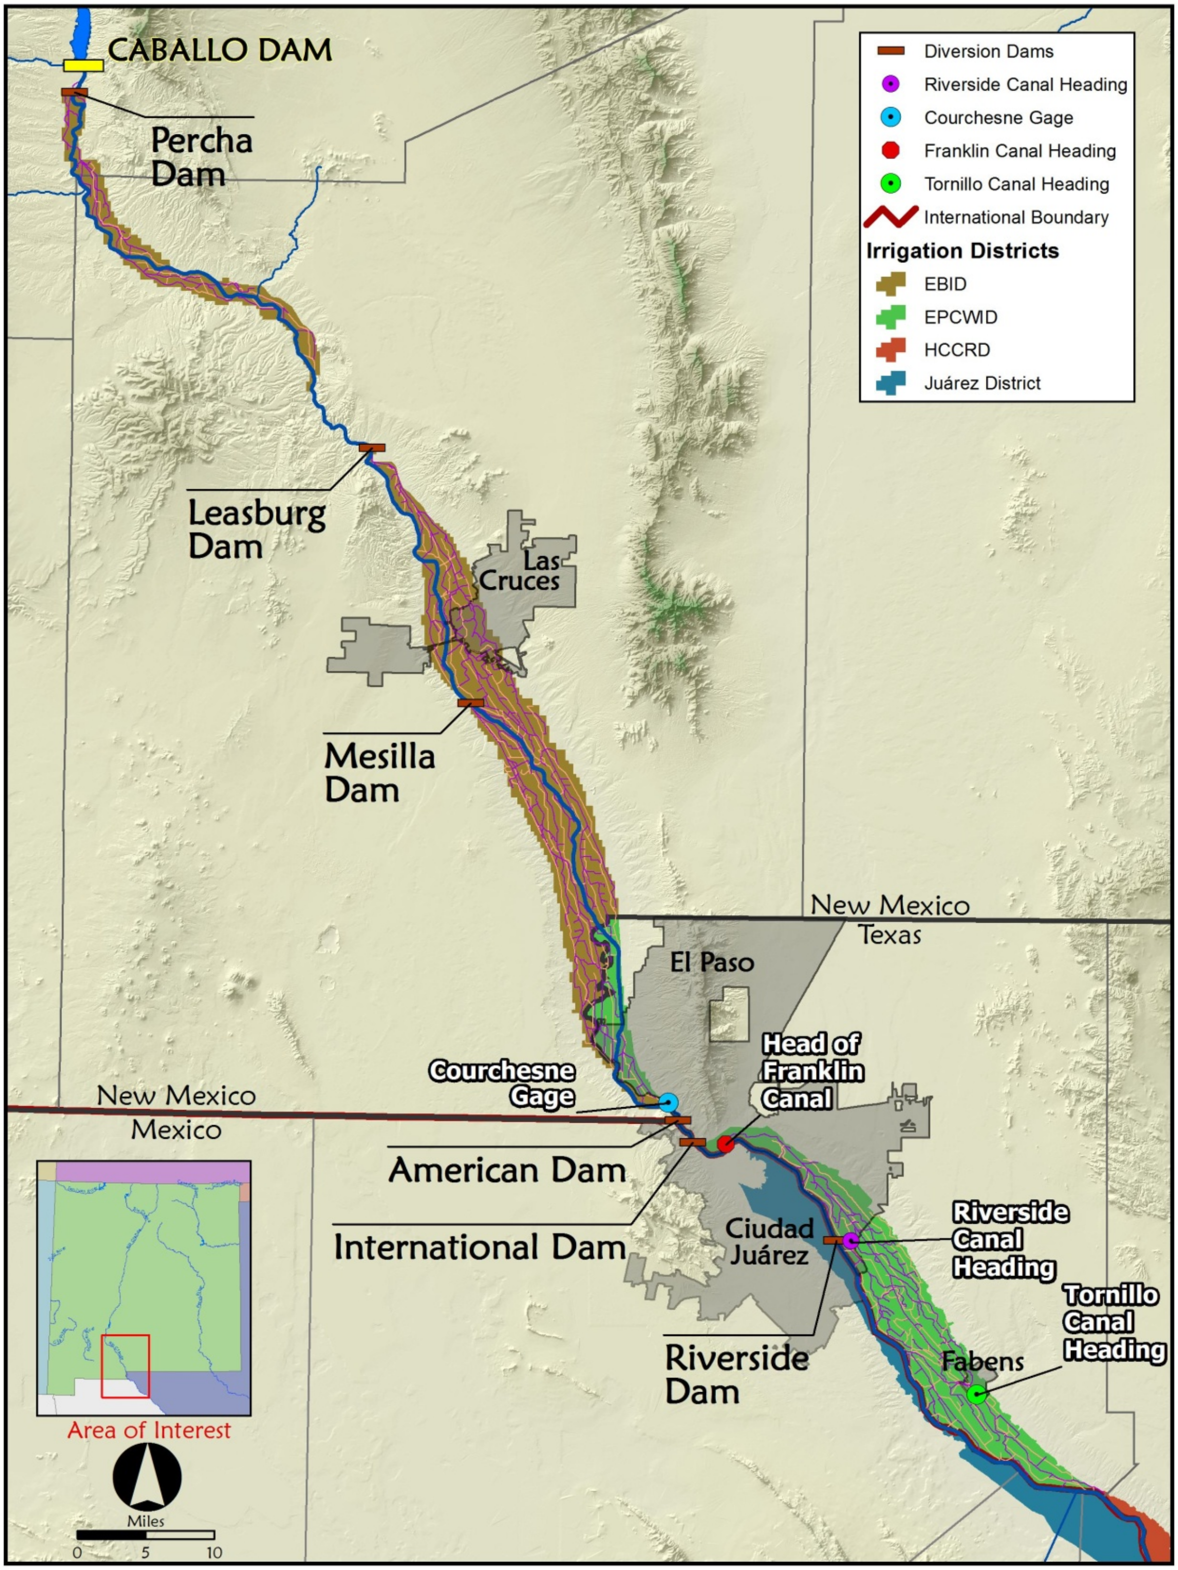
In Figure 1.3 the thin yellow area located under the "Mesilla Valley" label corresponds to the approximately 100 feet thick river valley alluvium, and the river itself is located on top of the river valley alluvium, near the center of the valley. Beige, tan and brown areas correspond to different sub-units of the Santa Fe group.

1.3 Current Description of the Rio Grande Project

The Project provides surface water for up to 155,000 acres of land in EBID and EPCWID. As recognized in the Inter-district Contract, approximately 57% (88/155) of the lands authorized to receive water directly from the Project are in New Mexico (EBID); while 43% (67/155) are in within EPCWID in Texas. Although municipal supply was not included in the original purposes of the Project, the City of El Paso now receives a substantial amount of its municipal supply from the Project through contracts with Reclamation and EPCWID. Figure 1.4 shows the general location of EBID and EPCWID, and the cities of Las Cruces, El Paso and Juarez, as well as the main diversion structures.

[4] Hawley, John and Kennedy, John, *Creation of a Digital Hydrogeologic Framework Model of the Mesilla Basin and Southern Jornada Del Muerto Basin*, WRRI Technical Report 332, New Mexico Water Resources Research Institute, June 2004. Plate 4.

Figure 1.4. Main Diversion Structures for the Project



The Project also serves as the means by which the United States provides water for diversion by Mexico to irrigate lands on the Mexican side of the El Paso Valley. Up to 60,000 acre-feet of water per year is also provided at Juarez, in accordance with the 1906 Convention between the United States and Mexico.[5]

Pursuant to Reclamation contracts, waste water from EPCWID Project lands can be used to irrigate about 18,000 acres in HCCRD, Hudspeth County, Texas.[6] The water delivered to lands in Hudspeth County is not part of the annual Rio Grande Project allocation, rather it is solely waste water and return flows from the Project.

Project water is stored in the Elephant Butte Reservoir and released at the Elephant Butte Dam (collectively, Elephant Butte) and also in the downstream Caballo Reservoir and Dam (collectively, Caballo). Once Project water is released from Caballo into the Rio Grande, it is conveyed in the bed of the Rio Grande to diversion dams along the river in New Mexico and Texas. *See* Figure 1.4. EBID diverts Project water from the Rio Grande at Percha and Leasburg dams in New Mexico to serve New Mexico farmers. EBID also diverts Project water from the Rio Grande at Mesilla Dam in New Mexico both to serve New Mexico farmers and to deliver water to EPCWID lands in the Texas part of the Mesilla Basin, north of El Paso.

The Project is naturally divided at the El Paso Narrows, which separates the El Paso Valley downstream from the Rincon and Mesilla Valleys upstream. The Courchesne stream gage ("Courchesne"; also known as the Rio Grande at El Paso stream gage) sits within the El Paso Narrows in Texas.[7] In the early decades of the Project the Project was organized in two branches: the Las Cruces Branch north of Courchesne, and the Ysleta Branch south of Courchesne.[8]

A couple of miles below Courchesne, the International Boundary and Water Commission: United States Section ("IBWC") diverts all the water in the river, except that needed to provide Mexico's water, and flood flows, at American Dam in Texas into the American Canal. EPCWID diverts water from the American Canal to deliver to farmers downstream in the El Paso Valley via the Franklin and Riverside canals. The El Paso Water Utilities ("EPWU") diverts Project water for municipal use from the American Canal and Riverside Canal. The IBWC diverts Mexico's portion of Project Supply at International Dam in accordance with an annual schedule. The water diversion and conveyance structures in El Paso area are portrayed in Figure 1.5.

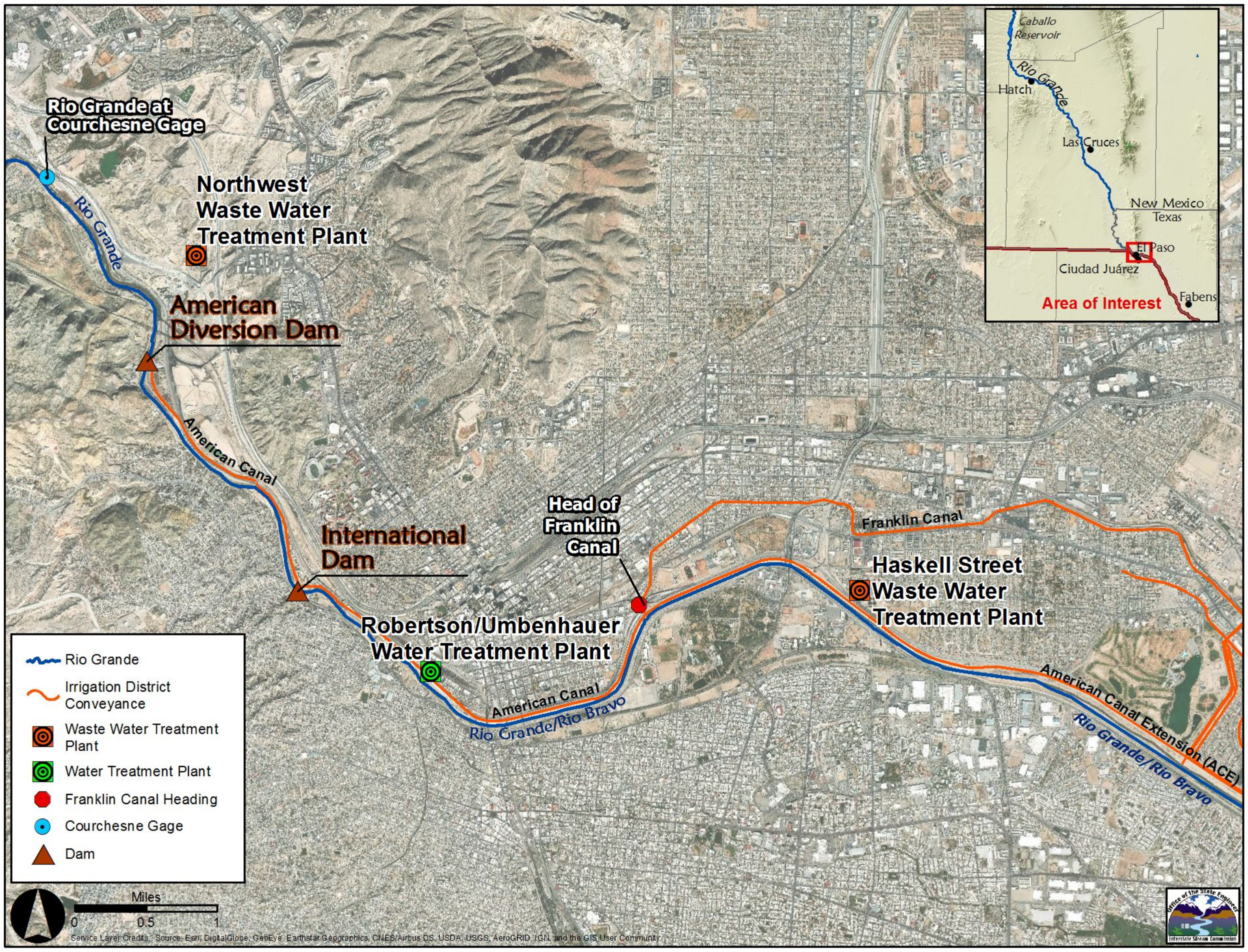
[7] A similar natural division takes place between the Rincon and Mesilla Valleys.

[8] Courchesne, depicted in Figure 1.4, is an important landmark because it generally marks the boundary between the Upper and Lower portions of the Project.

Figure 1.5. Detail Map of the El Paso Area showing Courchesne Gage, Diversion Dams, and El Paso Waterwater Treatment Plants



Reclamation's Rio Grande Project Office in El Paso, Texas, directs operation of Elephant Butte, Caballo, and Project diversion dams, and, together with EPCWID and EBID technical representatives, determines the allocation of Project Water. Current operations and maintenance of Project facilities within the EBID service area is conducted by EBID, while EPCWID operates and maintains the Project facilities within the Texas portion of the Project area.[9]

Elephant Butte and Caballo reservoirs store Project water, but not all of the water in these reservoirs is available to the Project. Only "Usable Water"[10] in Project storage, as defined by the Rio Grande Compact, is available for allocation and release by the Rio Grande Project.

---

[9] 2010 Operations Manual.

[10] "Usable water" is defined in the Rio Grande Compact as "is all water, exclusive of credit water, which is in project storage and which is available for release in accordance with irrigation demands, including

2 GENERAL INTRODUCTION TO PROJECT ALLOCATION, ACCOUNTING AND OPERATIONS

2.1 PROJECT ALLOCATION AND PROJECT ACCOUNTING

A detailed discussion of Project allocation and accounting follows in Section 6 and Appendix D.[11] A graphic of Key Time Periods in Rio Grande Project Allocation and Accounting is in Appendix F. The discussion herein is intended to generally introduce the concepts to provide context for other portions of this Report.

Project allocation refers to the amount of surface water each District is entitled to order each year, and the process and methods by which Reclamation determines those allocation amounts, as well as the amount Mexico is entitled to by Treaty. Historically Project allocation was based on equal delivery of water to each Project acre, with 57% of the U.S. share of Project Supply allocated to EBID, and 43% allocated to EPCWID. The current Project allocation method is set forth in the 2008 Operating Agreement, detailed in the associated Operations Manuals,[12] and is accomplished through an allocation spreadsheet. In general, each year the allocation process starts before the beginning of the irrigation season, and is updated monthly throughout the irrigation season to address increases in Usable Water or changes in hydrologic conditions.

Project accounting, on the other hand, is the process which tracks how much of the amount allocated to each District has, in fact, been diverted by the District and thus presumably used by the District. It is a post-fact calculation involving actual diversion data. The current Project accounting system was initiated in 1979 by Reclamation and basically charges District diversions against District allocations in accordance with a set of accounting rules, which include a systems of credits. In this report I will use the term "Charged Diversion" to refer to the net amount calculated from the diversions and credits assigned to that District and charged against that District's allocation.[13]

Prior to 1979, when Reclamation operated the entire system, it allotted and delivered water directly to individual farmers in both Districts. From 1979 forward, after the Districts took over ownership of the canals and laterals, Reclamation instead allocated water to the Districts, assuming equal delivery of water to each acre of Project land via the Districts, and delivered that water to District diversion

---

deliveries to Mexico", not including imported water such as water associated with the San Juan-Chama transmountain diversion." *See* Estevan Lopez Expert Report, 2019.

[11] The data underlying recitation of facts and my opinions in this Report are summarized and explained in the Appendices.

[12] Rio Grande Project Water Accounting and Operations Manual, 2008, and as amended in 2010 and 2012.

[13] Project Accounting records often refer to "Allocation Charges" which is generally equivalent to my use of "Charged Diversions."

headings when called for by the Districts. The allocation method developed for this new operational system is called the D1/D2 Allocation.

Beginning in 2006, and as formalized in the 2008 Operating Agreement between Reclamation and the Districts, Reclamation uses what is called the D3 Allocation method, which adds a component to the allocation method intended to penalize EBID for inefficiencies in the Project.

2.2 Project Operations

This section described the part of Project operations by which orders for Project water are fulfilled. The order and delivery process for the Project is described in more detail in Appendix B.

Prior to 1979 farmers ordered water directly from Reclamation, by making requests through Reclamation ditch riders for deliveries to farm headgates. Reclamation determined what releases and diversions were needed to fulfill those orders, released appropriate amounts of water from Caballo Reservoir, and then diverted water at appropriate canal headings. Reclamation ditch riders delivered the ordered water to individual farms. This process is described in detail in the Rio Grande Project Histories.[14] As part of this process, the necessary release from Caballo was calculated based on the sum of the water required at each Project diversion heading, adjusted for the estimated transit losses and "drainage flow" returns to the river above each diversion heading.

Since 1979 the order, release, diversion and delivery operational system is shared between the Districts and Reclamation. Reclamation determines Project allocations, takes orders from the Districts, releases water from the reservoir and makes deliveries to canal headings. The Districts take farm orders from their members, place orders to Reclamation for water to be delivered at canal headings, take delivery of that water and deliver to farm headgates. This operational system is generally described in a 1985 Draft Operating Agreement,[15] and also has been described by Reclamation and EBID personnel in numerous meetings.

During the irrigation season, on a regular basis, each District submits orders (in terms of cubic feet per second (cfs) at each of their canal headings)[16] to Reclamation. Reclamation releases from Caballo as much water as necessary to meet these District orders and supply the Mexican delivery schedule.

The release rate from Caballo is determined so that the sum of the return flows and other water present at each canal heading, plus water released from reservoir storage, will equal the Districts' orders at each canal heading. This is described in the 1985 Draft Operating Agreement as follows: "*The Bureau will tabulate and evaluate these orders, considering river losses or accretions … [and] notify the operating*

---

[14] Rio Grande Project Histories ("RGPH") were detailed annual reports prepared by Reclamation for the years 1912 through 1988. The information cited is found in RGPH 1943 (Daily Reports of Operations Divisions), pp. 53-65/366.

[15] 1985 Draft Operating Agreement for the Rio Grande Project, between the U.S. Bureau of Reclamation, EBID, and EPCWID, January 1985. This document is discussed in more detail in Section 6 but in essence it describes the Project operations, allocation, and accounting methods employed since 1979.

[16] A flow of 1 cfs, if kept up over one entire day, provides 1.98 acre-feet (AF) of water.

official of each District of the change in the release rate at Caballo Dam." Figure 2.1 is a Project Order Sheet extracted from the 1985 Draft Operating Agreement, including terms for the river losses ("Plus River Loss") and river accretions[17] ("Less Drain Water to River") that were used to calculate the release from Caballo required to meet the sum of the orders on the Order Sheet.

The 2008 Operations Manual associated with the 2008 OA (both discussed in greater detail in Section 6), describes a slightly modified process for orders and deliveries, in which the release from Caballo is to be based on "the information entered into Figure 1," consisting of District orders and river gains and losses

[17] Accretions to the river include return flows, groundwater discharge into the river bed, and side inflows (in this case, arroyos with temporary influx of water due to rain), and effluent.

combined with information from the "Flow Regulation Calibration at Caballo Dam" report. Figure 1 from the 2012 Operations Manual is provided here as Figure 2.2.

The 2008 Operations Manual and the 1985 Draft Operating Agreement both include a provision that in case there is a significant shortage at EPCWID's diversion headings, water will be wasted[18] from the EBID

[18] "Waste" is defined as an operational release of water from a canal or other conveyance, typically returning unneeded water to the Rio Grande. Often waste is associated with water that was diverted in order to keep the level of water in canals high enough to allow water to flow naturally from the canal into farm headgates. If such waste is authorized and planned so that the water can be re-diverted for Project use downstream, there may be a Project accounting associated with that waste. Examples: El Paso Carriage, by which EBID diverts water for delivery to EPCWID in the El Paso Valley in very dry years, and the Ascarate Credit, whereby EPCWID used to get credit for water diverted at the Franklin heading, wasted back to the Rio Grande at the Ascarate Waste Way, and rediverted at Riverside Dam. *See* Appendix D for a further explanation of this accounting.

canal system to remedy this shortfall. This process is described in the 1985 Draft Operating Agreement as follows:

> *Flows at Riverside Heading occasionally drop below the order of the EPCWID. When this flow is 100 cfs or more below the District's order and the District cannot tolerate the shortage, the following method of sharing the shortage between EBID and EPCWID will be implemented.*
>
> *As directed by the Bureau, the EBID will release additional water through wasteways equal to one half of the amount short at Riverside. The Bureau will release an equal quantity for diversion by EBID. EBID will be given credit for the additional water released at the wasteway to help relieve the shortage.*

EBID is required to release this water for EPCWID use, and then be "reimbursed" by Reclamation, so that the needed water reaches EPCWID farmers more quickly than if the needed water were released from Caballo. In other words, EPCWID has an effective and speedy remedy in the case of a water shortfall. A similar description for remediation of a shortfall at Riverside is provided in the 2008 Operations Manual.

As the irrigation season progresses each District may continue to order surface water during the time releases are made from Caballo until its Charged Diversions equal its allocation. Significantly, New Mexico has seen no evidence that Reclamation has ever failed to deliver the amounts ordered by the Districts. It is reasonable to conclude that the amounts delivered to the Districts each year since 1979 constitute the full amounts that the Districts ordered in each year.

Understanding of Project operations is essential to understanding how any changes in the hydrologic system would impact Project deliveries. Importantly, any change in the hydrologic system that result in increased drain flows in the upper Project (that is, the Project above Courchesne) would not necessarily lead directly to an increase in the flow available downstream. In years when the Project has allocated water to ECPWID in excess of its actual irrigation season demand, any increase in upstream drain flows, or reduction in upstream river losses, would result in a decrease in the rate of release from Caballo necessary to meet demand. Caballo is operated to release only the additional amounts needed to fulfill EPCWID's orders and the Mexican delivery schedule taking into account the already existing drain flows, Project waste, and effluent existing in the Project system.

As a result, an increase in Project drain flow above Courchesne in full-supply years would not lead to increased flows at Courchesne during the irrigation season. Flows could increase during the off season (when releases are not being made from Caballo), and the decrease in Caballo releases that occurs in the full-supply years could change water supply conditions in future low-supply years. The amount of that change in future supply conditions would depend on many factors: evaporation of the extra water in storage and whether or not that water released in a reservoir spill.

For example, the years 1979 through 2002 were full-supply[19] years for the Project,[20] and the Project allocated a full supply to EPCWID every year (376,862 AF each year starting in 1991, varying full-supply

---

[19] Historically, the Rio Grande Project was considered to have a full supply when the annual amount of Usable Water available to the Project was sufficient to deliver 3.024 AF/A to Project Lands, plus 60,000

amounts before 1991). There is no evidence that EPCWID did not receive all of the water that it ordered, and there is evidence that there was sufficient water in reservoir storage to have delivered more water during this time had EPCWID ordered it. I conclude that EPCWID ordered the water it needed to meet its farmers' delivery orders, as well as those for the City of El Paso.

There is no reason to believe that the existence of additional supplies of drain flow upstream of EPCWID would have caused EPCWID to order more water than it already had ordered in these full-supply years. And because Caballo releases are determined based on orders and intervening system gains and losses, I conclude that the presence of additional drain flows would have instead caused Reclamation to release less water from Caballo to meet the existing orders. The effect that reduced Caballo releases during this period would have is a complex problem, and would be impacted by the evaporation of the extra water in reservoir storage, and the reservoir spills occurring during the 1980s and 1990s.

AF to Mexico at International Dam. Reclamation and EBID recognize the years 1979 through 2002 as full-supply years, and the Districts and Mexico were allocated full-supply allocations in those years.

3 PROJECT INFRASTRUCTURE

Construction of the Project and Elephant Butte Dam were authorized by Congress in 1905. Construction of some Project infrastructure began shortly thereafter, and construction of Elephant Butte Dam began in 1912. Reclamation made the first deliveries of Project water in 1915.[21] Some of the information in this and other sections has been extracted from the Rio Grande Project Histories.

3.1 DIVERSION STRUCTURES IN NEW MEXICO: MESILLA AND RINCON VALLEYS

There are three main Project diversion structures in New Mexico:

- Percha Dam diverts water from the Rio Grande into Arrey Canal and Percha Lateral to supply New Mexico lands in the Rincon Valley.
- Leasburg Dam diverts water from the Rio Grande into the Leasburg Main Canal in the northern Mesilla Valley to supply New Mexico lands in the northern parts of Mesilla Valley.
- Mesilla Dam diverts water from the Rio Grande into the Eastside and Westside canals, and the Del Rio Lateral, to supply lands in the southern parts of the Mesilla Valley, including lands in both New Mexico and in Texas.

These points of diversion have remained unchanged since the early years of the Project.

Small amounts of Project water are diverted at other locations in New Mexico including the California Extension, and the Greenwood and Duran river pumps.

3.2 DIVERSION STRUCTURES IN TEXAS: EL PASO VALLEY

Diversion structures in the El Paso Valley have changed considerably through the history of Project and add complexity to the situation. These changes and their impacts are described in more detail, and illustrated, in Appendix C. Understanding these changes is important to evaluating the claims at issue in this case because changes in infrastructure in the El Paso Valley have changed Project accounting, and the way EPCWID can make use of Project Supply (return flows) generated within the El Paso Valley.

Prior to 1938, water was diverted from the Rio Grande to supply Project lands at a number of locations, including (but not limited to) major diversions at International Dam (which then supplied Franklin Canal as well as the Mexican diversion at Acequia Madre), Riverside Dam, and the Tornillo Canal heading. The Tornillo Canal, completed in 1925, was intended as "*the means to collect a large amount of recovered and developed water of the Project*"[22] and as the site of "*collection and diversion of irrigation water and return flow*."[23]

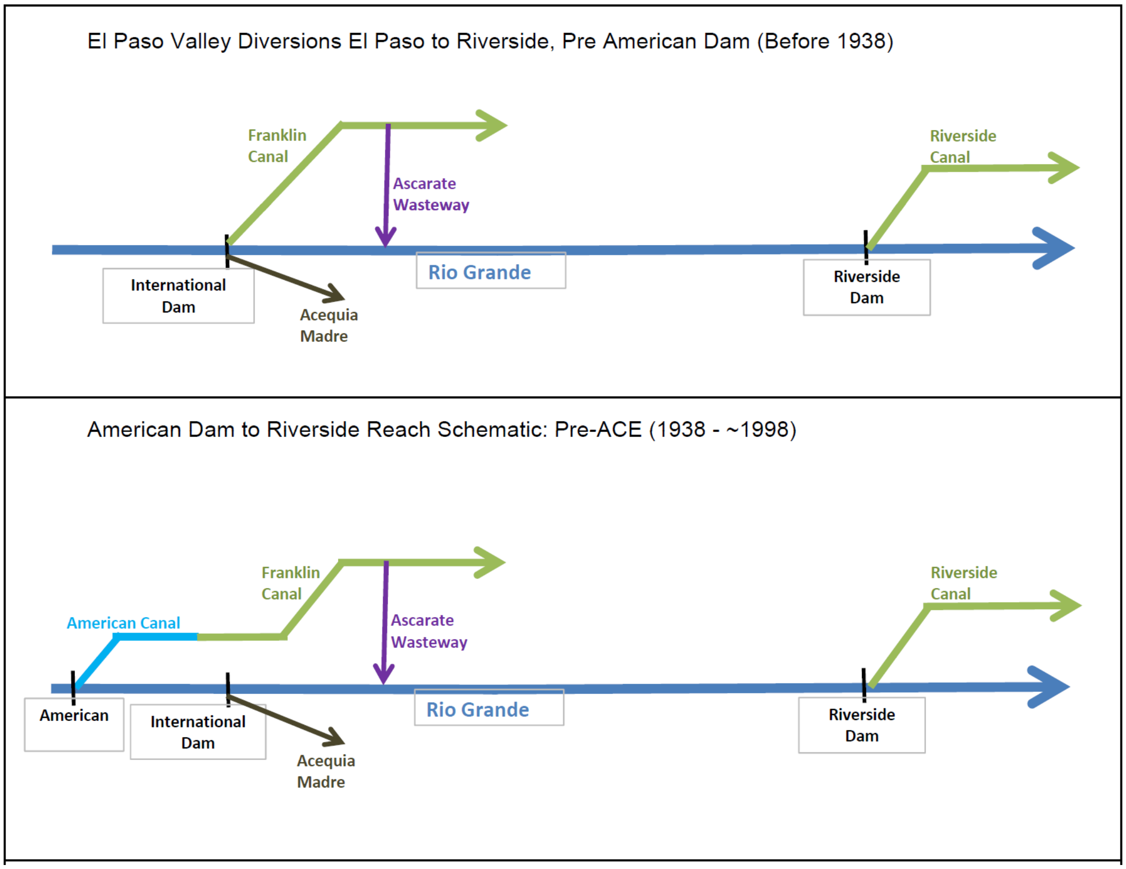
[22] RGPH 1923, p. 12/416.

[23] RGPH 1926, p. 18/172.

El Paso Valley diversions and conveyances changed dramatically after the construction of the American Dam and Canal and the reconfiguration of the Rio Grande. The American Dam and Canal were completed in 1938, allowing the U.S. to divert water for the Project above International Dam.[24] This reconfiguration is illustrated in the schematic in Figure 3.1.

FIGURE 3.1. Schematic of El Paso Valley Conveyance Reconfiguration above Riverside in 1938



Riverside Canal continued to divert water from the Rio Grande at Riverside Dam. However, further downstream, the realignment of the Rio Grande (part of the Rio Grande Rectification Project) had divorced the Tornillo Canal heading from the Rio Grande as reflected in Figure 3.2. The Tornillo Canal heading could no longer divert water from the Rio Grande and was instead supplied by water that had been diverted at Riverside Dam that had been conveyed through the Riverside Canal Extension, plus diversions of flow from some El Paso Valley drains. Despite these changes, the Reclamation 1943 Project History still describes the Tornillo heading as "*the last operational* diversion of the El Paso Valley."[25]

McDonald Morrissey Associates, LLC Ground Water Hydrologists

Confidential Draft - Privileged Pursuant to Rule 26 of the Federal Rules of Civil Procedure: Prepared for Litigation

In 1998, after the failure of Riverside Dam, the American Canal Extension ("ACE") was completed; a concrete-lined canal which connected the Riverside canal heading to the American Dam and Canal. Additional concrete lining was done of the upper (pre-existing) part of the American Canal. Following the completion of the ACE, Project water could be diverted at American Dam to supply both Franklin and Riverside Canals, with water conveyed to the Riverside Canal heading through a concrete-lined canal instead of through the bed of Rio Grande.

Canal lining and drain reconfiguration have continued over time within EPCWID.[27] While the ACE, and other canal lining in the El Paso Valley, may have made the distribution to farmers in the El Paso Valley more efficient, this lining cuts off the process of seepage from the canal, thereby reducing recharge to the El Paso Valley aquifer system, further aggravating groundwater declines in this part of the Hueco Bolson aquifer system.

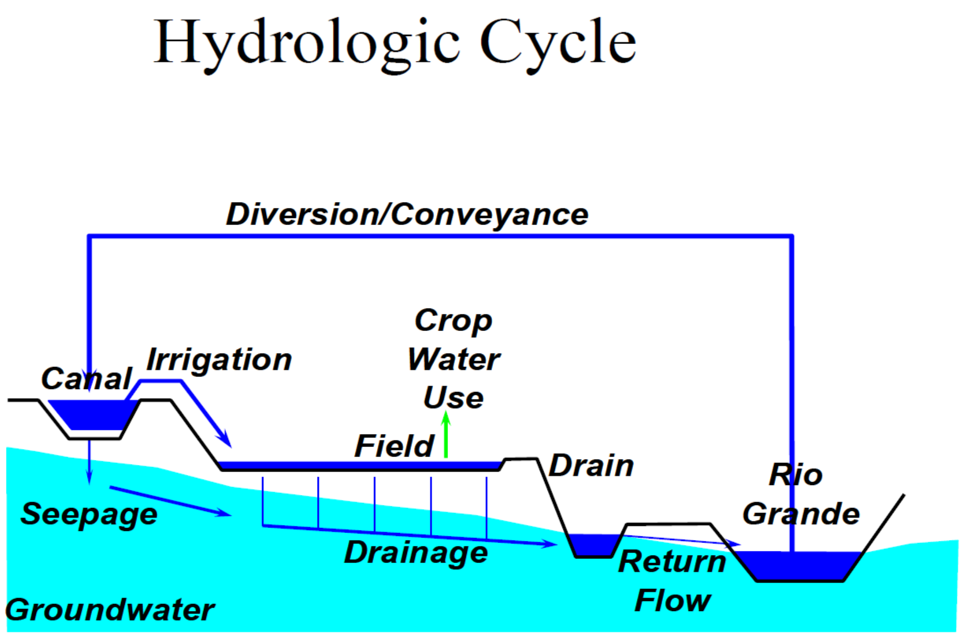
3.3 Project Drains

A drain is a conveyance that has been installed to intercept the water table and convey excess groundwater away, both to prevent land from becoming water-logged and to convey return flows to the river system. Within the Project, drains convey excess groundwater into the Rio Grande or into other Project conveyances.

Most drain flow originates as water released from Project storage and diverted into Project canals. Part of the canal water seeps into the ground, where it may be captured by drains. Another part of the canal water is delivered to farms and applied to irrigated lands, and a fraction of that amount percolates into the ground below the crop root zone, where it migrates and may be captured by drains. This process is illustrated in the Hydrologic Cycle provided in Figure 3.3.

Figure 3.3. Hydrologic Cycle of the Rio Grande Project Irrigation System, Illustrating the Source of Water in Project Drains[28]



The issue of Project drainage arose early. The diversion and application of large amounts of Project water in the first years of Project operation caused a build up of groundwater under Project lands. Shallow groundwater – meaning groundwater close to the surface of the land -- in parts of the Project made lands unable to support crops because it in effect "drowned" the crop. Review of Project Histories shows that "drainage investigations" began in 1914, and lengthy "Drainage Reports" are part of Project Histories starting in 1915. According to the Rio Grande Joint Investigation, "*About 1918 the necessity for*

[28] King, J.P., 2003 EBID Drought Update, February 2003 Presentation to EBID Farmers.

drainage on the Project became apparent and by 1925 a complete system of open drains were completed."[29]

The Rincon, Mesilla and El Paso Valleys each have a separate system of drains. *See generally* Figure 1.2. Rincon Valley drains discharge into the Rio Grande at the southern end of the Rincon Valley. Mesilla Valley drains discharge into the Rio Grande in the southern half of the Mesilla Valley, above Courchesne.

However, again, the story in the El Paso Valley is complicated as more fully described and illustrated in Appendix C. Before the Rectification of the Rio Grande by IBWC, a number of the El Paso Valley drains discharged into the Rio Grande above the town of Fabens. Following Rectification, these drains were rerouted, keeping drain flow, for the most part, within the boundaries of EPCWID and HCCRD.

Associated with the Rectification of the river, El Paso Valley drains that originally discharged into the Rio Grande below Fabens were routed to the HCCRD. Some drain outfalls (where the drain empties into the river), such as that of the Fabens Waste Channel, allow for water to be wasted to the Rio Grande, or for water to be diverted from the Rio Grande for delivery to the HCCRD.

As reflected in the findings of the Rio Grande Joint Investigation, drainage accounted for a significant portion of Project water deliveries in the early years of the Project. In fact, the Joint Investigation noted that some 35% of water diverted to EPCWID at Franklin Canal was composed of drain flow and seepage, and a full 57.7% of water diverted at the Tornillo heading consisted of drain flow and seepage.[30] The increase in the percentage of drain flow diverted at Tornillo in these figures, over that diverted at Franklin, indicates that Tornillo diverted significant amounts of El Paso Valley drain flow that was unavailable at Franklin. That is, there was significant El Paso Valley return flow between Franklin and the Tornillo heading at Fabens that was used to meet Project irrigation demand. At present, the diversion of El Paso drain flow into the Tornillo Canal is either not occurring, or if it is occurring, that water is not charged to EPCWID as diversions of Project Water.

The amount and distribution of drain flow depends on a number different factors, with the amount of surface water diverted and applied to lands being a primary factor. To the extent that Project Supply is low, drain flows will be reduced and vice versa. Urbanization and permanent fallowing of lands is another factor: a drain that passes through areas in which lands have been permanently fallowed will not generate as much water as it did before the fallowing occurred. Groundwater pumping by farmers and for municipal supply and other uses would reduce the flow in nearby drains.

---

[29] The Rio Grande Joint Investigation ("Joint Investigation") was a multi-agency scientific investigation in support of development of the Rio Grande Compact. It published the results of its findings in: *Rio Grand Joint Investigation in the Upper Rio Grande Basin in Colorado, New Mexico and Texas*, Regional Planning, Part VI, National Resources Committee; Volume I, Washington, D.D., Febraury 1938. The Joint Investigation is relied upon by anyone discussing the history of Rio Grande Project operations and is cited throughout this Report. This references is from p. 73.

[30] Joint Investigation, Part I,Table 90, page 100.

4 IRRIGATION WELLS

4.1 IRRIGATION WELL HISTORY

Irrigation pumping within the Rio Grande Project was minimal during the early years of the Project, until the drought of the 1950s.

Starting in the late 1940s, Reclamation warned farmers that reservoir levels were getting low and Project water supply might be inadequate, urging them to conserve and limit their application of surface water.[31]

In the June 20, 1950 Statement of Water Supply Reclamation warned farmers that "*rationing of water for 1951 will only be prevented by*" considerably above average runoff and early fall rains. The initial allotment of water to farmers in 1951 was 1.0 AF/A, rising only to 1.75 AF/A by the end of the year. Final allotments for the 1951 through 1957 irrigation seasons ranged from 0.42 AF/A to 2.5 AF/A (compared with a full-supply allotment of 3.024 AF/A.)[32]

In anticipation of low surface water supplies as predicted by Reclamation, farmers throughout the Project began to drill irrigation wells in the late 1940s. Conover[33] reports that there were only 11 irrigation wells in the Rincon and Mesilla Valleys in 1946,[34] but that by the beginning of 1948 there were 70. Irrigation well drilling increased dramatically during the 1950s. Gunaji,[35] a contemporary observer and engineering expert, states that approximately 1,200 irrigation wells were drilled within EBID during the 1950s. Gunaji's estimates of irrigation well pumping in New Mexico are provided here in Table 4.1.

---

[31] This is from various sources in RGPH 1946-1950: 1946 Notice to Project Users, Project Irrigation Schedule Announcement; 1947 Statement of Water Supply Conditions May 22, 2017 –August 8, 1947; Statement on Irrigation Scheduling, Rio Grande Project, January 7, 1948, and other announcements; Statement on the Status of Water Supply Grande Project, March 24, 1949, and other announcements; 1950 Project Irrigation Water Announcement February 21, 1950 and Water Announcements through August 28, 1950.

Table 4.1. EBID Irrigation Well Pumping Estimates from Gunaji (1961) Tables II and V

Table 4.1. EBID Irrigation Well Pumping Estimates from Gunaji 1961 Tables II and V		
Year	Surface Water Allotment (AF/A)	Estimated Quantify of Ground Water Pumped (AF)
1950	(No Limiting Allotment)	No significant pumping
1951	1.75	176,864
1952	2.50	101,388
1953	1.90	164,948
1954	0.50	286,122
1955	0.417	294,939
1956	0.392	282,732
1957	1.17	213,752
1958	4.00	No significant pumping
1959	3.50	No significant pumping
1960	3.25	No significant pumping

There was a parallel explosion of irrigation wells within EPCWID during the same time. Smith[36] reports that in the El Paso Valley in Texas "*wells were drilled to supplement the surface water supply. About 500 wells were in use in 1954, and about 120,000 acre-feet of water was pumped to irrigate approximately 45,000 acres.*" For the "Upper Valley" (Texas Mesilla Valley, but may include some lands in New Mexico) Smith reports that in 1954 "*about 40,000 acre-feet of water was pumped from approximately 250 wells to irrigate 15,000 acres of cotton and alfalfa*." Alvarez and Buckner[37] report irrigation wells pumping as high as 125,000 AF/Y in El Paso County and 26,000 AF/Y in Hudspeth County during this period.

---

[36] Smith, Ralph E., *Ground-Water Resources of the El Paso District*, Texas, February 1956. p.10.

[37] Alvarez, Henry J. and Buckner, A. Wayne, *Groundwater Development in the El Paso Region, With Emphasis on the Resources of the Lower El Paso Valley*, Texas Department of Water Resources, June 1980. Table 1, p.8.

Treaty deliveries of Rio Grande water to Mexico were also greatly reduced during this period due to the drastic reduction in Rio Grande flow during that severe and prolonged drought. Data from Carreno[38] suggests a similar increase in irrigation well drilling in Mexico during the early 1950s. Irrigation well pumping estimates for Mexico's Juarez Valley for this period, as reported by the IBWC,[39] range from 26,000 AF/Y to 75,000 AF/Y.

Project Histories report on the importance of groundwater, as combined with surface water, to supply Project crops. For example, the 1953 Project History Operation and Maintenance of Irrigation System Report (O&M Report)[40] for the Ysleta Branch (El Paso Valley) states that the surface allotment of 1.90 AF "*was supplemented by water pumped from private irrigation wells, and from Project drains to the extent that the total use averaged 2.51 acre-feet per acre.*" The 1953 O&M Report for the Las Cruces Branch[41] states "*The conveyance of pumped water through the Bureau of Reclamation canals and laterals was again necessary to raise a normal crop.*"

In 1954, the O&M Report for the Ysleta Branch[42] reports "*The year of 1954 was one of the most favorable on record for growing cotton, and as a result the yields were record breaking. This was in spite of a reduction in cotton acreage, [and] a very small water allotment …This supply [0.5 ft] together with several small storm flows originating below Caballo Reservoir, during July and August, drain return flow, and water from some 418 irrigation wells, installed since 1950, was enough irrigation water for almost normal requirements."* The 1954 O&M Report for the Las Cruces Branch[43] reports "*The water users and Bureau personnel again faced a severe year from the point of available water supply, in fact the storage water carryover was so limited that even the first irrigation had to be made with a combination of water pumped from farm wells and water from the storage supply…. So, with the limited storage water, water pumped from farm wells, and conveyed in part through the project canals and laterals and the summer showers, a combination that made possible the production of one of the best yielding crops ever produced by this Branch."*

Project Histories also show that Reclamation actively promoted the use of irrigation wells during the 1950s drought. For example:

---

[38] De La Carreno, Alfonso, *Preliminary Geohydrological Study of the Juarez Valley and Surrounding Areas*, State of Chihuahua, Department of Water Resources, Technical Advisory Memo No. 13.6-18, 1957, Parts 1 and 2.

[39] Ground Water Conditions and Resources in El Paso/Juarez Valley, Hydraulics Branch, Planning Division, U.S. Section, International Boundary and Water Commission, November 1989.

[40] RGPH 1953, O&M Report.

[41] RGPH 1953, O&M Report (Las Cruces Branch (Rincon and Mesilla Valleys)).

[42] RGPH 1954, O&M Report (Ysleta Branch).

[43] RGPH 1954, O&M Report (Las Cruces Branch).

> Reclamation Water Announcement of August 1, 1951[44] states "*Water users who have pumps of good capacity that will supply their needs are requested to arrange for transfer of a part of their unused allotment water to those who are in need of additional water.*"
>
> Reclamation Water Announcement of March 7, 1952[45]: *"Water users who intend to use their pumps for all or a part of their planting requirements and are willing to transfer their allotment to other water-right lands should contact the Elephant Butte Irrigation District or the Bureau of Reclamation in Las Cruces, and the El Paso County Water Improvement District in El Paso, or the Bureau of Reclamation office in Ysleta."*
>
> Reclamation Water Announcement of March 1, 1954:[46] "*Farmers with good irrigation wells are requested to use them to the greatest extent possible as a source of supply and to make available for transfer their allotment water to those farmers who do not have satisfactory wells.*"

Irrigation well pumping was not metered in New Mexico or Texas before or during the drought of the 1950s. It appears that irrigation well capacity in the Project was small until 1948, but increased rapidly in the years that followed, so that by 1955 100% of irrigation demand could be met during low-surface-supply years.

In New Mexico, a comprehensive set of irrigation well meter data is available starting in 2009, following the implementation of the New Mexico State Engineer's LRG Metering Order.[47] In Texas, irrigation wells were not and are not currently required to be metered.[48]

---

[44] RGPH 1951: Reclamation Water Announcement of August 1, 1951.

[45] RGPH 1952: Reclamation Water Announcement of March 7, 1952.

[46] RGPH 1954: Reclamation Water Announcement of March 1, 1954

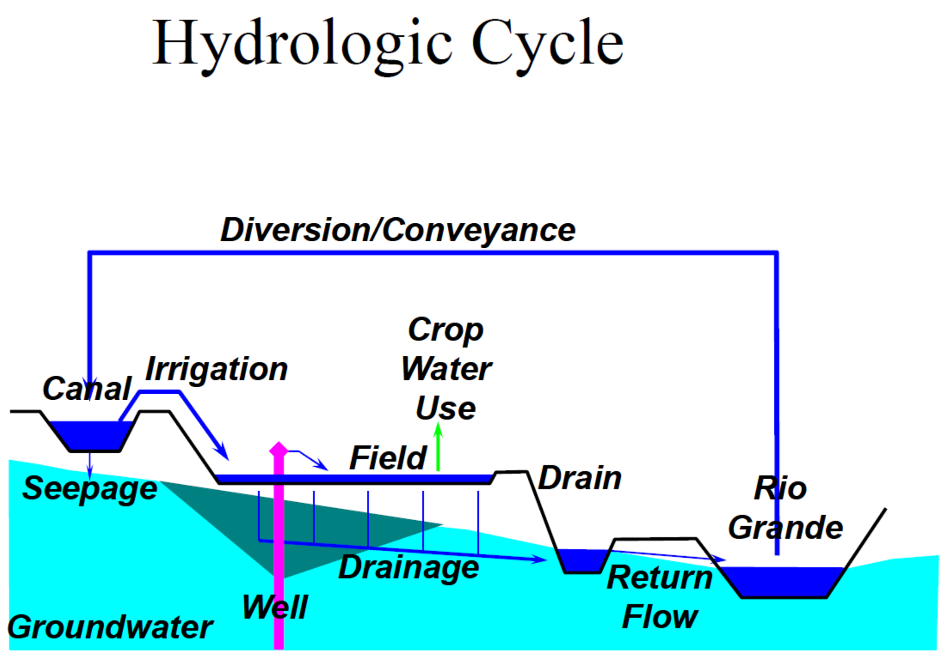
[47] New Mexico State Engineer Order #168. In the Matter of the Requirements for Metering Groundwater Withdrawals in the Lower Rio Grande Water Master District, New Mexico, December 3, 2004 (the "Metering Order"). In the New Mexico Rio Grande basin, State Engineer permits are required to replace an existing well, to supplement an inadequate well, or to drill a well to facilitate the use of an existing groundwater right on lands that have been separated from the well originally serving that right. NMSA 72.12.1 *et* seq. Most irrigation wells in the LRG supply EBID Project lands and are part of combined groundwater-surface water rights.

[48] By contrast, pursuant to NMSA 72-2-9.1, the New Mexico LRG Water Master regularly collects groundwater meter data and provides annual summaries in the LRG Water Master Annual Reports, available to the public at https://www.ose.state.nm.us/WM/WMdistrict4.php. In addition, the LRG Water Master and his staff:

- Monitor groundwater pumping by water right and enforces the groundwater diversions limits as set by permit or by the LRG Adjudication Court,
- Enforce meter installation on all active wells (unless covered by the domestic/stock exclusion),
- Enforce meter data reporting,

Irrigation well pumping (and other pumping) has an impact on the hydrologic cycle as illustrated in Figure 4.1. Well pumping can capture the water that has seeped from canals, or drained from fields, before it reaches drains and ultimately the river or other conveyance structures. Furthermore, groundwater pumping can lower groundwater levels to reduce gains and increase losses from the Rio Grande. Figure 4.1 shows the hydrologic cycle of the Project irrigation system, including the effect of irrigation well pumping.

Figure 4.1. Hydrologic Cycle of the Rio Grande Project Irrigation System, Illustrating the effect of groundwater pumping[49]



More recent data indicates that supplemental pumping for irrigation is still important in both New Mexico and Texas. A complete set of annual meter data is available for the New Mexico LRG starting in 2009. Table 4.2 provides a comparison of surface water supply to EBID and metered groundwater pumping for irrigation (including water to non-EBID lands) for the 2008-2019 period. This data shows that irrigation well pumping increases in response to low surface water supplies. The data also show

- Perform field spot checks of meter data on an ongoing basis,
- Perform field checks on meter accuracy.

The LRG Water Master reports high levels of completeness in the collection of irrigation well metering data. The 2017 LRG Water Master Report states that "98% of the actively metered irrigation wells in the LRG Water Master District have a meter reading entered into the WATERS database to close out the accounting year 2017." The efforts by the Office of the State engineer allow New Mexico to accurately determine how much groundwater is being pumped; Texas has no such mechanisms.

[49] King, J.P., 2003 EBID Drought Update, February 2003 Presentation to EBID Farmers.

that the total farm delivery per irrigated acre ranges from 3.7 to 4.4 AF/A. If this calculation is done using the entire EBID assessed acreage in the denominator, it results in a total farm delivery of 3.1 to 3.5 AF/A.

Table 4.2. Surface Water Delivery and Irrigation Well Pumping Data in New Mexico, Calculation of Total Farm Delivery per Acre

Calculation of the Total Farm Delivery to Irrigated Lands in New Mexico, 2008 - 2018								
	Surface Water Charged to EBID Canal Headings	EBID Reported Farm Delivery	Metered Irrigation Well Pumping	Total Farm Delivery of Water (GW + SW)	Irrigated Acreage	Average Farm Delivery per irrigated acre	Assessed Acreage	Average Farm Delivery per assessed acreage

2017	258,954	139,589	157,000	296,589	74,218	4.0	90,640	3.3
2018	130,000	67,366	244,000	311,366	73,849	4.2	90,640	3.4
Estimated Values: **2008 Irrigation Well Pumping assumed equal to metered 2009 Irrigation Well Pumping,** **EBID Farm Deliveries in 2013 - 2015 calculated assuming 40% delivery efficiency, 2016 EBID Farm delivery calculated assuming delivery efficiency of 50%.**								

Irrigation well pumping in Texas is not metered or reported. However. Texas farms are known to have and use irrigation wells, and EPCWID itself has installed 62 high-capacity District-owned wells in the El Paso Valley, which are intended to pump water directly into EPCWID canals in low-supply conditions.[50]

5 PROJECT SUPPLY

Project Supply refers the water that is delivered (or is available for delivery) to Project beneficiaries. Project Supply is derived from several sources, including the water released from Project storage, drain flows, Project return flows, useable tributary inflows to the stream system below Caballo Dam, and wastewater effluent from municipal sources.

5.1 WATER RELEASED FROM PROJECT STORAGE

The main source of Project Supply is water released from Project storage in Elephant Butte and Caballo. Not all water stored in these reservoirs is Usable Water available to the Project. The water stored in Elephant Butte also includes Compact Credit water[51] which is not available for Project use unless certain terms of the Rio Grande Compact are met (i.e. relinquishment),[52] and storage associated with San Juan-Chama water,[53] which is imported water reserved for use by the City of Albuquerque and, at times, the City of Santa Fe.

5.2 DRAIN FLOWS AND PROJECT RETURN FLOWS

Return flows have always been an important part of the Project Supply since drains were first installed in approximately 1919, as demonstrated in Section 3.3. As the Project has been operated, these return flows consist of drain flows, water wasted (i.e. released back to the Rio Grande) from the canal system, and surface run off of excess irrigation water.

In an irrigation system, “waste” refers to water in a canal or lateral, which is not delivered to farms, but instead is returned to the river, typically through wasteways designed for this purpose. Wasted water is often associated with extra water needed to keep canal levels high enough to allow water to flow by gravity from the canal onto farms, or water bypassed through canals to avoid losses. Some occurrences of waste are anticipated and approved Project operations, such as the waste of water from the southern end of the Mesilla Valley canal system, and conveyance and waste of EPCWID’s water through EBID canals during low supply years to reduce losses.

5.2.1 New Mexico Drain Flows

Historically all drain flow discharging from the Rincon Valley to the river entering Seldon Canyon has been available for Project diversion downstream in the Mesilla and El Paso Valleys. *See* Figure 1.2. Mesilla Valley drain flow discharging above Mesilla Dam was available for diversion into the Eastside and Westside canal. The rest of the drains in the Mesilla Valley discharge into the Rio Grande below Mesilla

---

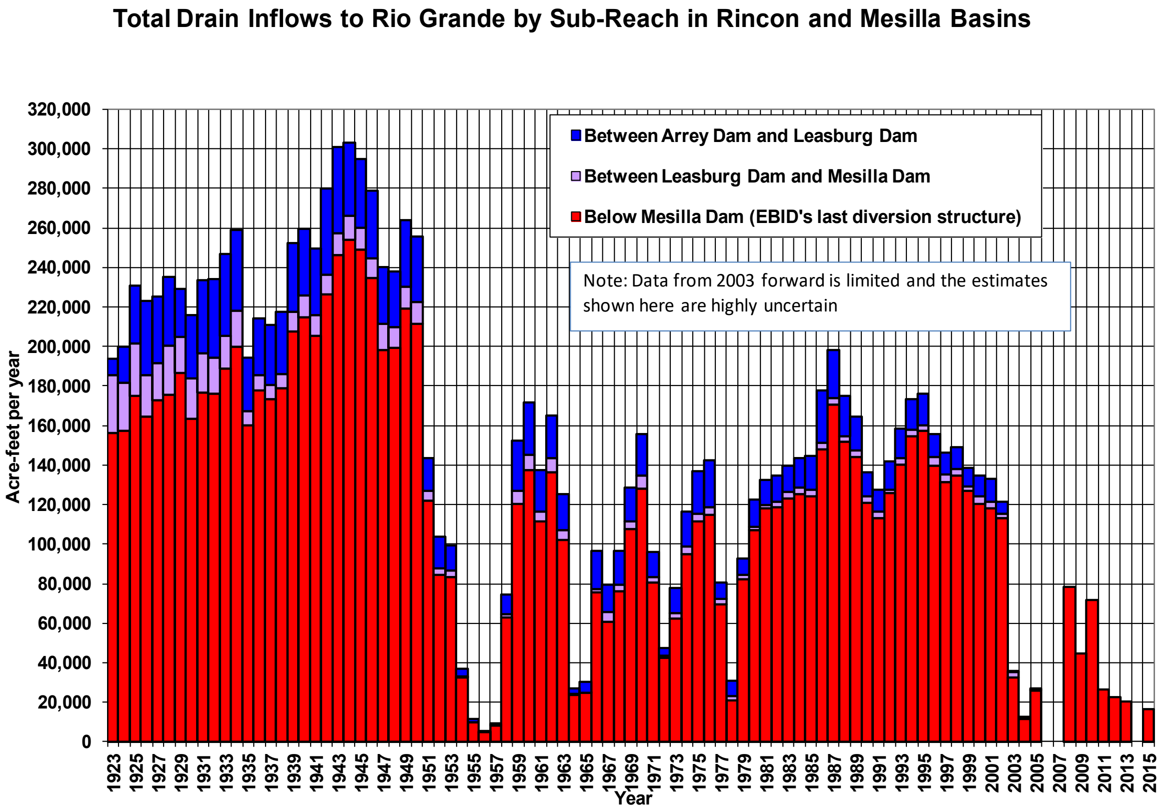
[51] Compact Credit Water, as defined in the Rio Grande Compact is that amount of water in Project storage which is equal to the accrued credit of Colorado, or New Mexico, or both.

[52] *See* Estevan Lopez Expert Report, 2019.

[53] San Juan-Chama water is water imported into the Rio Grande through a transmountain diversion. It is considered imported water, not native water subject to the Rio Grande Compact or available to the Rio Grande Project.

Dam, and the water from these drains is available for diversion in the El Paso Valley. Figure 5.1 shows the total amounts drain discharge originating in the Rincon and Mesilla Valleys, by sub-reach of the Rio Grande between major diversion headings.

Figure 5.1: Total Annual Gaged Drain Flow in the Rincon and Mesilla Valleys, Drain flows combined by reach into which drain flows discharge



5.2.2 Texas drain flows

Historically, water from some El Paso Valley drains was available to, and diverted by, Project canal headings, although, again, the situation in this region is more complex than in the Mesilla Valley. El Paso Valley drains and the issues surrounding them are fully discussed and illustrated in Appendix C.

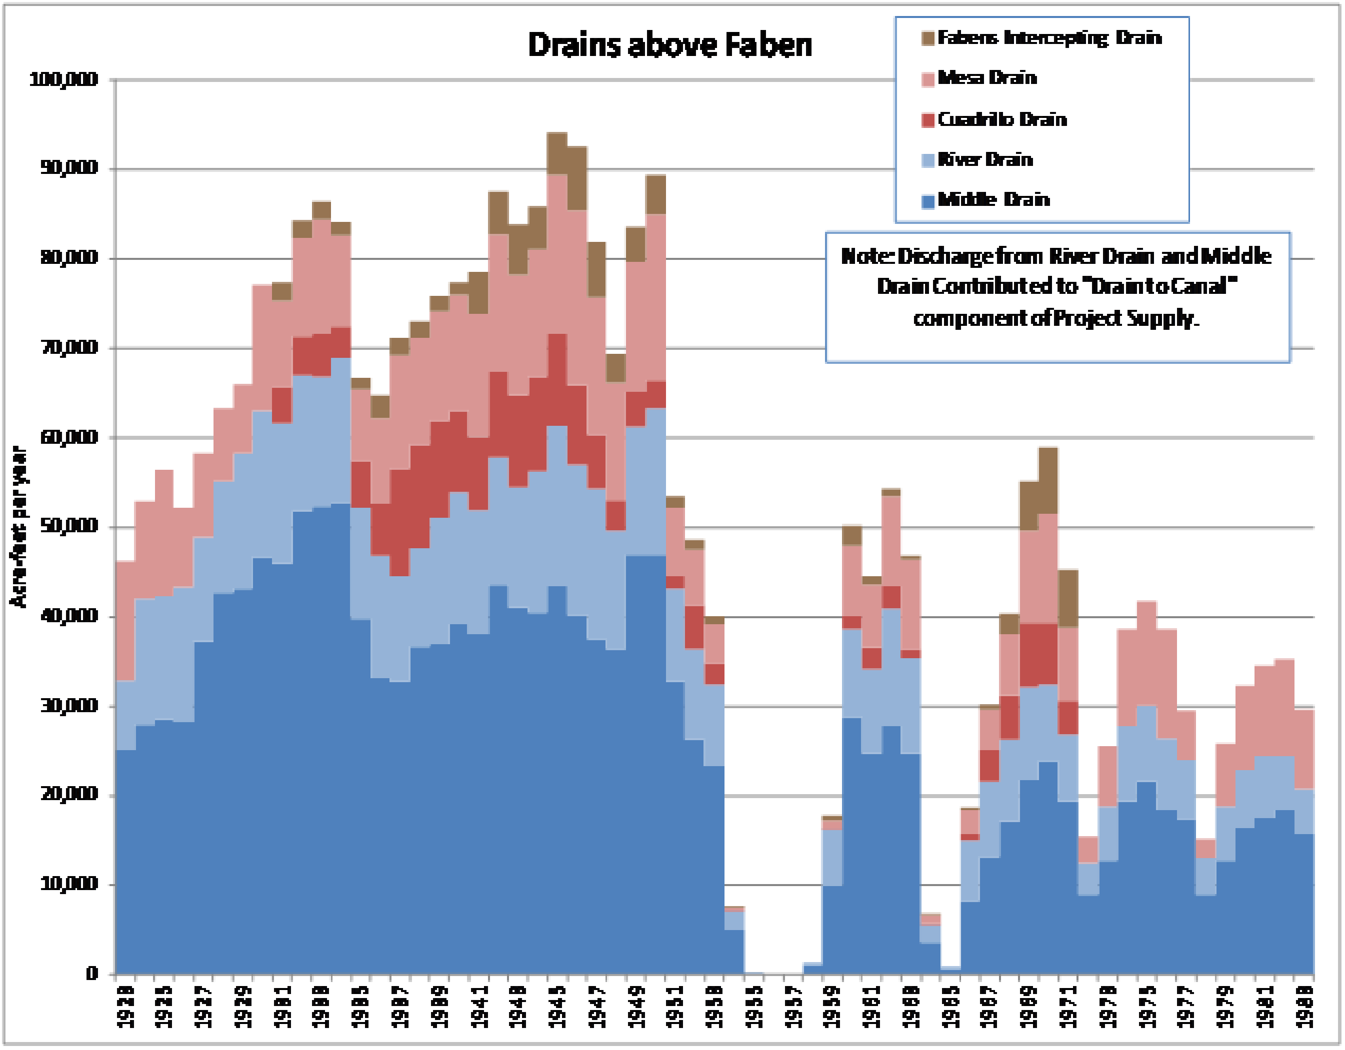
El Paso Valley drains can be divided into two groups: those discharging water into Project conveyances or the Rio Grande above Fabens (Drains Above Fabens), and those discharging into Project conveyances or the Rio Grande (Drains Below Fabens).[54]

Figure 5.2 shows the total reported discharge of the Drains Above Fabens. Data reported by Reclamation is available through 1983.[55] Prior to 1938, the entire amount plotted (65,000 AF/Y to

[54] This division is consistent with Project Drainage Reports, which starting in 1935 tabulate the "Total above Faben" as well as the "Total for [El Paso] Valley."

85,000 AF/Y) would have been available for diversion and counted as Project Supply at the Tornillo Heading. Diversion of El Paso Valley drain flow into the Tornillo Canal is consistent with the data and descriptions included in the Joint Investigation.

Figure 5.2. Total Annual Gaged Drain Flow for El Paso Valley Drains Above Fabens

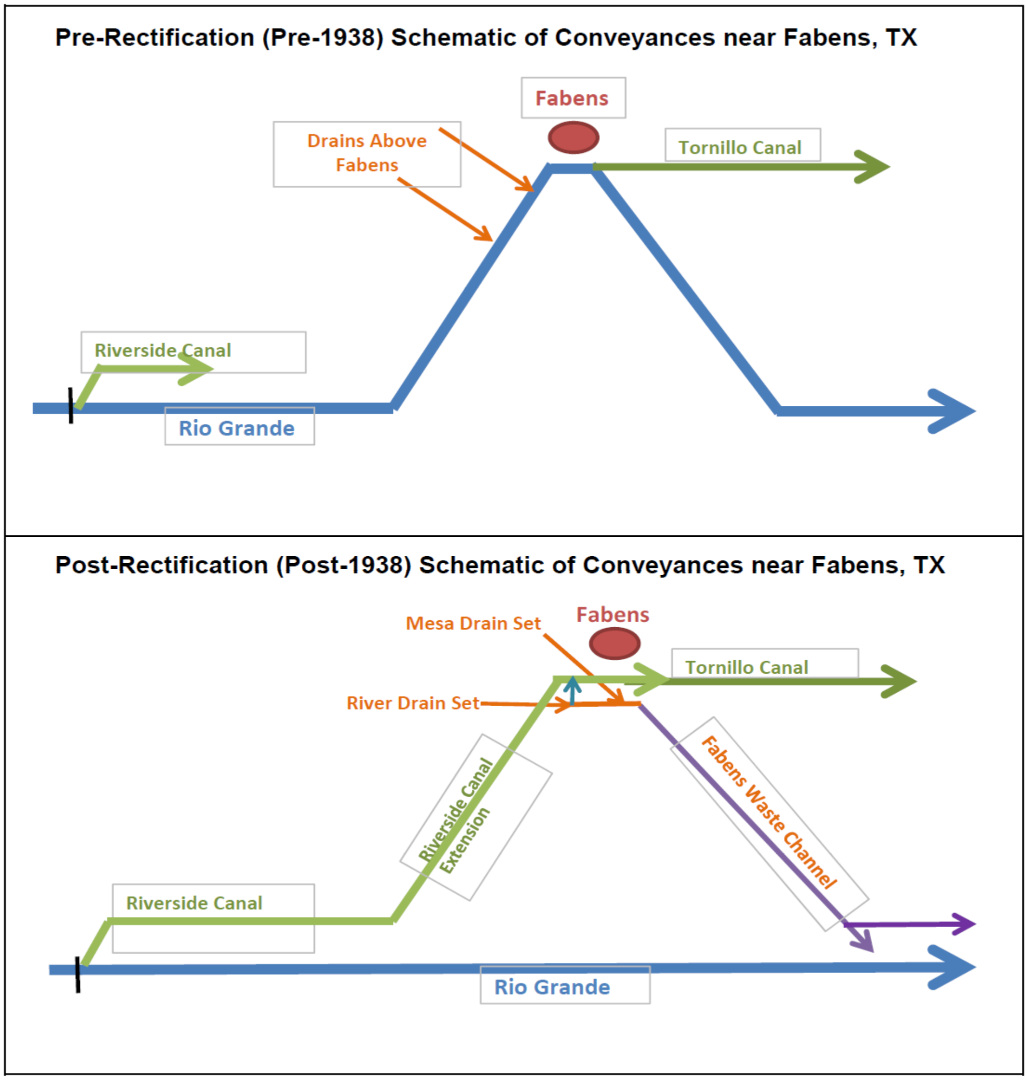


After the Rectification Project realigned the Rio Grande, the amounts of drain water shown in blue in Figure 5.2 (water from the River and Middle drains) were available for diversion into the Riverside Canal Extension. Figure 5.3 is a schematic diagram showing the Rio Grande near Fabens before and after Rectification, and the resulting treatment of the Drains Above Fabens.

---

[55] RGPH 1919 – 1983; Reclamation Drainage Data Reports 1921 – 1983 as compiled by NMSU (Data Collection Effort for Flow Data from Sites along the Rio Grande between Elephant Butte Reservoir and Fort Quitman, TX. Released by NMSU in 2004).

Figure 5.3. Schematic showing Rio Grande and Project conveyances and drains before and after Rectification realignment of river



Today, however, Project accounting does not include a term for diversion of El Paso Valley drain flow at the Tornillo heading, and if any such diversion does occur, it is not considered a diversion of Project Water.

5.2.3 Historical Drain Flow Trends

The drain flow data from the Rincon, Mesilla and El Paso Valleys plotted in Figures 5.1 and 5.2 show that drain flows throughout the Project decreased substantially starting during the 1950s drought, in response to reduced Project Supply conditions and increased groundwater pumping throughout the Project during that time. Fluctuation in drain flows are observed in the 1960s and 1970s in response to intermittent low-supply condition. Afterwards, during the full-supply years of the 1980s and 1990s, drain flows largely rebounded.

5.3 Tributary Inflows

Tributary inflows within the Project consist of occasional flood flow from usually dry arroyos caused by local precipitation events. The amounts of water involved are usually small, and the amount of this water that can be used within the Project is smaller still because tributary inflows may not coincide with irrigation demands, or may be superfluous given the amount of Project Supply already available at the canal headings. Tributary inflows may also be difficult to use due to the presence of sediments in the water.

5.4 Municipal Wastewater Effluent

Treated effluent from municipal water suppliers such as Las Cruces and El Paso is used by the Project as it becomes available for diversion at downstream canal headings, or is pumped into Project canals.[56] The City of Las Cruces, and other smaller entities, discharge effluent into the Rio Grande above Courchesne. The El Paso Water Utility ("EPWU") discharges effluent into the Rio Grande upstream of American Dam from the City's Northwest Treatment Plant located along the El Paso Narrows (*see* Figure 1.5). This water is treated as Project Supply, and diversion of this water is included in Project accounting. In the El Paso Valley, EPWU discharges effluent from its Haskell R. Street Wastewater Treatment Plant ("Haskell WWTP") into the ACE canal, and from its Bustamante Wastewater Treatment Plant ("Bustamante WWTP") into EPCWID's Riverside canal. A large part of EPWU's water supply in the El Paso Valley consists of Project water,[57] and so part of their effluent is Project return flow.

However, EPCWID and Reclamation treat all EPWU effluent in the El Paso Valley as non-Project Water, and EPCWID is not charged for diversion or use of this water. Originally the effluent from the Haskell WWTP discharged into the Rio Grande above Riverside Dam and was considered to be Project Water; until 1999 EPCWID's diversion of this water was charged against its allocation. In 1999, after the completion of the American Canal Extension, Haskell WWTP effluent could be discharged to ACE, and EPCWID and Reclamation agreed that as a result, Haskell WWTP effluent was no longer Project Water.[58] This issue is discussed in more detail in Appendix D of this report. Effluent from the Bustamante WWTP discharges into the EPCWID Riverside Canal below the Riverside Canal gage, and the Project does not charge EPCWID for the use of this water, either.

---

[56] To avoid confusion with Project waste, in this report I will refer to municipal treated waste water as "effluent."

[57] Project water comprises an average of 40% of El Paso Water Utility's supply in non-drought years, closer to 50% in recent years. 6 OVERVIEW OF PROJECT ALLOCATION AND ACCOUNTING

This section provides an overview of the allocation and accounting methods of the Project at different periods of time. A more detailed description and analysis of Project allocation and accounting is provided in Appendices A and D. As a result of my analysis of pertinent data and extensive years of research and involvement in Project allocation and accounting, I have concluded that:

- The 1938 Inter-district Contract sets forth a division of Project water supply between the Districts in accordance with the proportions of Project acreage: 88,000 of 155,000 Project acres (57%) to EBID, and 67,000 of 155,000 Project acres (43%) to EPCWID. From 1938 through 1978, Reclamation operated the Project so that EBID farmer were entitled to 57% of the U.S. share of Project Supply and EPCWID farmers were entitled to 43% of the U.S. share of Project Supply.

- From 1979 through 2005, Reclamation explicitly allocated the U.S. Share of Project Supply to the Districts in the ratio of 57% to EBID and 43% to EPCWID. The amounts allocated were derived from the D1 and D2 Curves. The amounts of water diverted by the Districts were consistent with this 57:43 ratio.

- In 2006 an alternative allocation procedure, "D3 Allocation," was proposed by EBID, and EPCWID demanded the right to carry over unused allocation from one year to the next. Reclamation began implementing these allocation principles in 2006.

- The 2008 Operating Agreement ("2008 OA") was reached between Reclamation, EBID, and EPCWID as part of a settlement agreement between those parties as to two different litigations, without the involvement or approval of New Mexico, Colorado, or the Rio Grande Compact Commission, except for the participation of the Texas Compact Commissioner as a mediator. The 2008 OA adopts D3 Allocation and "Carryover" of unused allocation.

- Under the D3 Allocation, and the 2008 OA, EPCWID and Mexico are allocated Project water based on Project performance during the 1951 – 1978 period (the D1 and D2 Curves), and EBID is allocated whatever Project Supply is left over.

- Before D3 Allocation as initiated in 2006, Reclamation allocated the U.S. share of Project supply 57:43 to EBID and EPCWID, respectively. Under the 2008 OA, EPCWID's allocated share has increased to an average of 56% (not including Carryover) or 62% (including Carryover). EPCWID's actual Charged Diversions (that is, water actually called for and received) during this period (2008-2018) have averaged 55% of total District diversions.

- Starting in the year 2003, EPCWID has received an allocation credit for the American Canal Extension ("ACE"). The ACE Credit increases EPCWID allocation by up to approximately 20,000 AF. Under the allocation method in the 2008 OA, this same amount (up to ~20,000 AF) is subtracted from EBID's allocation, reducing EBID's total allocation, and the amount EBID can order.

- Because of the decrease in EBID's allocation under D3 Allocation, and because EPCWID is now allocated more water than it diverts in full-supply (or near full-supply) years, EPCWID makes much more use of Carryover than EBID, and EPCWID has had a large Carryover account in several years. EPCWID's Carryover account includes the effects of Project accounting credits, which do not represent water left in reservoir storage. Carryover accounts are not reduced to account for evaporation. As a result, some amount of water in EPCWID's Carryover account is not associated with actual "wet" water. The amount of allocation carried over, and the extra water needed to deliver the Carryover, is subtracted from Usable Water before any new allocation is made. Therefore, part of the inflow to Elephant Butte is not available for allocation, but instead is used to support and fulfill EPCWID's Carryover account. This has had a significant negative effect on EBID's allocation.

6.1 Accounting and Allocation Before 1979

From the inception of the Project until about 1979, Reclamation delivered Project water to individual New Mexico and Texas farm head gates in response to farm orders. Each acre of Project land was entitled to an equal pro-rata share of Project water. The 1938 Inter-district Contract sets forth the principal that in the event of a shortage of water, "*the distribution of the available supply in such a year, shall so far as practicable, be made in the proportion of 67/155 thereof to the lands within [EPCWID], and 88/155 to the lands within [EBID]*." It is clear that the Districts and the United States agreed that the appropriate division of Project Supply was 57:43.

Until the 1940s there is no evidence that Reclamation set any limits on farm orders. During the 1940s, in some years Reclamation made restrictions on farm orders before the irrigation season began, but according to Project records those the restrictions were lifted as the season progressed.[59] Starting in 1951, at the beginning of a major drought cycle, Reclamation set a limiting allotment of Project water to individual U.S. farms each year, on an acre-feet per acre (AF/A) basis.[60] Thereafter, Reclamation announced limiting allotments before the beginning of each irrigation season, and adjusted the allotment as appropriate in response to any increase in Project Storage.

At some time during the early 1950s, Reclamation defined a "normal delivery to the Project lands" to be 3.024 AF/A[61] based upon the delivery records from 1946 through 1950; that is, presumably based on actual usage by the farms.

In the years preceding 1979, Reclamation did not provide an accounting of Project deliveries to the Districts. The closest thing to accounting records before 1979 are the Project Water Distribution Reports ("WDRs"), which tabulate diversions and deliveries by "Valley" or by "Unit," not by District. I have

---

[59] RGPH 1940-1950 (Irrigation Schedule and Other Announcements).

[60] RGPH 1951 (Irrigation Schedule and Other Announcements).

[61] Friedkin, J.F. and Resch, W.F., 1906 Treaty Deliveries to Mexico, International Boundary and Water Commission, June 29, 1956.

constructed and include in Appendix A to this Report a post-fact estimate of how much water was delivered to each District during this period based on the WDRs.

From Appendix A, which fully discusses the issue, Table A.2 and Figure A.3 present the resulting annual Project diversions by District from 1931 (when consistent data of this type starts to become regularly available) through 1978. On average during the time period, EBID diverted an average of 54.5% of the U.S. share of Project Supply, and EPCWID diverted 45.5%. Table A.3 and Figure A.4 present the resulting farm deliveries by District for this same time period, 1931 – 1978. On average EBID farmers received 55.8 % of the U.S. farm deliveries, and EPCWID received 44.2%. This distribution of Project diversions and farm deliveries is generally consistent with the Project allotment by acre process which entitled EBID farmers to 57% the available supply and EPCWID farmers 43%. What amounts these Districts and farmer actually diverted and received at farm headgates is controlled both by the allotment amounts (equal for all farm acreage) and the amounts the farmers actually ordered.

6.2 Accounting and Allocation 1979 - 2006

Project operations changed after EBID and EPCWID paid off their loans to the Federal Government in 1972 and 1975. In 1979 and 1980, EBID and EPCWID signed contracts with Reclamation (the "Transfer Contracts")[62] that transferred various infrastructure (canals, etc.) to the Districts, and gave the Districts responsibility for delivering Project water to the farmers. In order to effect the goals of the Transfer Contracts, Reclamation changed its operations so that instead of allotting and delivering water to individual farms, Reclamation now allocated water to each District for delivery at the District's canal headings (i.e. Arrey, Leasburg, Mesilla, Franklin, Riverside), and the Districts became responsible for delivery to individual farms.

To support this change in operations and delivery to Mexico and the Districts, Reclamation developed a new allocation method (the "D1/D2 Allocation" method) and new accounting system. The new method and system explicitly divided the U.S. share of Project water to the Districts 88/155 (57%) to EBID and 67/155 (43%) to EPCWID. This new method and system also continued the historic process of including any unused allocation (or allotment) from one season in the pool of water available for allocation in the next year to the Districts and Mexico.

The Transfer Contracts contain language requiring that *"[a] detailed operating plan will be concluded between the United States and the District setting forth procedures for water delivery and accounting*."[63] Accordingly, during the 1980s Reclamation performed analysis of historical water distribution data as reflected in Reclamation's WDRs from 1951 to 1978, and developed allocation and operating procedures

---

[62] 1980 Contract No. 0-07-54-X090, for Transfer of the Operation and Maintenance of Project Works, between Bureau of Reclamation and El Paso County Water Improvement District No. 1, March 14, 1980, and 1979 Contract No. 9-07-53-X0554, for Transfer of the Operation and Maintenance of Project Works, between Elephant Butte Irrigation District and Bureau of Reclamation, February 15, 1979 (the "Transfer Contracts").

[63] Transfer Contracts, section 6, paragraph d.

for the Project based upon that analysis. This analysis is the basis of the D1/D2 Curves and Allocation method, and this time period (1951 – 1978) shall be referred to as the "D2 Period."

In 1985 Reclamation released a Draft Operating Agreement,[64] including an early version of the D1/D2 Allocation method, and documentation of an accounting system that describes how the Districts' diversions would be accounted, or charged, against their allocations. Reclamation documented a modified version of these allocation procedures in its Water Supply Allocation Procedures document ("WSAP"),[65] which Reclamation used as the basis for Project allocation until the mid-2000s and which is relied upon extensively in this Report. These and other draft allocation procedures documents include different versions of the D2 Curve. In this report, I will work with the D2 Curve and underlying data set extracted from the WSAP document. This data is described and analyzed in Appendix E.

Throughout the 1980s and 1990s the Districts and Reclamation did not come to a full agreement concerning these proposed operating procedures, and for many years there was no signed operating agreement for the Rio Grande Project. Reclamation, however, continued to allocate Project water during the 1980s, 1990s and early 2000s in accordance with the principles and methods they had proposed: the D1/D2 Allocation.[66]

6.2.1 D1/D2 Allocation[67]

The historical water supply relationships that Reclamation developed and referred to as the "D1/D2 Curves" are shown in Figures 6.1 and 6.2.

The D1 Curve was designed to determine the amount of the Mexican Allocation as a function of Project Storage, based on the historical relationship between Project Release (from storage) and farm deliveries plus Mexican delivery. The D1 Curve is still used for this purpose in current Project allocation.

The D2 Curve was designed to determine the entire amount of Project Supply that would be available for delivery to the Districts and Mexico, as a function of Project storage. The D2 Curve is based on historical relationship between Project Release and total Project diversions, including Mexico. It is in effect an historical efficiency or Project performance relationship for Project delivery. Under D1/D2

---

[64] *1985 Draft Operating Agreement* for the Rio Grande Project, between Reclamation, EBID, and EPCWID, January 1985.

[65] Bureau of Reclamation: U.S. Department of the Interior, Rio Grande Project: Water Supply Allocation Procedures (undated, circa 1990) ("WSAP"). This document was provided to New Mexico Interstate Stream Commission staff by Filberto Cortez of Reclamation in 2005.

[66] The Project allocated full-supply amounts of Project Supply to EBID and EPCWID, as defined by the sometimes-shifting D1/D2 analysis, from 1979 through 2002. In the low-supply years of 2003 and 2004, Reclamation allocated EBID and EPCWID pro-rata shares (57% and 43% respectively) of the water Reclamation estimated that it could deliver. In 2005, Reclamation again allocated EBID and EPCWID full-supply allocation amounts.

[67] A fully detailed description of the D1/D2 Curve and Allocation is in Appendix D.

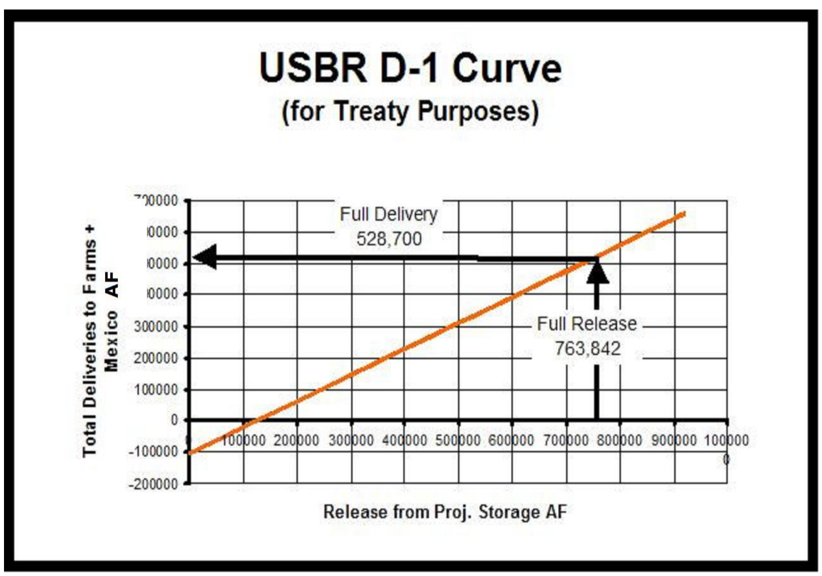
Allocation the total amount of Project Supply calculated by the D2 Curve is divided among the parties as follows: Mexico gets the share calculated using the D1 Curve, and the remainder is split 57:43 between EBID and EPCWID respectively.

Significant although largely unmeasured groundwater pumping was known to have occurred in Texas and New Mexico during the 1951 – 1978 period, and is reflected in the Project water distribution data from that period; thus the D1 and D2 Curves would have reflected the hydrologic effects of these groundwater diversions. *See* Section 4 for estimates of historical irrigation pumping throughout the Project.

The D1/D2 Allocation method explicitly divided the U.S. share of Project Supply 57:43 to EBID and EPCWID, respectively, in keeping with earlier agreements and historical practice. This division of water is illustrated in Figure 6.4, which shows the D2 Curve, with colored areas representing Mexico's, EBID's, and EPCWID's share of Project Supply. D1/D2 Allocation determined each District's annual allocation, and there was no provision for either District to "carry over" unused allocation for individual District use from one year to the next. Instead, any water associated with unused allocation was essentially put in the pool of water available for next year's allocation.

In Figure 6.3 I have plotted the underlying data from the D2 Curve (extracted from the WSAP document) and calculated a linear regression using Excel. The resulting line is identical to the D2 Curve.

Figure 6.1. Reclamation's D1 Curve from F. Cortez[68]



[68] Cortez, F., PPT: U.S. Bureau of Reclamation / Rio Grande Project, 2003 (PPT named: TCEQ_BOR_PP_121103.ppt), provided to the New Mexico ISC March 2005.

Figure 6.2. Reclamation's D2 Curve from F. Cortez[69]

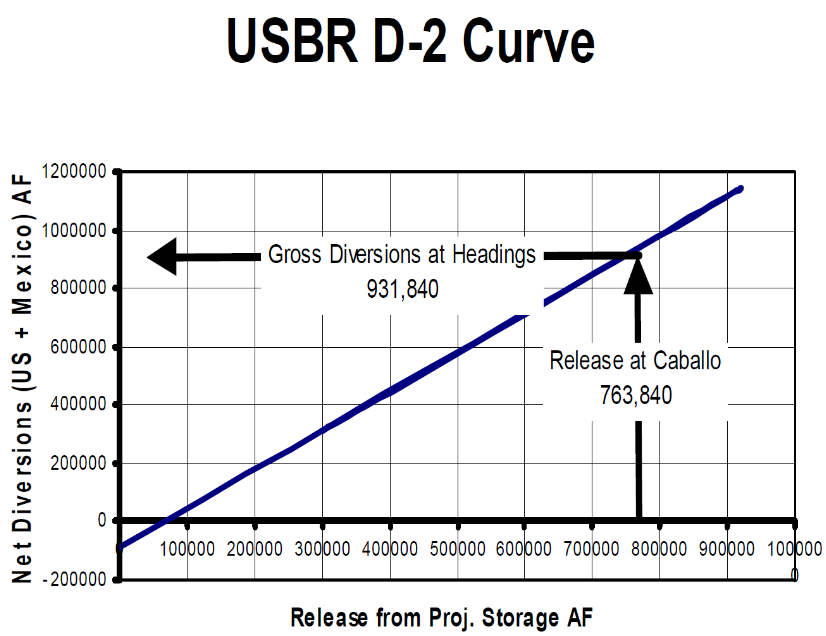


Figure 6.3. D2 Curve (or D2 Relationship) plotted with Original D2 Data from 1951-1978

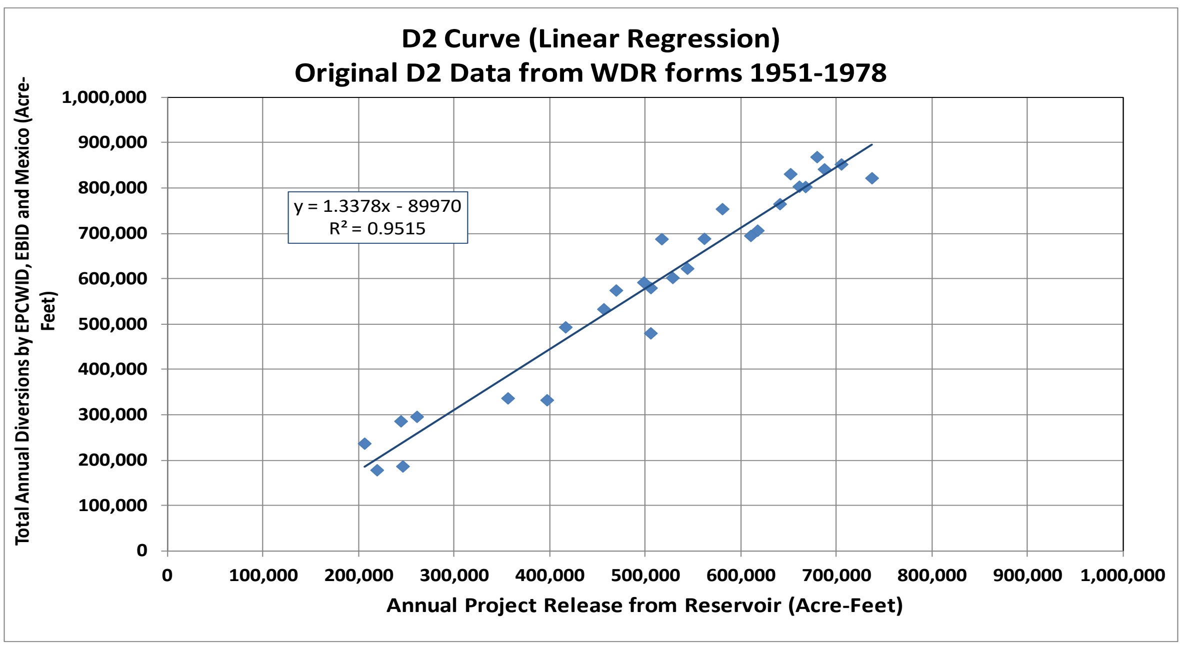
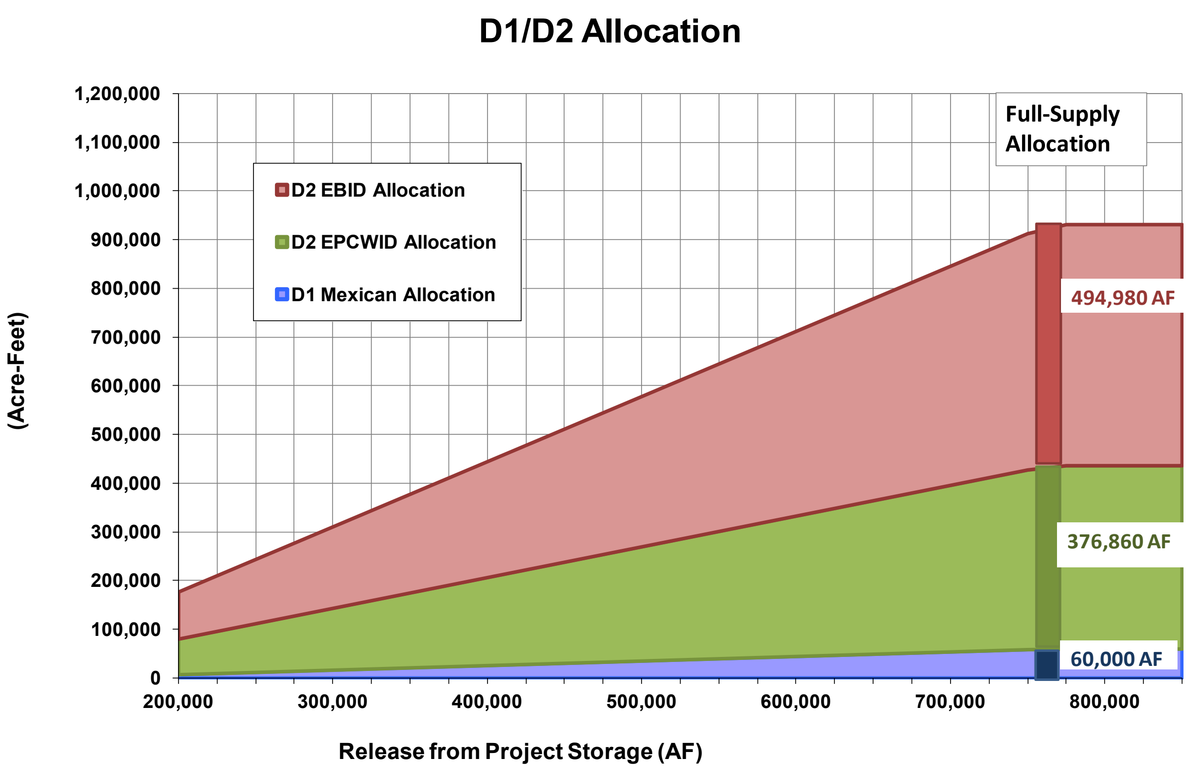


69 Cortez, F., PPT: U.S. Bureau of Reclamation / Rio Grande Project, 2003 (PPT named: TCEQ_BOR_PP_121103.ppt). Figures on the Y axis are cut off in the original of this document.

Figure 6.3 shows that the D2 Curve is a good linear representation of the diversion data, although there are some significant deviations in the data. That is, Project performance during this period was generally consistent with the D2 Curve during the 1951-1978 time period.

Figure 6.4. Illustration of Project Supply based on WSAP D2 Analysis, and D1/D2 Allocation among Districts and Mexico



6.2.2 Post-1978 Accounting

Once Reclamation began allocating and delivering water to the Districts in 1979, it needed a system for charging each District's diversions against its allocation. I am not aware of any description of the accounting Reclamation used for this purpose until the 1985 Draft Operating Agreement; however, the available accounting data from 1979 through 1985 suggests that the general accounting methodology described in that 1985 document was used starting in 1979. This accounting system has been modified since it was first documented in the 1985 Draft Operating Agreement, but to a large degree this same accounting system is in place today, and will be referred to here as "Post-1978 Accounting." This accounting system includes a complex system of charges for diversion, credits and charges for deliveries to EPCWID lands within the Mesilla Basin, for excess waters diverted but not used by EPCWID, and for the operations of El Paso Water Utilities. The Post-1978 Accounting system, and the accounting credits that are part of the system, as well as the significant changes made to the processes as part of the 2008 OA, are described in more detail in Appendix D.

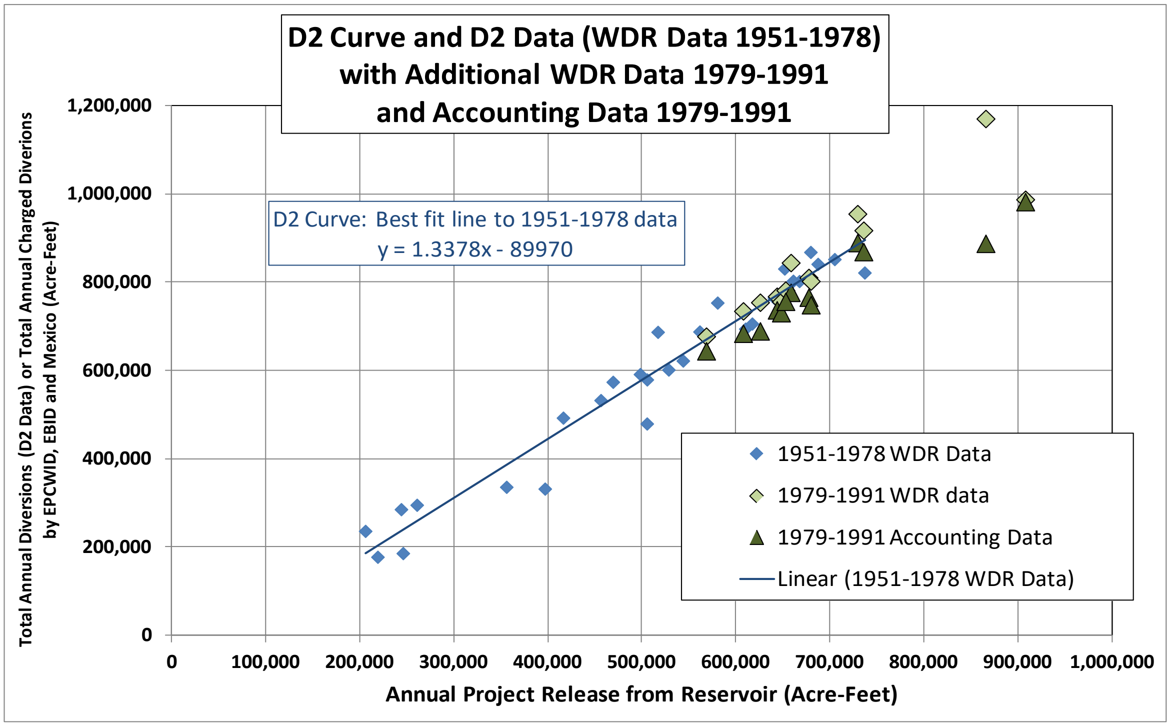
It is important to note that the Post-1978 Accounting rules are different than the way Project deliveries were tabulated and reported during the D2 Period of 1951 - 1978. The D2 data set largely consists only of actual diversion data, with some adjustment for waste. Current accounting data reflects a complex set of rules, and numerous accounting credits, that can result Charged Diversions that are less than the actual diversions that occurred in those years.

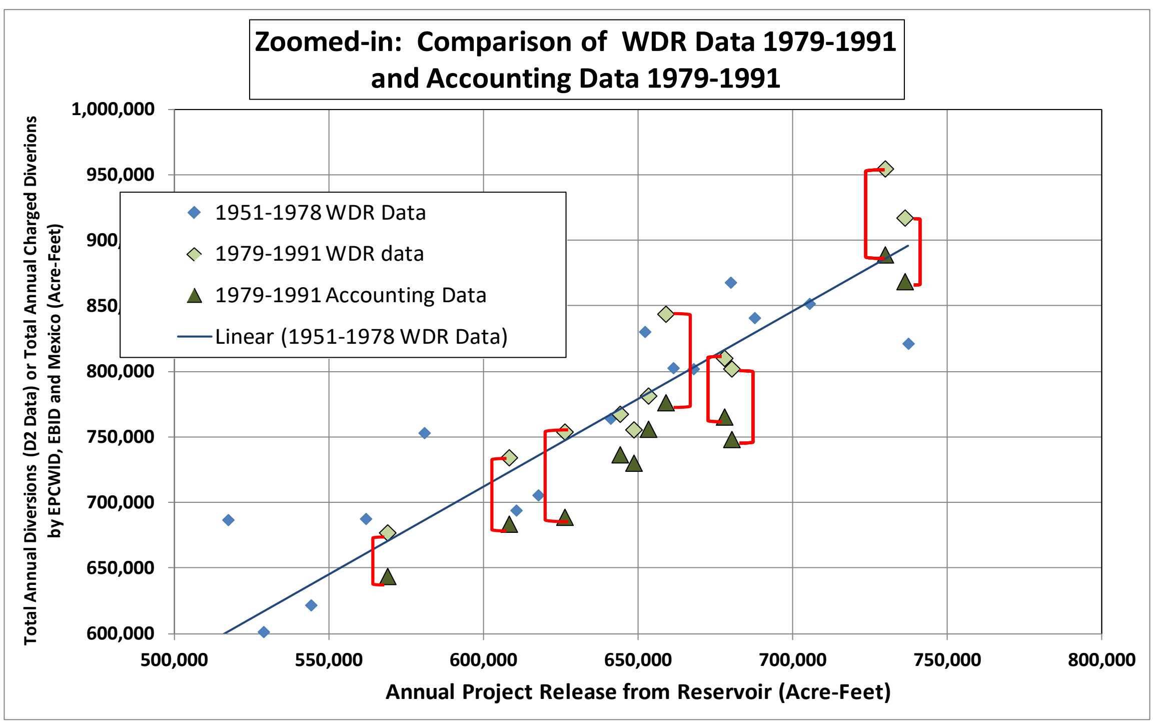
Figure 6.4 is an illustration of the D1/D2 Allocation among Mexico, EBID, and EPCWID.

The impacts theses changes in accounting rules cause is illustrated in Figure 6.5, which compares D2 Curve data (WDR Data 1951-1978), additional WDR data (from 1979 through 1991), and Project accounting data (from 1979 through 1991).

The upper graph in Figure 6.5 shows all of these data sets together, while the lower graph is focused, or zoomed-in, on the 1979 – 1991 data sets. Red brackets are included to show which two data points represent the same year. This data show that even in the 1979 through 1991 period, Project accounting data (or Charged Diversions to EBID, EPCWID and Mexico) are systematically lower than the Diversions tabulated in the WDR forms. If the accounting data is used to measure compliance with D2, there is a negative discrepancy. If the WDR data are used to measure compliance with D2, there is no apparent departure. I conclude that part of the negative departure from the D2 Curve that is observed with current accounting is caused by the effect of the accounting change itself.

Figure 6.5. Upper Graph: D2 Curve and D2 Data from WDR forms, Additional WDR Data 1979 – 1991, and Accounting Data 1979 – 1991. Lower Graph: Zoomed to Facilitate Comparison of WRD Data 1979 – 1991 and Accounting Data 1979 – 1991





US_MSJ_00000639

The practical effect of a negative departure from the D2 Curve is that more water will have to be released from Caballo to deliver a given amount of Charged Diversions to the Districts and Mexico than the D2 Curve would predict.

The allocation, charged diversion, and farm delivery data from the period 1979 through 2005 are presented in Appendix A. Table A.4 and Figure A.5 present District allocations. The split of allocation between the Districts is exactly 57:43, as provided for in the D1/D2 Allocation method, except for 2003 and 2004 in which ACE Credits were awarded to EPWCID, bringing its share of the allocation up to 45%. The District's Charged Diversions are provided in Tables A.5 and A.6, and Figure A.6. This data shows that the Charge Diversions to the Districts were divided on average 58% to EBID and 42% to ECPWID.

Other data from this period is also presented in Appendix A, such as EBID's final allotments to farms (Table A.7) and farm delivery data (Table A.8 and Figure A.7).

In Table A.9 and Figure A.8 I present a comparison of District allocations to each District's Charged Diversions. This data show that in many years EBID and EPCWID did not order or receive all of the water they were allocated.

6.3 ALLOCATION AND ACCOUNTING 2006 – 2019 (D3 ALLOCATION WITH CARRYOVER)

6.3.1 Adoption of D3 Allocation with Carryover

In 2006, after years of controversy, EBID proposed a new allocation method, "D3 Allocation," which was adopted by Reclamation in that year. The D3 Allocation method is intended to reduce EBID's allocation to account for all negative departures from the Project's historical performance. At the same time, EPCWID demanded the ability to "carry over" unused allocation from year to year for its individual use, rather than the historic practice of incorporating any water associated with that unused allocation into pool of water available for next year's allocation. Reclamation implemented D3 Allocation in 2006, and also allowed each District to carry over half (1/2) of its unused 2006 allocation into 2007. EPCWID sued Reclamation as a result of this partial implementation of what is now known as "Carryover," contending that it should be able to carry over its entire unused allocation.

6.3.2 2008 Operating Agreement

On March 10, 2008, Reclamation, EBID, and EPCWID entered into an operational plan for the Rio Grande Project referred to as the 2008 Operating Agreement ("2008 OA")[70] which incorporates both D3 Allocation and Carryover. The 2008 OA was created and adopted in confidential litigation settlement negotiations, exclusive to the aforementioned three parties, with participation by the Texas Rio Grande

---

[70] *Operating Agreement for the Rio Grande Project,* Agreement between Elephant Butte Irrigation District, El Paso County Water Improvement District No, 1, and the United States through the Bureau of Reclamation, signed March 10, 2008 ("2008 OA").

Compact Commissioner as a mediator.[71] Neither New Mexico nor Colorado was a party to the associated litigation and did not participate in these negotiations.

In the months that followed adoption of the 2008 OA, Reclamation, EBID and EPCWID developed an operations manual as required by the 2008 OA providing detailed information on Project operations, equations, and methods. A large part of this 2008 Operations Manual describes Project accounting, which is similar to the Project accounting system already in use as described in the 1985 Draft Operating Agreement. The 2008 Operations Manual was updated in 2010 and 2012, as new issues arose and additional data analysis warranted.

The D3 Allocation method is described in more detail in Appendix D, but put simply: under the D3 Allocation method, Mexico and EPCWID are generally allocated water according to the D1 and D2 Curves but EBID's allocation depends on the Project Diversion Ratio, a new term in Project allocation. The Diversion Ratio for each year is calculated as the ratio of the annual Project Charged Diversions (including Mexico), divided by the annual Project release from Caballo. Under D3 Allocation, the Diversion Ratio is used to calculate Project Supply.

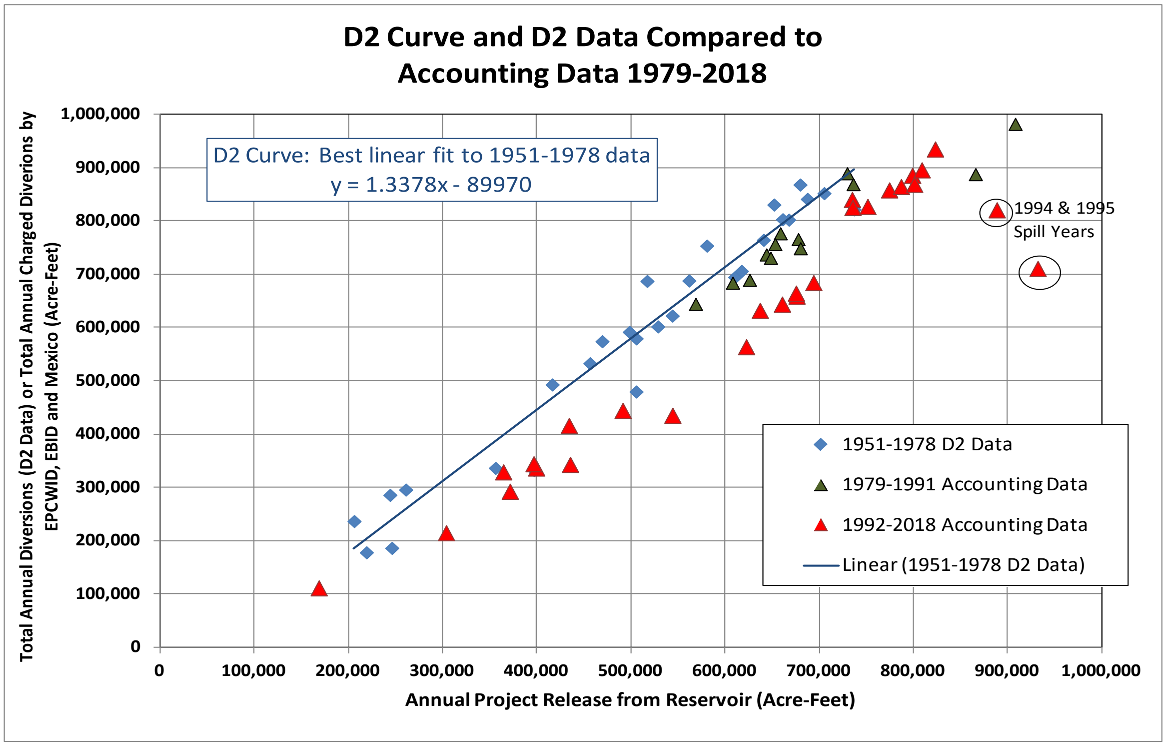
Roughly speaking, under the D3 Allocation method, Mexico's D1 Allocation and EPCWID's D2 Allocation are subtracted from that Project Supply (calculated using the Diversion Ratio), and whatever remains is allocated to EBID. D3 Allocation has the effect of reducing EBID's allocation by any amount by which the estimated deliverable Charged Diversions falls short of the Project Supply (or Net Diversions) calculated by the D1/D2 Allocation method.

In Figure 6.6, Project accounting data from 1979 through 2018 are plotted together with the D2 Curve and associated D2 data. The accounting data consists of annual total Charged Diversions from EBID, EPCWID and Mexico (the "Charged Diversions" for Mexico being equal to the gaged Mexican diversion at Acequia Madre.)

---

[71] 2008 Settlement Agreement, between the U.S. Bureau of Reclamation, Elephant Butte Irrigation District, and El Paso County Water Improvement District No. 1, Including the 2008 Operating Agreement, April 10, 2012.

Figure 6.6. D2 Curve and D2 data plotted together with 1979 – 2018 Charged Diversions as reported by Reclamation, calculated using Post -1978 Accounting



The 1979-2018 Charged Diversions in Figure 6.6 are systematically lower than the D2 Curve. This means that in these years, the total amount of chargeable water delivered to the Districts and Mexico was less than what would be predicted by the D2 Curve, and therefore less than what was allocated under D1/D2 Allocation

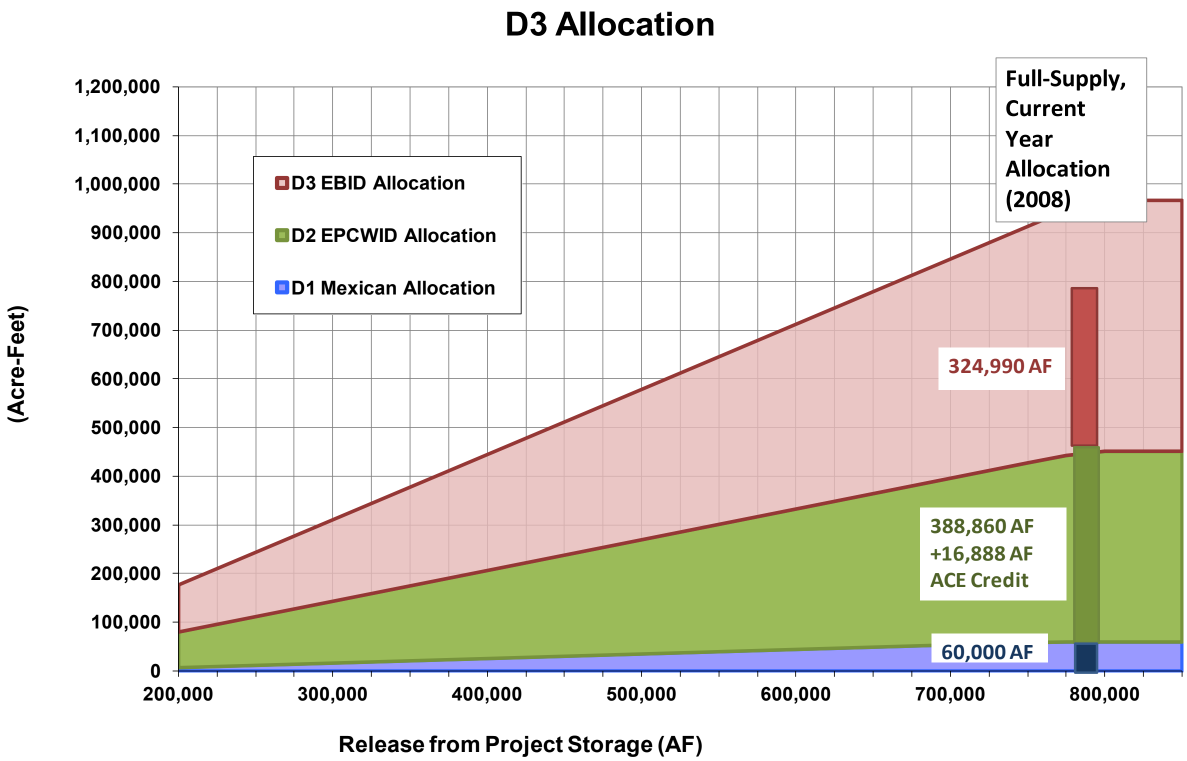
As applied, the D3 Allocation method uses the Diversion Ratio to reduce the total amount allocated each year to account for deficiencies in overall Project performance. The total D3 Allocation should, in theory, closely approximate the amount of Charged Diversions the Project can deliver to canal headings under the hydrologic conditions existing in each year. Mexico's and EPCWID's allocations, however, are still determined using the old D1/D2 method. EBID's allocation is reduced to make up the difference, or the negative departure from the D2 Curve.

D3 Allocation is illustrated for a representative full supply year (2008) in Figure 6.7, which superimposes a bar showing 2008 current-year allocations on top of a D1/D2 Allocation distribution graphic.[72] The large downward change to EBID's allocation cause by D3 Allocation is illustrated by comparing the full-supply allocation bar in Figure 6.6 to that of Figure 6.4.

---

[72] The D1/D2 allocation graphic includes the "extension of the D2 curve" which increases EPCWID's full-supply, current-year allocation from 377,000 AF to 388,000 AF, not including ACE credit. This is more fully explained in Section 8.

Figure 6.7. Illustration of D3 Allocation with Current-Year Allocation Data from 2008



The D2 Curve, a plot of total water delivered to canal heading versus total release from Caballo, is in effect a historical efficiency or performance relationship for Project delivery. The D3 method is intended to reduce EBID's allocation to account for all negative departures from the Project's historical performance.[73] As described in an email by F. Cortez, June 16, 2006: "*The main points [of D3 allocation] are that the D-1/D-2 curves will be used to determine allocations and the EBID proposal stipulates that any river system losses in New Mexico that affect the deliveries in EPCWID and Mexico will be replaced from EBID allocated water.*"[74]

This result is also described in the Final Environmental Impact Statement for the Project:[75]

> *The diversion ratio provision of the OA ensures that annual allocations and deliveries to EPCWID are consistent with historical performance. Moreover, it ensures that deviations in*

---

[73] In theory, EBID's allocation would be increased above their D2 allocation if Project performance is better than the D2 curve would predict, but this happened only in 2011 (*see* Appendix D).

[74] Email from Filiberto Cortez, Bureau of Reclamation to Al Blair, Gary Esslinger, EBID, Jesus Reyes, EPCWID, June 16, 2006 (underlining added).

[75] Continued Implementation of the 2008 Operating Agreement for the Rio Grande Project, New Mexico and Texas, Final Environmental Impact Statement, Bureau of Reclamation, September 30, 2016 ("2016 FEIS"), p. 7 (underlining added).

performance relative to historical conditions would be accounted for by adjusting the annual allocation to EBID.

> *Under the diversion ratio provision, the annual project allocation to EPCWID is equal to the district's historical diversion allocation, based on a regression line reflecting past delivery performance, as defined by the D-2 Curve (Appendix A, Section 2.5). The annual allocation to EBID is adjusted to reflect current year (actual) project performance, as reflected by the project diversion ratio. Again, when the diversion ratio is high relative to the baseline delivery performance defined by the D-2 Curve, EBID generally receives an increase in annual allocation compared to its diversion allocation under prior operating practices. When the diversion ratio is low relative to the D-2 Curve baseline, EBID generally receives a decrease in project allocation compared to prior operating practices.*

As described in the 2016 FEIS for the Project: "*The diversion ratio adjustment of the [2008] OA therefore mitigates potential negative effects of changes in Project performance, which result predominately from the actions of individual landowners within EBID, by ensuring that Project allocations and deliveries to EPCWID remain consistent with historical Project performance.*"[76] In fact, the D3 Allocation procedure reduces EBID's allocation to account for ***all*** negative departures from the D2 Curve (unless multi-year drought conditions apply, in which case the standard for Project performance is eased). The assumption that all negative departures from the D2 Curve are caused by New Mexico is unsupported, and as will be shown in this Report, is contradicted by fact.

Allocation and accounting data from 2006 through 2018 is contained in the third part of Appendix A. Table A.10 provides Current-Year Allocation to the Districts (exclusive of Carryover) and Table A.11 provides Total Allocation to the Districts (and Mexico). Note that the ACE Credit, which increases EPCWID's allocation, is included here as part of that District's Current-Year Allocation. The data in these Tables shows that EPCWID's Current-Year allocation is an average of 56% of District Allocation, while EBID's Current-Year Allocation is 44% of District Allocation. If Carryover is considered, EPCWID's Total Allocation is 62% of the District Allocation. EPCWID's Total Allocation includes significant amount of Carryover that has been carried over for multiple years, and does not reflect the amounts of water that EBID has actually been delivered or charged. The amounts each District were delivered and charged are provided in Table A.12, and this data shows that EPCWID's Charged Diversion are on average 55% of the District supply. This upends the decades-long 57:43 (EBID:EPCWID) distribution ratio.

Table A.13 and A.14 show a comparison of the amounts allocated and the amounts delivered and charged for each of the Districts, including unused allocations, Carryover and Carryover Transfers.

6.3.3 EBID's View of 2008 OA

The 2008 OA significantly penalizes EBID for Project-wide inefficiencies, and the question arises: why would EBID enter such an agreement? EBID made several public statements about why it found the 2008 OA necessary. EBID's Manager, Gary Esslinger, met with New Mexico's Water and Natural Resource Committee in August of 2011, and his handout indicates that key features of the 2008 OA are:

---

[76] 2016 FEIS, p. 9 (underlining added).

- *Answers the question of "How much water does Texas get?" by tying the Texas allocation to storage levels in Elephant Butte and Caballo reservoir*
- *Protects Texas and Mexico from impacts of groundwater pumping in New Mexico*
- *The threat of interstate litigation over New Mexico's groundwater pumping in the LRG is eliminated*
- *New Mexico maintains flexibility to conjunctively manage surface water and groundwater without outside interference*
- *Cost to State of New Mexico: $0.00*
- *Any storm water New Mexico can capture and use, store or recharge to the aquifer does not change the Texas or New Mexico allocations.*[77]

In a 2008 copy of The Water Report[78] key points of the 2008 OA include the following:

- *With the implementation of D3, EBID/NM constituents and other ground water users in New Mexico's Lower Rio Grande basin can now plan for the most efficient and equitable use of its groundwater resources without the threat of Texas. EBID/NM users may continue to use groundwater to supplement surface water as long as the delivery requirements [based on D3 Allocation] are met.*

It appears likely that EBID was anticipating the benefits of the 2008 OA would be flexibility of ground-water use without fear of interstate litigation.

6.3.4 New Mexico's Early Concerns about 2008 OA

When EBID first proposed D3 Allocation in 2006, the New Mexico State Engineer supported its proposal, while suggesting additional study before a permanent change be adopted.[79] However, the 2008 OA was adopted by the Districts and Reclamation to "be in effect from January 1, 2008 until December 31, 2050."[80]

Following the adoption of the 2008 OA, there were a series of meetings between Reclamation and Rio Grande Compact Commission staff. In 2009, New Mexico and Colorado expressed to Texas and Reclamation their concerns about the effects of the 2008 OA, at the Rio Grande Compact Commission. These concerns were documented in letters to Reclamation from the Texas and New Mexico Rio Grande Compact Commissioners.[81] More meetings followed, in which Reclamation and District staff explained

and provided information about the 2008 OA to New Mexico OSE and ISC staff (including the author), but New Mexico's primary concerns related to D3 Allocation and Carryover remained unresolved.

In 2010, the New Mexico State Engineer sent a letter to the Commissioner of Reclamation to further emphasize New Mexico's key concerns about the 2008 OA. Further correspondence and meetings failed to resolve these issues, and in 2011, after the Credit Water release, New Mexico filed suit against Reclamation, [82] citing issues related to the 2008 OA, the lack of meaningful NEPA (National Environmental Protection Act) process for the 2008 OA,[83] and Reclamation's treatment of New Mexico's Rio Grande Compact Credit Water.[84]

Since that time, Reclamation has performed two extensive NEPA processes, resulting in a supplemental Environmental Assessment (and FONSI) in 2013,[85] and a Final Environmental Impact Statement in 2016 for the "Continued Implementation of the 2008 Operating Agreement…"[86] New Mexico was not a cooperator in either of the processes, but repeatedly raised its concerns about the 2008 OA during these processes through the formal comment process.

6.3.5 Post-2008 Changes to the 2008 OA Allocation Process

The Project Allocation Committee has made modifications to 2008 OA allocation process as issues arose in the application of the 2008 OA. Three significant changes have been made since 2008. Two of these changes: the "Multiyear Extreme Drought D2 Correction Factor" and the "Estimate End of Season Adjustment of Project Water Due to Evaporation," are discussed in more detail in Appendix D.

The third important change was introduced in 2011 and is associated with the calculation of "Usable Water Available for Release." In the first years of the 2008 OA Allocations, Usable Water was calculated in accordance with the Compact, using the amounts of Compact Credit determined by the Compact Commission each March. Starting in 2011, the Project Allocation Committee started to estimate

[86] Continued Implementation of the 2008 Operating Agreement for the Rio Grande Project, New Mexico and Texas, Final Environmental Imapact Statement, September 30, 2016, Bureau of Reclamation.

Compact Credits by other methods, reducing the Compact Commission's values for additional evaporation during the irrigation season, thus freeing up more "Usable Water" for allocation and release,[87] at the expense of New Mexico and Colorado. By reducing New Mexico's and Colorado's Compact Credits over the course of the irrigation season, and thus increasing Project Supply, Reclamation reduces the likelihood that Texas will either request or accept a relinquishment of Compact Credit Water. New Mexico objected forcefully to this change, and it has had repercussions on Compact Accounting that continue to the present time. This issue is also discussed in more detail in Appendix D and in Estevan Lopez Expert Report, 2019.

6.3.6 Post-2008 Changes to 2008 OA Project Accounting

Following the adoption of the 2008 OA, there have also been a number of modifications to the Project accounting process. These changes have taken the form of additional charges against EPCWID's allocation.

- In 2012 a charge for "Upper Valley Pumps" was added to EPCWID's accounting summary. According to Reclamation staff, this term is intended to account for the water pumped by EPCWID District-owned and operated wells in the southern Mesilla valley. The amounts of water associated with this new charge have been small (less than 500 AF/Y) and in some years this term is omitted from the accounting summary altogether. There is still no term associated with farmer-owned and operated irrigation wells in the Texas part of the Mesilla Valley, which are estimated to pump over 10,000 AF/Y in low supply years.[88]

- Another charge was added in 2016 to EPCWID's accounting summary, labeled "Proposed 2016 CWF Resolution and NWWTP Flow." This charge reappears in 2017, and in 2018 is replaced by a charge for "CWF Technical Memorandum 1/9/2019." These charges appear to be associated with the El Paso Water Utility's Canutillo Well Field. The Canutillo Well Field is located in the southern Mesilla Valley in Texas, along the Rio Grande. The Canutillo Well Field pumps 20,000 AF to 24,000 AF annually, depleting the flows of the Rio Grande. The associated annual "CWF" charges to EPCWID range from 4,500 AF to 8,000 AF. It is my understanding that the discrepancy between the amount pumped and the amount charged to EPCWID is caused by 1) an assumption that pumping effects that occur outside of the irrigation season do not have to be charged, and 2) return flow credit awarded for waste water effluent from the North West Water Treatment Plan.

  Unfortunately, the Project accounting details are not always provided in a transparent manner to the states and details of these yearly changes are not publicly documented. Based on my own modeling work and research on the effects of Canutillo Well Field pumping on the Rio Grande River, and as agreed to by the District and Reclamation members of the Project Allocation

---

[87] As a result of this calculation, in 2011 Reclamation released Compact Credit water from Elephant Butte reservoir, leading to New Mexico's lawsuit against Reclamation in August of 2011. *State of New Mexico v U.S. Bureau of Reclamation, et al.*, Case No. 1-11-cv-00691-JB-KK, In the United States District Court, District of New Mexico.

[88] *See* Spronk Water Engineers, Inc. Expert Report, 2019.

Committee,[89] the actual Net Depletion to the river caused by Canutillo Well Field pumping is 95%. That is, for every 100 AF pumped by EPWU, 95 AF comes directly from the stream system (the river and drains). This actual impact to the river, and thus the Project Supply, is not adequately offset by the CWF charges in EPCWID's accounting summary.

Thus, while it appears that EPCWID is being assessed charges for some of its groundwater pumping, in fact such charges do not reflect the actual depletions to the river caused by EPCWID pumping.

6.3.7 Concerns with the 2008 OA Allocation Process

An important concern with the allocation process of the 2008 OA is that all negative departures from the D2 Curve, regardless of the actual causes of the departure, are subtracted from EBID's allocation. D3 Allocation was designed this way on the assumption that all, or almost all, of the recent departure of accounting data from the D2 Curve is caused by actions in New Mexico. This assumption has never been adequately demonstrated. Already I have presented evidence that current accounting data is not equivalent to the type of data from which the D2 Curve was derived (*see* Appendix E), which indicates that part of the negative departure from the D2 Curve is due to accounting issues unrelated to New Mexico. In Section 7, I will present evidence quantifying more of this accounting-related departure.

Another concern with the 2008 OA allocation process is related to the magnitude and the treatment of Carryover accounts. Allocation that is not used by a District in one year is now carried over into the District's allocation the following year. The limits on these Carryover accounts are high: 232,915 AF/Y for EPCWID, and 305,918 AF/Y for EBID.[90] Recall that prior to 2007, allocated water not used by either District was simply included in Usable Water for the next year.

In practice, EBID has only carried over small amounts of water from one year to the next. In fact, EBID's allocation under the D3 Curve has been insufficient to supply EBID's irrigation water needs, and typically any unused allocation EBID carries over results from late season increases by Reclamation to allocation that EBID cannot make use of in that irrigation season. EPCWID, on the other hand, has carried over large amounts of water in some years. For instance, in 2009 EPCWID reached its Carryover limit of 232,915 AF, and transferred 82,044 AF of excess Carryover to EBID.[91]

Early in the allocation process under the 2008 OA, Carryover accounts, plus additional water needed to deliver the amount carried over, are subtracted from the Usable Water in storage and effectively sequestered from the allocation process. Current-year allocation is then calculated from the remainder

---

[89] December 8, 2010 Rio Grande Project – Allocation Committee Memorandum: Proposed Accounting Procedures Regarding Appendix C of the 2001 Contract.

[90] 2008 OA, p 3.

[91] Carryover Transfer data is shown in Table A.13 of Appendix A. The Carryover Limit transfer of 82,044 AF is shown in 2009. In 2010 a transfer of 10,271 AF was made from EPCWID to EBID, but this transfer appears to be associated with an attempt to address depletions to Project Supply caused by EPWU's Canutillo Well Field. The transfer associated with Canutillo impacts was not repeated; however, starting in 2016 an accounting charge averaging 6,700 AF/Y associated with Canutillo impacts was applied to EPCWID. *See* Section 6.3.5.

of Usable Water. Some part of the Carryover accounts, however, may not actually be associated with water in storage. Carryover accounts are not reduced for evaporation.[92] Since evaporation does in fact occur, inflows to the reservoir that otherwise would have been available for allocation are instead sequestered to make the Carryover accounts whole.

In addition, some of the allocation that was carried over may be associated with Project credits, such as the ACE Credit, or the accounting credits, rather than any reduction in District orders. As a result, some part of a Carryover account may consist of "paper water."[93] Despite this fact, the allocation process gives the Carryover accounts first priority in allocation, and therefore new inflows to the reservoir are first assigned to fulfill, and reserved for the delivery of, the Carryover accounts, before any of these inflows are available for current-year allocation. This results in a reduction to the current year allocation of both Districts, but the final effect is a negative impact on EBID's total allocation because EBID gets so little of the benefits of Carryover.

A clear example of this occurred in late 2010 through early 2011, as described in detail in Appendix D. In that year, 62,846 AF of the inflow to Elephant Butte occurring after the end of the 2010 irrigation season was required to fulfill Carryover obligations (mostly to EPCWID) under the 2008 OA. As a result there was 62,846 AF less water available for Current-Year Allocation. Both Districts received lower Current-Year Allocations, but EPCWID received the benefit of the addition of a large Carryover account from which no evaporative losses had been subtracted, nor had any deduction for paper water been made. As it turned out, the inflows to Elephant Butte during 2011 were very low, and EBID's Current-Year Allocation was only 67,000 AF. Presumably, if 62,846 AF of the reservoir inflows had not been sequestered to make up EPCWID's large Carryover Account and the resulting Carryover obligation, EBID's Current-Year allocation would have been considerably larger.

6.3.8 Concerns with the Current Accounting Process

One issue with current Project accounting relates to the treatment of El Paso Water Utilities ("EPWU") effluent: EPWU operates waste water treatment plants in the El Paso area which discharge water into the Project. EPCWID receives a credit for the El Paso Haskell WWTP effluent, essentially obviating any charge for its diversion of this water at Riverside and subsequent use of this water. Neither is EPCWID charged for diversion and use of effluent from the El Paso Bustamante WWTP. EPWU's effluent originated either as water diverted directly from the Rio Grande by EPWU for municipal purposes, which is Project water, or as water pumped by EPWU wells, which pumping would have impacted Project water through depletion of El Paso Valley drain flows or aggravation of the losses to the Rio Grande.[94]

---

[92] By contrast, Compact accounting has a specific formula to account for evaporation, recognizing that significant amounts of Useable Water are lost through evaporation. *See* Estevan Lopez Expert Report, 2019.

[93] "Paper water" is water that ostensibly exists, based on records, but may not in fact exist as actual "wet water."

[94] The alleviation of Rio Grande seepage losses between International Dam and Riverside Dam was part of the impetus for the construction of the ACE and the rational for the ACE Credit, which increases EPCWID's allocation at the expense of EBID (*see* Section 9).

There is no reason to consider EPWU effluent as imported or non-Project water. By contrast, similar municipal effluent in New Mexico is treated as Project water, and the diversion of this water is charged in Project accounting.

It is my understanding that the reason that diversion of Haskell WWTP is not charged against EPCWID is because that water does not reach the bed of the Rio Grande, and so EPCWID and Reclamation do not consider it to be Project water. *See* Section 5.4. This position appears unreasonable both because of the source of the water, and because the Project has not used the bed of the Rio Grande as the main Project conveyance in the El Paso Valley since 1999.[95] Instead of conveying water, including the wastewater treatment plants' effluent water, to EPCWID canal headings through the Rio Grande, the Project uses a parallel conveyance system: the American Canal and ACE. Any water entering the American Canal system should certainly be considered Project Supply and charged to EPCWID accordingly.

6.4 Issues Related to American Canal Extension Allocation Credit

Starting in 1938, the American Dam and Canal were used to provide water to EPCWID's Franklin Canal heading, which previously had been supplied by the International Dam. Much of the water diverted at American Dam was then wasted back to the Rio Grande at locations below International Dam for delivery to Riverside Dam further downstream. For many years, the possibility and desirability of extending the American Canal directly to the Riverside heading had been proposed and investigated.[96] Such an extension would eliminate the need to waste so much water back to the Rio Grande, and mitigate conveyance loses associated with conveyance of that water in the bed of the Rio Grande to Riverside Dam.

In 1976, Congress approved a bill authorizing extension of the American Canal, providing that construction not be undertaken until the U.S. and EPCWID had entered into a repayment contract for the value of the 11,600 AF of "salvaged water."[97] In 1987 Riverside Dam failed, and was replaced by a temporary coffer dam, exacerbating EPCWID's delivery problems. In 1992, EPCWID and EPWU entered into a Memorandum of Understanding providing for EPWU to pay "the 'local cost share' of costs for constructing the extension of the American Canal" in exchange for more access to Project water for municipal use. [98]

---

[95] Prior to 1999, Haskell WWTP effluent discharged into the bed of the Rio Grande and diversion of that water at Riverside Dam was charged to EPCWID. Since 1999, Haskell WWTP effluent is intercepted by the ACE before it reaches the bed of the Rio Grande. The ACE also conveys Project water from American Dam to the Riverside heading, bypassing the bed of the Rio Grande.

[96] IBWC, January 31, 1964, Report on Studies of Rio Grande Channel Losess from International Dam to Riverside Canal Heading.

[97] 1974 Act: Public Law 94-423, 94th Congress, S. 3283, September 28, 1974.

[98] Memorandum of Understanding between the Public Service Board of the City of El Paso and the El Paso County Water Improvement District No. 1, dated April 23, 1992. ("1992 MOU"). The Public Service Board of the City of El Paso is now known as EPWU.

As a result, in 1998 the American Canal was improved and extended to the Riverside heading. With the completion of the ACE, water could now be delivered to the heading of Riverside Canal through the ACE, entirely bypassing the bed of the Rio Grande between the American Dam and Riverside heading altogether. Citing to reports that the bed of the Rio Grande in that particular reach lost water to seepage, Al Blair of EPCWID estimated the amounts of water salvaged by conveying EPCWID's water through the ACE rather than in the Rio Grande itself.[99] Blair's calculations were based on data contained in a 1964 report by Raymond Hill,[100] and groundwater model results.[101] Blair generated a table of "Salvaged Water" for differing amounts of EPWCID diversion, with a maximum salvaged water value of 20,252 AF/Y, significantly higher than the amount contemplated in the 1976 Act of Congress (11,600 AF). Starting in 2003, Reclamation awarded EPCWID the ACE Credit as an increase in the District's allocation for "ACE Conservation." The annual amount of the ACE Credit varies depending on EPCWID's diversion, with a maximum possible value of 20,052 AF/Y.[102] The ACE Credit amounts awarded to date range from 7,485 AF to 17,998 AF (with zero in some years.)

The ACE Credit is embedded in the Allocation Spreadsheet of the 2008 OA. The effect of this Credit is to increase EPCWID's allocation by the amount of the Credit, and reduce EBID's allocation by the same amount. I have demonstrated this by testing the allocation spreadsheet itself. Figure 6.7 is a modified copy of the final allocation spreadsheet for 2009. The column labeled "Original Data" contains the final allocation calculations for 2009 as provided by the Allocation Committee to the New Mexico OSE/ISC. The column labeled "Modified: No ACE credit" contains the same data and calculations, using the equations embedded in the spreadsheet, except that the ACE Credit is set to 0. A comparison of the two columns shows that the effect of the ACE Credit is to increase EPCWID's allocation by 17,998 AF (the amount of the ACE Credit) and decrease EBID's allocation by the same amount.

In summary, the ACE Credit gives EPCWID an increase in allocation for bypassing Project conveyance inefficiencies associated with the bed of the Rio Grande. The reach of the Rio Grande between International Dam and Riverside Dam loses water to seepage. The seepage in that reach was caused by, or at least greatly enhanced by, groundwater pumping in the Hueco Bolson by Texas and Mexico. In effect, EPCWID and Texas are given a credit for mitigating a condition that they themselves caused.

7 ANALYSIS OF THE REASONS FOR THE NEGATIVE DEPARTURE FROM THE D2 CURVE

As discussed in Section 6, D3 Allocation reduces EBID's allocation by the amount of any negative departure from the D2 Curve, regardless of the actual cause of that negative departure. In this Section I discuss the actual reasons for the negative departure from the D2 Curve, and demonstrate that a significant portion of that departure is unrelated to actions by New Mexico but is rather the result of changes in Project accounting methods.

The underlying data and support for the conclusions in this Section are in Appendices A, D, and E.

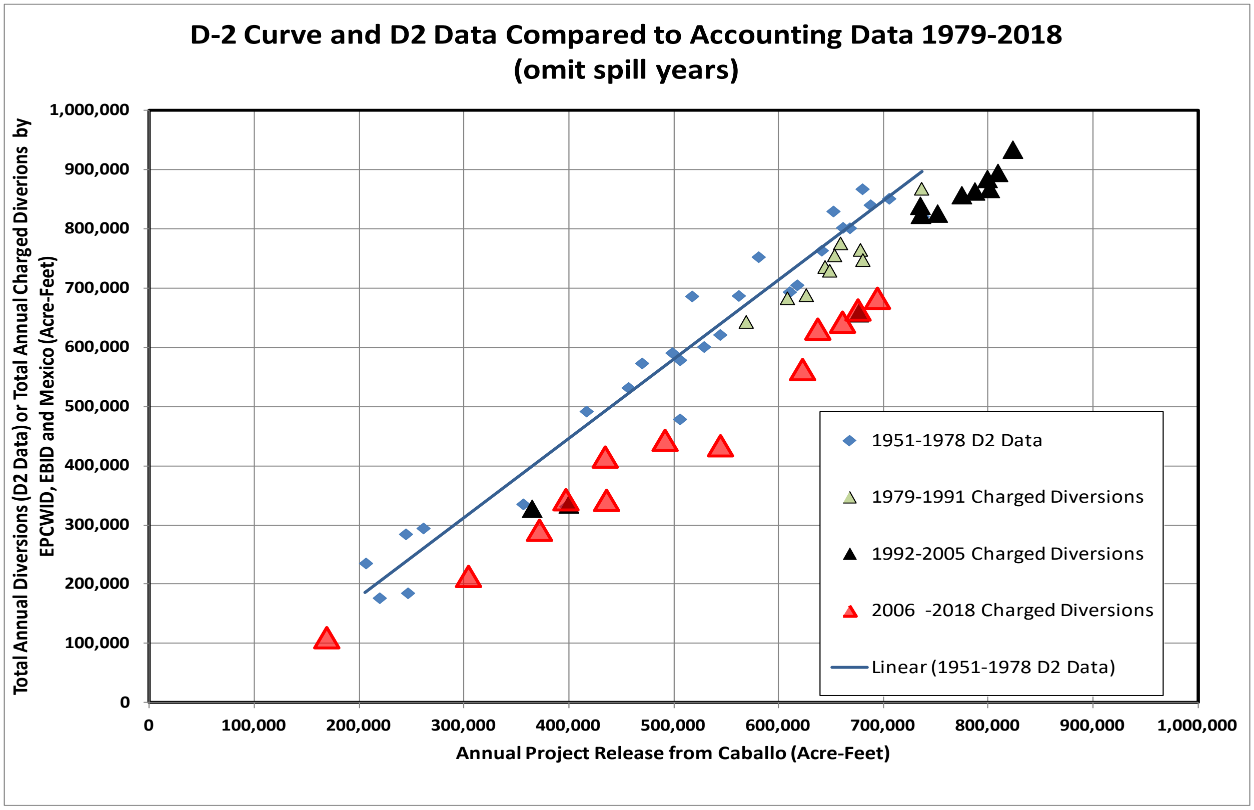
7.1 DEPARTURE DATA

Figure 7.1 shows the D2 Curve and D2 data set (1951-1978) together with Post-1978 Accounting data from 1979 through 2018. The accounting data is broken out by time periods:

1) 1979 – 1992 Accounting Data (D1/D2 Allocation)
2) 1993 – 2005 Accounting Data (D1/D2 Allocation, greater District control of records)
3) 2006 – 2018 Accounting data (D3 Allocation with Carryover)

As shown in Figure 7.1, all Post-1978 Accounting data is below the D2 Curve, to varying degrees. This can also be described as the Post-1978 Accounting data having a negative departure from D2, meaning that the Districts receive less Charged Diversion than would be predicted by the D2 Curve.

Figure 7.1. D2 Curve and D2 Data (from WDR forms) Compared with Accounting Data (Charged Diversions) from 1979 – 2018



7.2 Reasons for Negative Departure from D2

There are a number of reasons that Post-1978 Accounting data shown in Figure 7.1 show negative departures from the D2 Curve.

Accounting Differences. The data from the WDR forms used to derive the D2 Curve (that is, the D2 data set) are systematically different than the Post-1978 Accounting data. *See* Appendix E for a complete discussion. Of prime importance, the data in the 1951 – 1978 WDR forms includes off-season diversions, and diversion of El Paso Valley drain flows. Post-1978 Accounting omits these terms. In addition, Post-1978 Accounting includes credits that did not exist during the 1951-1978 D2 Period. As a result, Post-1978 Accounting data are systematically low compared with the D2 data set. D3 Allocation is built upon a comparison of these two different kinds of data, and EBID's allocation is reduced for any discrepancy between the data sets, even though there are fundamental accounting discrepancies between these two methods. In other words, even if Project efficiency in a given post-1978 year were the same as during the 1951-1978 period, the Charged Diversions for that year would ***still*** show a negative departure from the D2 Curve simply as a matter of the accounting changes.

Decreased Recharge and Increased Depletions. It is likely that there has been a net increase in irrigation depletions above Courchesne caused by increases in agricultural efficiency and increased acreage of more productive and more water-intensive crops such as pecans and alfalfa. These increases are offset to some extent by a reduction in the total amount of irrigated acreage.
Furthermore, groundwater pumping in both New Mexico and in Texas tends to lower groundwater levels in the Rincon, Mesilla and El Paso Valleys. Lower groundwater levels impact surface water flows in the Rio Grande by reducing gains to the Rio Grande from groundwater, and/or increasing seepage losses from the Rio Grande. Lower groundwater levels also reduce the discharge of groundwater into drains which discharge into the river. Both of these changes reduce the amount of water available for diversion within the Project and would tend to increase any negative departure from the D2 Curve already taking place by the changes through accounting differences.

Other Unexplored or Un-quantified Causes. These causes may include other physical changes within the Project, such as river bed aggradation, or causes related to Project operations such as deliveries to the HCCRD, or the effects of growing municipal use of Project water in Texas.

Increases in depletions and decreased recharge occurring above Courchesne would have the effect of decreasing the amount of water available for diversion at American Dam. Project operations, described in Section 2, would compensate for these depletions by increasing the release from Caballo in order to meet District orders. The net result of this operation would be to reduce the Project Diversion Ratio.

Increasing depletions in the El Paso Valley have already increased losses to the Rio Grande mainstem, and depleted El Paso Valley drain flows that used to contribute to Project Supply.

7.3 Issues Related to Post-1978 Project Accounting

There are three accounting issues which can be readily quantified that impact the negative departure between current total Charged Diversions and the D2 Curve.

7.3.1 Off-Season Diversions

The data from which the D2 Curve was developed is found in Project WDR sheets from 1951 through 1978 (the D2 Period). I have analyzed this data, and found that it includes diversions that occurred when no water was being released from Caballo Dam (i.e. the "Off Season"). I present this analysis in Appendices A and C. The water diverted at such times includes drain flows, effluent, and any gains to the Rio Grande below Caballo, and the lion's share of these diversions were made by EPCWID.

Post-1978 Accounting, and therefore recent accounting data, does not include any charge to the Districts for diversions made outside of the release season.[103]

---

[103] 1985 Draft Operating Agreement, p.3: "All diversions made by the Districts during the nonirrigation season utilizing return flow waters shall not be charged against the Districts' respective allocations"; 2008 Operations Manual, p.3: "All diversions made by the Districts during the non-irrigation season utilizing return flow waters shall not be charged against the District's respective allocations."

The fact that current accounting practices do not count a component of flow that was part of the D2 data set, and therefore incorporated into the D2 Curve, causes a discrepancy between current accounting data and the D2 Curve.

It is not known how much water is currently being diverted outside of the irrigation season. However, successive years of low Project Supply, exacerbated by the even lower EBID allocations, have greatly reduced drain flows in the upper Project (above Courchesne). It is likely the amounts of water available for diversion outside of the irrigation season are currently low, but would become larger if groundwater conditions in the Rincon and Mesilla Valleys were allowed to recover. Such recovery is unlikely if current allocation procedures remain unchanged, and even if such recovery did occur, 2008 OA accounting rules mean that EPCWID could continue to divert off-season flow at no charge.

I calculate the amounts of off-season diversion occurring during the D2 period in Appendix C by comparing WDR monthly data with daily Caballo release data. In general, I considered monthly WDR diversions to be off-season when the gaged flow below Caballo was less than 100 cfs for at least a week before the beginning of that month. The amounts so derived range from about 5,000 AF/Y in low-supply years such as 1954 and 1955, to approximately 40,000 in high-supply years such as 1962 and 1969. That is, the D2 data set contains 5,000-40,000 AF each year that would not be charged against the Districts' allocation under current accounting rules.

7.3.2 El Paso Valley Drain Flows

The WDR data that forms the basis of the D2 Curve explicitly includes diversions of drain flows at Fabens as I have demonstrated in Appendices C and D of this report. Post-1978 Accounting has no term for the diversion of El Paso Valley drain flows, so if such drain flows are now diverted, they are not being charged. El Paso Valley drains flow have probably been smaller than in past years, depleted by the large amount of municipal and irrigation pumping that has occurred in the Hueco Bolson, and by the effect of urbanization on aquifer recharge. The absence of these drain flows, either as accounting terms or as physical flows, is responsible for part of the negative departure of current accounting data from the D2 Curve, and also for a reduction in supply compared to the conditions obtaining at the time of the Joint Investigation.

The reported amounts of El Paso Valley drain flow diverted in the El Paso Valley are tabulated in Appendix C. Drain flow ranged from approximately 20,000 AF to 40,000 AF during the 1940s and early 1950s. Diversions of El Paso Valley drain flow decrease to zero during the mid-1950s, presumably because of the immediate effects of low-supply conditions, and the effects of the resulting irrigation pumping in the El Paso Valley. As described in Section 5 and shown in Figure 5.2, El Paso Valley drain flows decreased substantially when extensive groundwater pumping for supplemental irrigation began in the El Paso Valley in the 1950s. Increasing groundwater pumping for municipal use by El Paso and Juarez in Mexico have also contributed to the decline in El Paso Valley drain flows.

7.3.3 Project Accounting Credits

The D2 data set forming the basis of the D2 Curve do not include the complex accounting associated with the delivery of water to EPCWID lands from Mesilla Dam that is a part of Post-1978 Accounting. These complex calculations cause the total Charged Diversion associated with Mesilla Dam to be systematically less than that amount diverted at Mesilla Dam. The D2 data set do not include other credits that are applied as part of Post-1978 Accounting with the exception of the Ascarate Credit. The net effect of these current credits in high-supply years is to reduce the total Charged Diversions below the amounts actually diverted,[104] which increases the negative departure from the D2 Curve, thereby decreasing the Diversion Ratio, which then decreases EBID's allocation.

7.3.4 Combined Effect of These Accounting Issues

The three accounting issues described above cause Charged Diversions to be systematically lower than the total diversions used to create the D2 Curve, especially in high-supply years. The result of this systematic discrepancy is that allocations made using the D2 Curve are already systematically high compared with the associated Charged Diversions. I have attempted to quantify this effect for one of the years in the D2 Period by breaking out different components of the actual diversion: off-season diversions, diverted El Paso Valley drain flows, and estimates of the amounts of credit that would be applied to Districts under Post-1978 Accounting. I have selected the year 1969 for this analysis for two reasons: 1) the 1969 point falls almost directly on the D2 curve, and 2) there is a recent year, 2008, which has almost exactly the same release from storage, and therefore I can use the accounting data from 2008 as an estimate of how accounting would be applied in 1969.

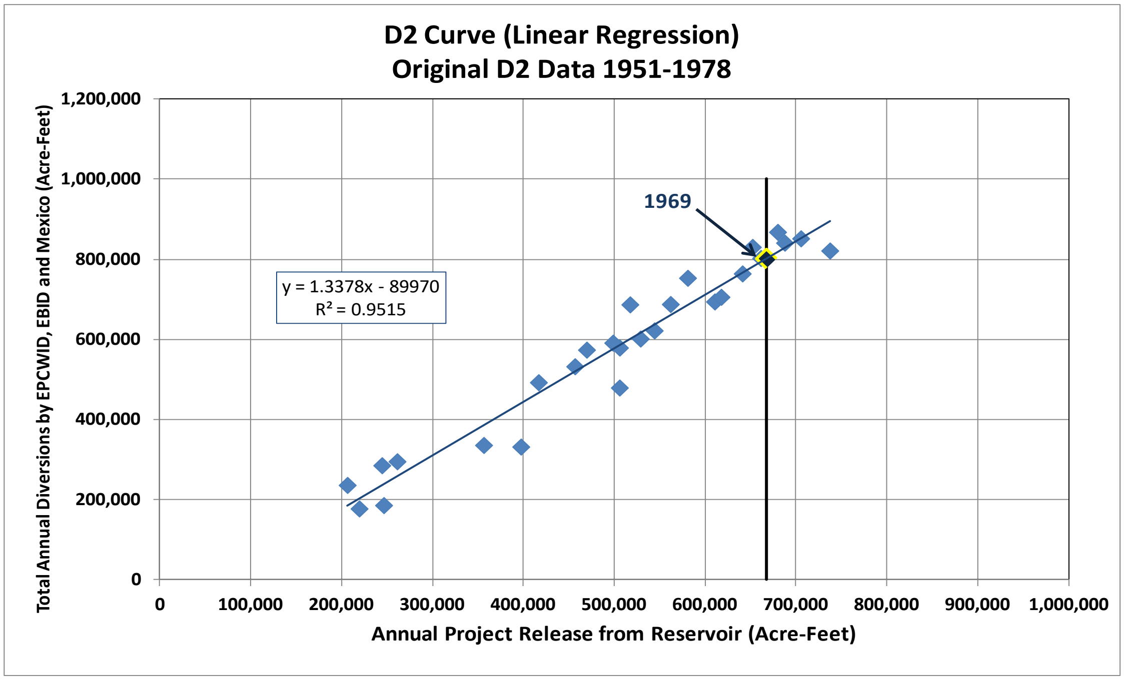
Figure 7.2 shows the D2 data set, highlighting the 1969 data point.

In Table 7.1 I provide the amount of diversion in 1969 that occurred outside of the irrigation season, from the analysis in Appendix E, and the amount of El Paso Valley drain flow that was included in the WDR data for 1969 from the compilation in Appendix A.

---

[104] Post-1978 Accounting rules provide for a District to be charged for the full release from Caballo during times when that District is the only one ordering water. Under these circumstances charged diversions may exceed total diversions. The effect of this provision was not significant during the period from 1979 through 2005, but has become very important during recent post-2005 years in which EPCWID has had a much larger allocation than EBID, and has diverted water over a much longer time period.

Figure 7.2. D2 Curve and D2 Data, Highlighting the 1969 data point



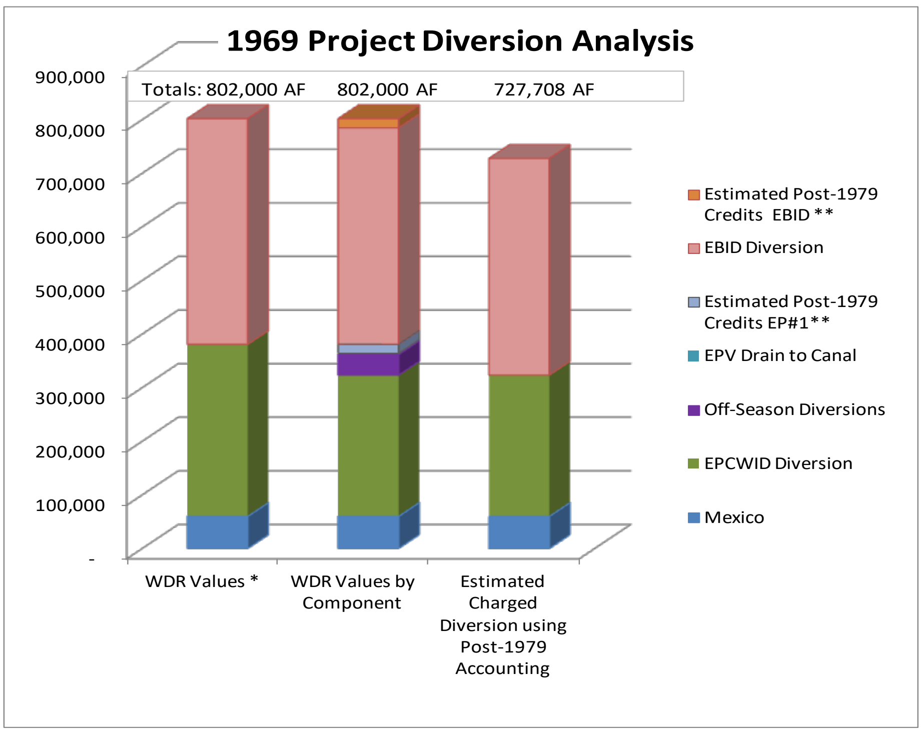
I constructed estimates of the accounting credits that would have been applied to 1968 using Post-1978 Accounting by looking at a post-1978 year with modern accounting and a similar Caballo release amount. In 1969 the release from Caballo was 668,000 AF, and the comparable year I chose is 2008, in which the Caballo release was 675,000 AF. In 2008 the total diversion (calculated using diversion data extracted from detailed District accounting records) is 699,000 AF, while the total Charged Diversion is 665,000 AF. The difference between those two numbers, 34,000 AF, is the net effect of the accounting credits in 2008, and in my analysis I split that amount 50/50 between the Districts.

These resulting diversion analysis for 1969 is tabulated in Table 7.1 and plotted in Figure 7.3.

Table 7.1. Analysis of 1968 Diversions as reported in Reclamation WRD forms

Analysis of 1969 WDR Diversions			
	WDR Values*	WDR Values by Component	Estimated Charged Diversion using Post-1978 Accounting
EBID Diversion	421,000	404,000	404,000
EPCWID Diversion	321,000	263,708	263,708
Mexico	60,000	60,000	60,000
Off-Season Diversions		38,000	
EPV Drain to Canal		2,292	
Estimated Post-1978 Credits EBID **		17,000	
Estimated Post-1978 Credits EP#1**		17,000	
Total	802,000	802,000	727,708
* WDR Values adjusted so that Mesilla Dam Diversions are split between the Districts Pro-Rata			
** Total Estimated Post-1978 Credits calculated as the difference between total diversions and Charged Diversion in a year of similar water supply to 1969. This total was split 50:50 between EBID and EPCWID			

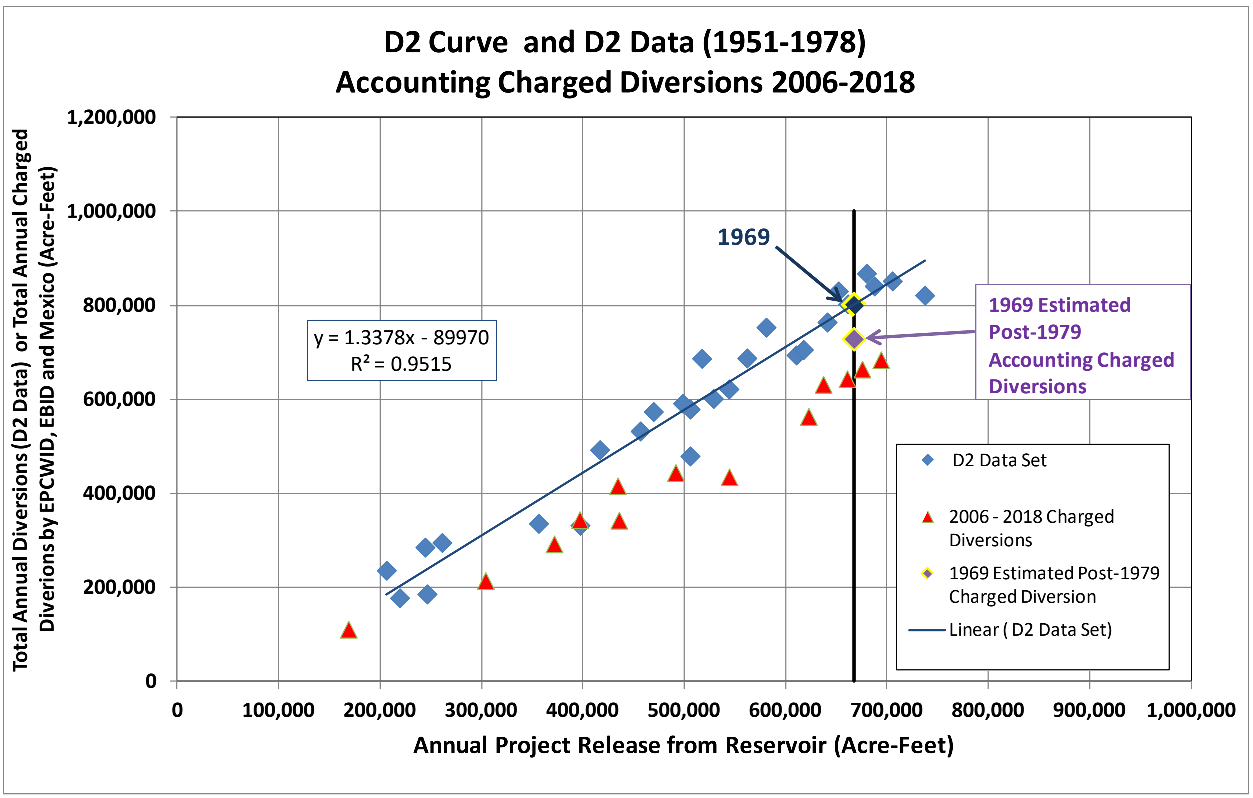
Figure 7.3. 1969 Project Diversion Analysis



The results shown in Figure 7.3 and Table 7.1 suggest that if Post-1978 Accounting rules were applied in 1969, the total Charged Diversions would have been 727,000 AF instead of the 802,000 AF actually diverted. The D1/D2 Allocation method allocates water based on actual diversion, and so for a release of 668,000 AF, would have allocated a total of 802,000 AF. The Charged Diversions associated with that release would only have totaled 727,000 AF, and so under Post-1978 Accounting, 1969 would have been 74,000 AF below the D2 Curve, as shown in Figure 7.4. I have attempted this analysis for other years and have achieved similar results.

For comparison, Charged Diversions for 2006 through 2018 are also shown on Figure 7.4. The data from my example years, 1969, suggests that a significant part of the negative discrepancy from the D2 Curve is the result of the difference in accounting between the D2 Period (1951-1978) and current accounting methods, and not related to New Mexico pumping and depletions.

Figure 7.4. D2 Curve and D2 Data, Accounting Data from 2006-2018, Illustrating effect of Post-1978 Accounting on 1969 Diversion Data



7.4 Decreased Recharge and Increased Depletions

Changes in depletion and recharge, including changes associated with the 2008 OA, are likely responsible for part of the negative departure from the D2 Curve. Increased depletions are associated with increased consumption of water for irrigation and municipal purposes, and increased pumping of groundwater for those purposes in New Mexico and Texas. Decreases in recharge are associated with increased irrigation efficiencies throughout the Project, and changes in Project allocation starting in 2006 which reduce the allocation of Project water to the upper part of the Project (above Courchesne).

Between 1979 and 2002 the Project enjoyed full-supply conditions, and Districts were allocated full supply amounts. As a result, irrigation well pumping was probably relatively low in both Districts until 2003, especially compared with the pumping levels during the preceding drought years. Both Districts, however, increased their acreages of high-demand crops, such as pecans, and worked to increase their irrigation efficiency, thus reducing return flow to the valley aquifer system, and reducing drain flows.[105] Furthermore, there was some increase in municipal groundwater pumping in both New Mexico and Texas. These changing conditions probably contribute to part of the negative departure from the D2 Curve during the 1979 through 2005 time period.

From 2006 through 2018, these factors (increased agricultural and municipal depletions) are aggravated by the change in water distribution caused by D3 Allocation. The water supply in EBID was sharply reduced to below irrigation demand, leading to a decrease in aquifer recharge from irrigation water and an increase in irrigation well pumping. As a result, drain flows above Courchesne were further depleted and the seepage from the Rio Grande was increased, leading to a decrease in Project performance and increased negative departure from the D2 Curve.

Agricultural and municipal depletions have increased throughout the Project, as farmers have improved irrigation efficiency, changed the crops they grow to adapt to market conditions, and worked to improve crop yield. This has occurred in the Rincon and Mesilla Valleys in New Mexico, and the Mesilla Valley of Texas. The changes in cropping and irrigation methods above Courchesne would impact drains and river losses above Courchesne, impacting Project performance. Changes in the El Paso Valley in Texas would have similar effects, and despite the changes in Project conveyance that have been made to mitigate losses, these changes may have, and may continue, to effect Project performance. It is my opinion that increases in irrigation efficiency, and associated increases in irrigation depletions, throughout the Project contributed to the departure from the D2 Curve observed since the mid-1990s.

Extensive groundwater pumping by Mexico and Texas in the Hueco Bolson have also contributed to reduction in drain flow and increased river losses in the El Paso Valley, impairing Project performance. Currently the Project diverts water from the Rio Grande in the El Paso Valley at American Dam, and not further downstream. While eliminating the EPCWID diversions from the Rio Grande further downstream may mitigate some of the negative effect of this groundwater pumping, it also eliminates past sources of supply, such as the El Paso Valley Drains. *See* Appendix C.

---

[105] For the impact of changes in agricultural practices on consumptive use of Project water, *see* David's Engineering Expert Report, 2019.

8 COMPARISON OF PROJECT ALLOCATION AND DELIVERY AMOUNTS UNDER D1/D2 ALLOCATION AND D3 ALLOCATION METHODS

In this section I will quantify the effects of the change in allocation methods from the 2006 change from D1/D2 Allocation to D3 Allocation, summarizing the allocation and delivery amounts starting in 1996 through 2018. I will show that:

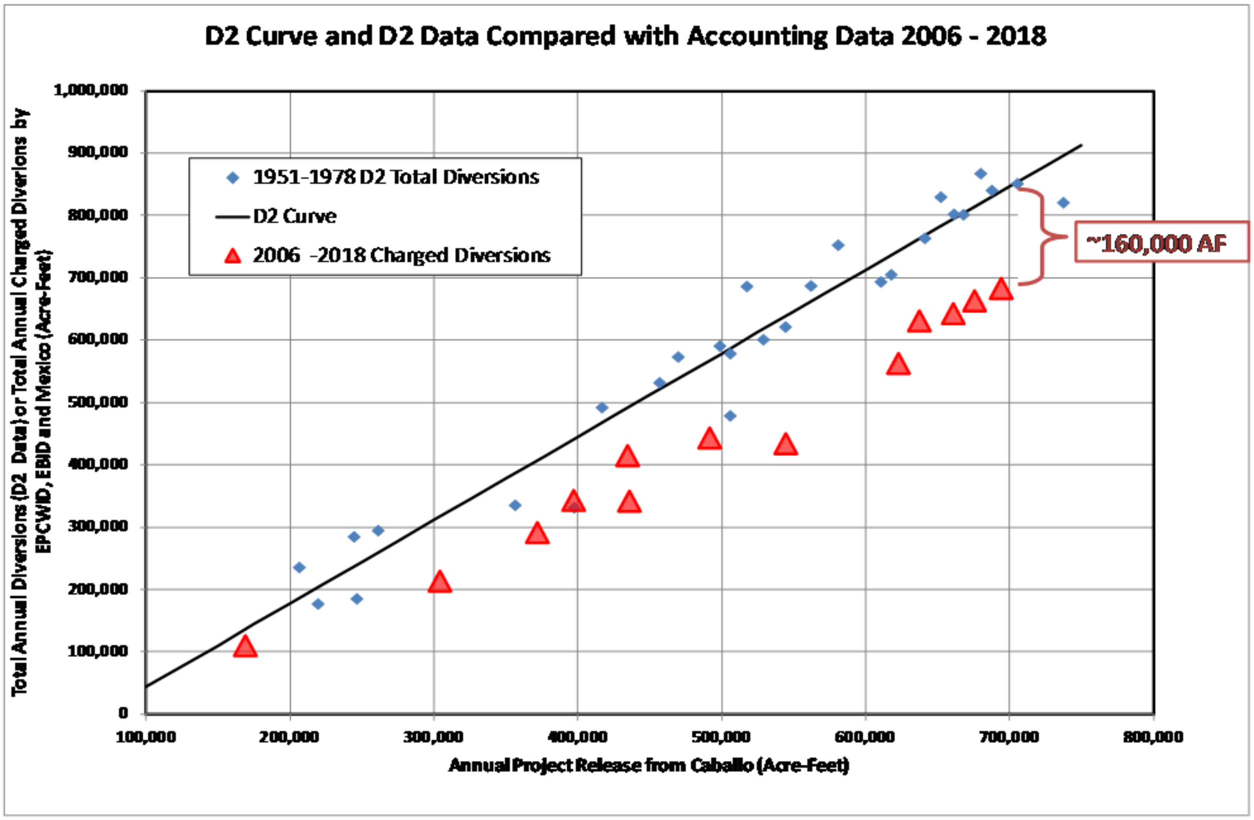
- Under D3 Allocation, EPCWID's current-year allocation (allocation apart from Carryover) in full-supply years has increased from 377,000 AF to an average of 391,500 AF. Including Carryover, EPWID's total annual allocation has exceeded 500,000 AF in some years. EPCWID Charged Diversions (water actually called for and received) in full-supply years under the 2008 OA have averaged less than 300,000 AF, leaving large amounts of unused, unneeded allocation which is "placed" in its Carryover account for its exclusive use the following year.

- By contrast, the D3 Allocation has reduced EBID's full-supply allocation and the amount of water Reclamation has diverted to EBID in full-supply years by approximately one-third (1/3). EBID's full-supply allocation has dropped from 495,000 AF to less than 330,000 AF; EBID's diversion in full-supply years decreased from an average of 464,000 AF (in 1996-2002) to an average of 312,000 AF (2007-2009).

In order to compare the allocation and delivery amounts under the different allocation methods, it is necessary to eliminate the effects of variation in water supply. Allocations and deliveries are always smaller under low-supply conditions than under full-supply conditions, regardless of allocation method. In order to eliminate supply-caused variability, I compare years in which the Project had a full supply available.

Figure 8.1 shows the D2 Curve and D2 data plotted together with Charged Diversion data from the D3 Allocation period (2006-2018). These data indicate that in years of relatively high supply (that is, when Caballo release is ~700,000 AF), the accounting data show a negative departure of approximately 160,000 AF from the D2 Curve. In the following section I compare actual allocation and diversion data from full-supply years.

Figure 8.1. Project Accounting Data 2006 – 2018 (Charged deliveries to EBID and EPCWID plus the delivery to Mexico) Plotted together with the D2 Curve



8.1 SELECTION OF FULL-SUPPLY YEARS FOR COMPARISON

Prior to the implementation of D3 Allocation in 2006, full-supply years and full-supply allocation amounts are easy to determine. The D1/D2 method, as documented in the WSAP, defines a full supply allocation to EBID as 494,979 AF and to EPCWID as 376,862 AF, and those amounts were allocated to those Districts from 1990 through 2002, and in 2005.[106] Furthermore, Mexico's full-supply allocation is 60,000 AF in full-supply years, and Mexico was allocated that amount from 1979 through 2002, and in 2005.

Following the adoption of D3 Allocation, allocation becomes more complex. The 2008 OA extended the D2 Curve, and EPCWID's full-supply allocation is now about 388,000 AF.[107] Each District has both a "Current-year Allocation" which does not include Carryover, and a "Total Allocation" which is the sum of Current-year Allocation plus Carryover. On paper, a District's Total Allocation under the 2008 OA can

---

[106] 1979 – 1989 are described by Reclamation as full supply years also, but the amounts allocated to the Districts are slightly different, reflecting the evolution of the D1/D2 methodology before the adoption of the WSAP.

[107] EBID's full-supply allocation is now considered to be approximately 510,000 AF, but this is irrelevant to the current discussion because EBID's allocation has come nowhere near this amount since 2006.

exceed that District's full-supply allocation, even in years for which Project storage cannot support a full-supply release. Furthermore, because Carryover is sequestered out of Usable Water before calculating Current-year Allocation, it is possible for those Current-year Allocations to be lower than full-supply even when the Project has a full supply available to it.

In order to define full-supply years from 2006 through 2018, I choose years in which EPCWID's Current-year Allocation exceeds 360,000 AF. Based on this criterion, the years tabulated in Table 8.1 constitute the full-supply years for the time period in which D3 Allocation has been applied.[108]

Table 8.1. Reported Usable Water, EPCWID Current-Year Allocation and Mexican Allocation for Years Designated "Full-Supply" Under D3 Allocation

Year	Total Usable Water Available for Release (Allocation Spreadsheet, Row 8)	EPCWID's current-year allocation	Mexican Allocation
2007	Unknown	367,291 AF	58,769 AF
2008	1,118,436 AF	405,073 AF	60,000 AF
2009	1,010,021 AF	402,159 AF	53,386 AF
2017	876,901 AF	401,842 AF	60,000 AF

For comparison, in the following section, I show Project allocation and delivery data for the 10 years before the initiation of D3 Allocation: 1996 through 2005, along with the allocation and delivery data generated by D3 Allocation from 2006-2018.

To quantify this comparison, I have calculated the averages of the allocation and delivery for full-supply years 1996-2002 (pre-D3 Allocation full-supply years) and years 2007-2010 (D3 Allocation full-supply years).

8.2 Comparison of Current-Year Allocation 1996 – 2018

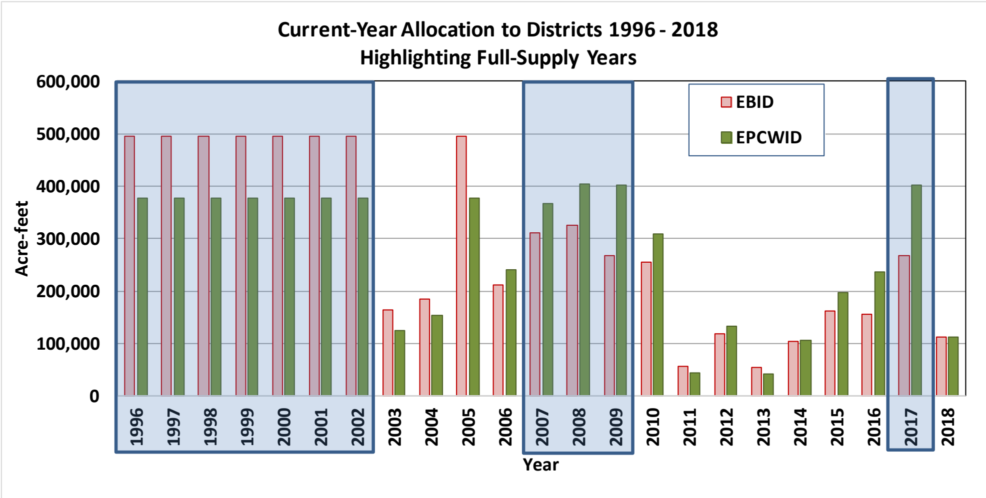
Figure 8.2 shows Current-year Allocation for the years 1996 through 2018 from Reclamation allocation and accounting records. Current-year Allocation is calculated as the total annual District allocation for each year, minus any allocation carried over from the previous years. Prior to the initiation of Carryover in 2007, Current-year Allocation was equal to Total Allocation.

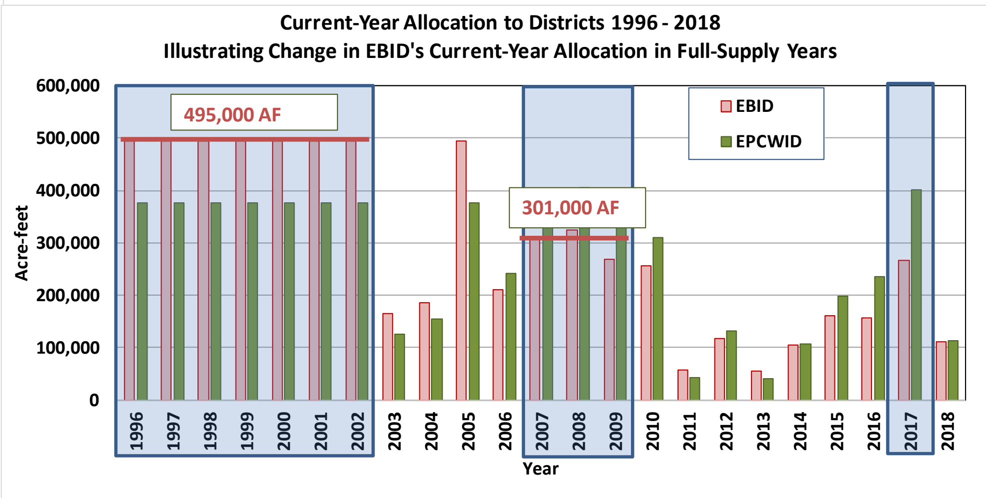
[108] Arguably, 2010 could be considered a full-supply year as well, since according to the Project allocation report for that year the amount of Usable Water Available for Release was 888,423 AF. Because EPCWID's large Carryover allocation (232,915 AF) took up a substantial amount of the Usable Water, there was not enough remaining Usable Water available for a full-supply allocation. As a result, EPCWID's 2010 Current-year Allocation was only 309,515 AF (or 291,905 AF excluding ACE Credit), which was significantly less than a full supply allocation. However, EPCWID was able to supplement this allocation with the full value of its Carryover account, 232,914 AF, for a Total Allocation in 2010 of 532,158 AF. By contrast, EBID's Total Allocation for the same year was 305,870 AF.

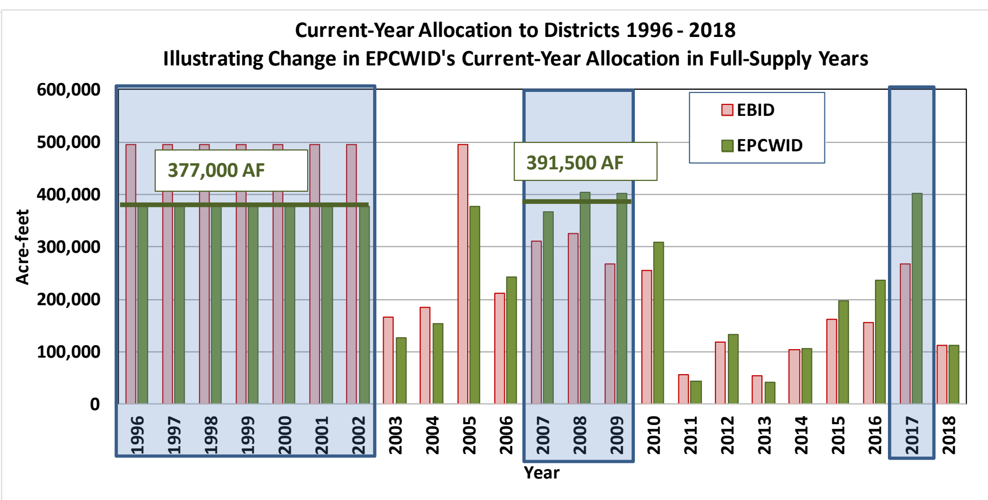
Figure 8.2 has three parts: The upper graph shows the Current-year Allocation data with full-supply years highlighted. The middle graph shows the same data, with the average of EBID's Current-year Allocations shown for the periods 1996 through 2002 and for 2007 through 2009. The lower graph in Figure 8.2 shows the same data, with the average of EPCWID's Current-year Allocation shown for the periods 1996 through 2002 and for 2007 through 2009. (Figures 8.3 and 8.4 are similarly organized for Total Allocation and Charged Diversions).

- The middle graph in Figure 8.2 shows that in full-supply years EBID's Current-year Allocation has decreased from 495,000 AF to an average of 301,000 AF under D3 Allocation. This decrease is a result of using the Diversion Ratio to calculate EBID's allocation.
- The lower graph in Figure 8.2 shows that in full-supply years EPCWID's Current-year Allocation has increased from 377,000 AF to 391,500 AF under D3 Allocation. This increase is the effect of two factors: 1) the extension of the D2 Curve, increasing the amount of a full-supply allocation under the modified D2 Curve, and 2) application of the ACE Credit, which had not been awarded to EPWID prior to 2003.

Figure 8.2. Current-Year Allocation Data for EBID and EPCWID, 1990 – 2018





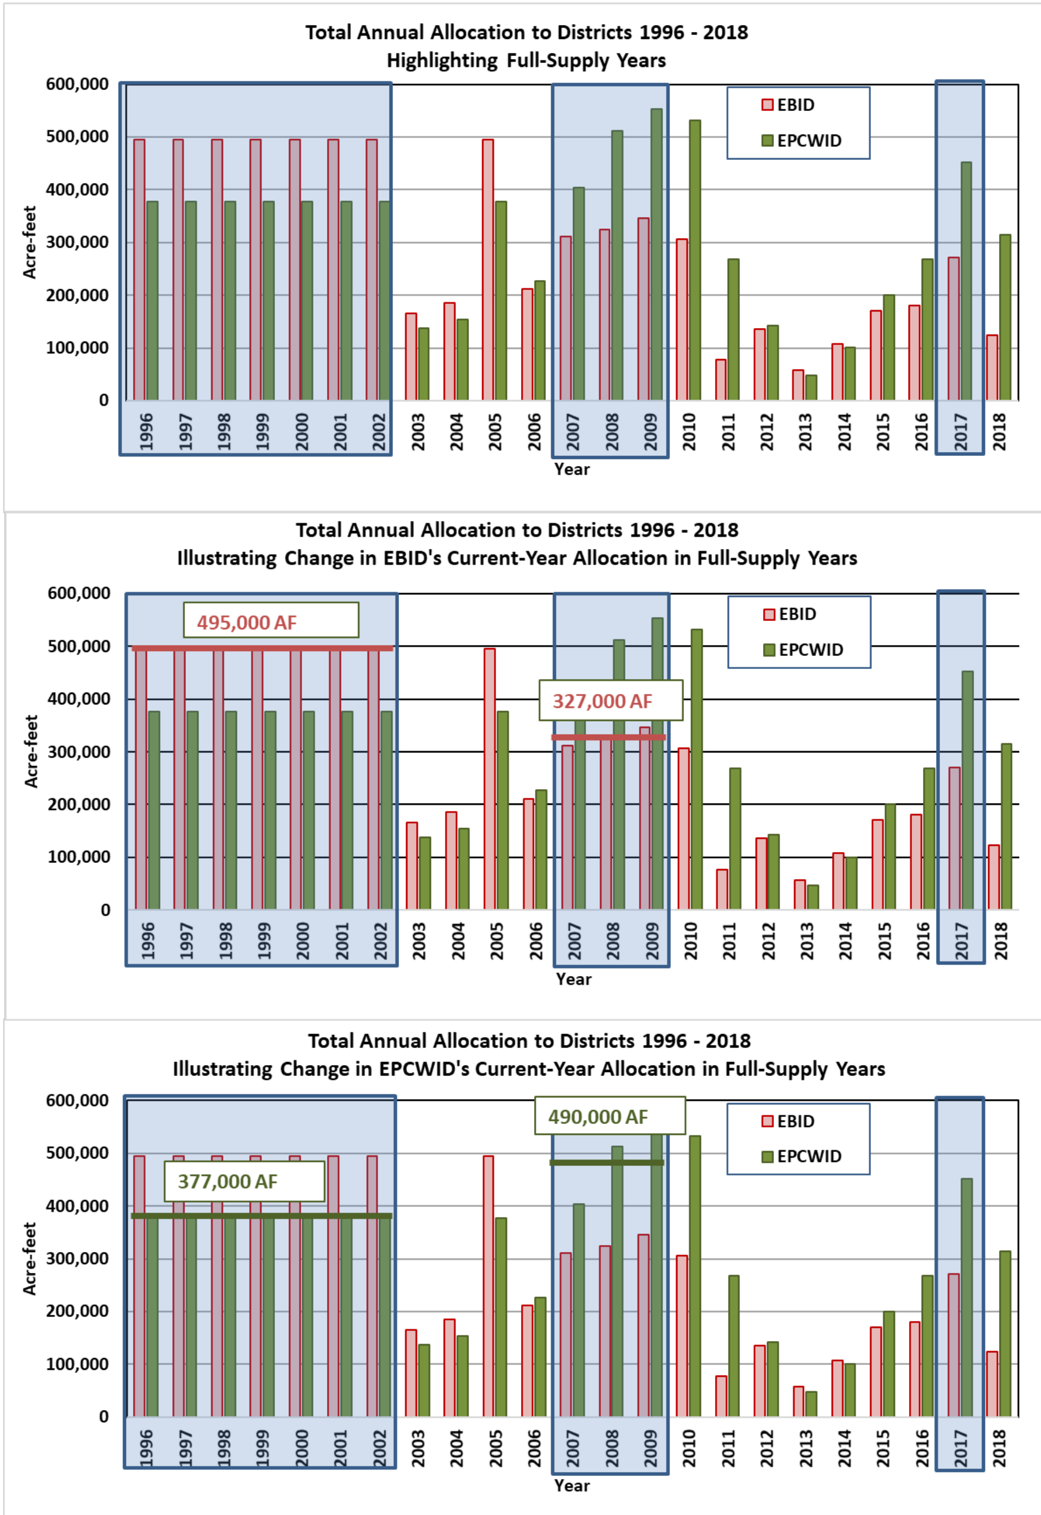


8.3 Comparison of Total Allocation: 1996 – 2018

The graphs in Figure 8.3 show Total Allocation (including Carryover) for the years 1996 through 2018 from Reclamation allocation and accounting records. Total Allocation included the Current-year Allocation of supply, the ACE Credit (for EPCWID) and any allocation carried over from the previous year.

- The middle graph in Figure 8.3 shows that in full-supply years, EBID's Total Allocation has decreased from 495,000 AF to an average of 327,000 AF under D3 Allocation. This decrease is a result of using the Diversion Ratio to calculate EBID's allocation under D3 Allocation. Comparison of the middle graphs of Figures 8.3 and 8.2 suggests that the benefit of Carryover to EBID in full-supply years has been an average of 26,000 AF.
- The lower graph in Figure 8.3 shows that in full-supply years, EPCWID's allocation has increased from 377,000 AF to an average of 490,000 AF. This large increase is the benefit of Carryover to EPCWID. A significant amount of EPCWID's large Total Allocation represents water that has been carried over for multiple years, and as such, does not reflect the amounts of water that EPCWID has actually been delivered or has diverted. The amounts the Districts were actually delivered are shown in the following section.

Figure 8.3. Total Allocation Data (including Carryover) for EBID and EPCWID 1990 – 2018



8.4 COMPARISON OF AMOUNTS DELIVERED (CHARGED DIVERSIONS) TO DISTRICTS 1996 – 2018

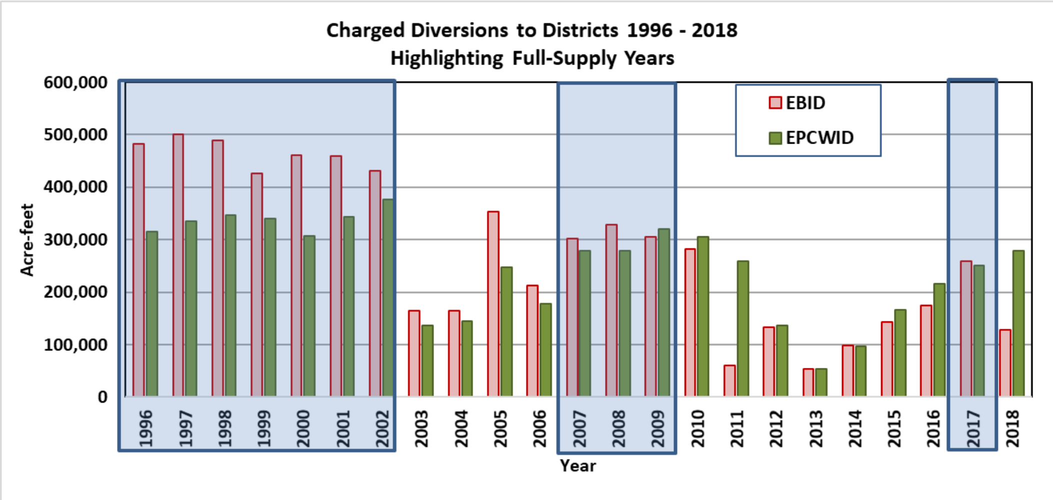
The graphs in Figure 8.4 show the Charged Diversions to each District for the years 1996 through 2018 from Reclamation allocation and accounting records. Charged Diversions (or allocation charges) reflect the amounts of water actually delivered to and diverted by the District, accounted for in accordance with the Project operations manual or operational procedures, including accounting credits.

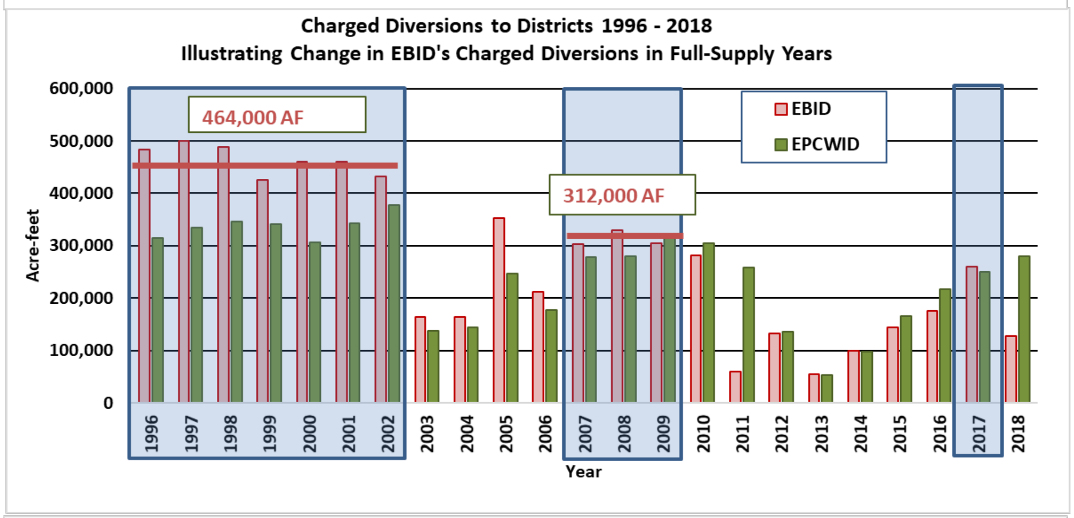
- The middle graph in Figure 8.4 shows that the average annual amount that EBID has received (its Charged Diversions) has decreased from 464,000 AF to 312,000 AF under D3 Allocation. This decrease in EBID's Charged Diversion reflects the decrease in EBID's allocation. For the time period 2007-2009, EBID's average total allocation was 327,000 AF. In some years, EBID's final allocation amount was not determined until after that District had ceased to distribute surface water, and therefore some part of EBIDs' allocation could not be ordered or used during that year.

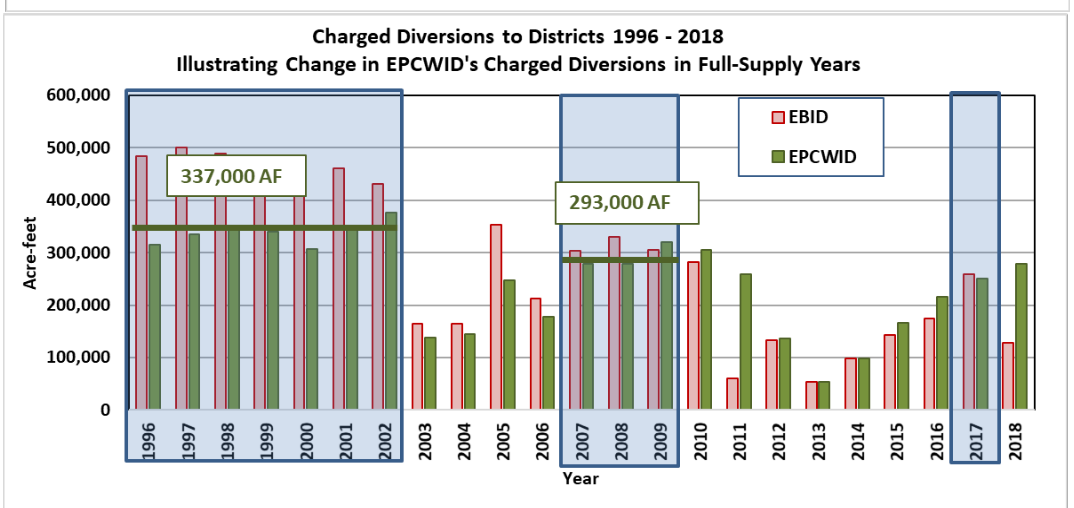
- The lower graph in Figure 8.4 shows that the average annual amount that EPCWID has received (its Charged Diversion) has also decreased from 337,000 AF to 292,000 AF. EPCWID's low Charged Diversions may reflect decreased demand for water within EPCWID, or the use of treated effluent for which EPCWID is not charged in Project accounting. Alternatively, EPCWID's Charged Diversion amounts may reflect conservation of water so that EPCWID can make use of its Carryover account to improve its supply during drought and thus provide a more reliable municipal supply to El Paso Water Utility.

  Note that even prior to the initiation of D3 Allocation in 2006 and Carryover in 2007, EPCWID's Charged Diversion in full supply years only averaged 337,000 AF out of a total allocation of 377,000 AF. Given Reclamation's operating procedures described in Section 2.2 of this report, EPCWID was entitled to order Project water as long as it had allocation remaining. Furthermore, Reclamation's procedure is, and has been historically, to adjust the gates of Caballo as necessary (given current flow conditions at each diversion heading) to ensure that all water ordered is delivered. Therefore, EPCWID's failure to divert its entire allocation in these years indicates that EPCWID's demand was significantly less than their full-supply allocation.

Figure 8.4. Delivery Data (Total Charged Diversions) for EBID and EPCWID 1990 – 2018







9 EFFECTS OF 2008 OA REDUCTION IN EBID ALLOCATION

In this Section, I demonstrate that because the 2008 OA has reduced EBID's share of Project supply during full-supply years below the amount needed to supply EBID's lands, EBID farmers have increased groundwater pumping. In addition, the reduction in EBID's share of Project water has reduced the amount of recharge to the aquifer in the Rincon and Mesilla Valleys. As a result, following implementation of D3 Allocation, shallow groundwater levels have dropped during low supply years but have not recovered in the full-supply years that follow. The combined effect of reduced recharge and increased groundwater pumping under the 2008 OA is that the groundwater budget of the Rincon and Mesilla aquifer system has been reduced by more than 100,000 AF in full-supply years. Thus, while shallow groundwater levels in the Rincon and Mesilla Valleys historically responded to surface water supply variation and recovered losses in full supply years, they no longer have the ability to recover, to the detriment of the aquifer and the Project as a whole.

9.1 EBID SURFACE WATER SUPPLY IS INSUFFICIENT TO MEET DEMAND

As previously discussed, D3 Allocation plus Carryover has resulted in a decrease in EBID's full-supply year allocation from 495,000 AF to an average of approximately 330,000 AF. As a direct result of this loss of Project water, EBID's full-supply year diversions have decreased from an average of 464,000 AF/Y to an average of 312,000 AF/Y (*see* Figure 8.4). Furthermore, EBID's farm deliveries in full-supply years decreased from approximately 250,000 AF before 2006, to less than 190,000 AF in 2008 and 2009, and 140,000 in 2017 (the difference between EBID's total diversion and its total farm delivery represents canal losses and canal waste).

EBID's diversions and farm deliveries in the full-supply years before 2006 constitute a rough estimate of EBID's irrigation demand. It is reasonable to conclude that the amounts of Project water allocated under the 2008 OA is insufficient to supply EBID's irrigation demand, even in full-supply years. Under the 2008 OA, a full-supply year for the Project is no longer a full-supply year for EBID.

9.2 EBID GROUNDWATER IRRIGATION PUMPING INCREASE

Because EBID's share of Project water is no longer adequate to meet EBID's irrigation demands, EBID farmers have become increasingly dependent on groundwater pumping. Estimates of irrigation pumping prior to 2009 have been made based on irrigation demands. These estimates suggest that New Mexico's irrigation well pumping in full-supply years of the 1980s and early 1990s averaged 60,000 AF/Y.[109] By contrast, New Mexico irrigation well meter data since 2009 shows irrigation well pumping of 131,000 AF to 157,000 AF in recent years of full Project Supply.

9.3 DECREASE IN AQUIFER RECHARGE FROM CANAL SEEPAGE

The EBID conveyance system is still largely unlined, and seepage from these canals is one of the main sources of recharge to the alluvial aquifer of the Rincon and Mesilla Valleys. Analysis of Project delivery

[109] *See* Spronk Water Engineers, Inc. Expert Report, 2019.

records, and modeling studies, suggest that, on average, aquifer recharge from canal seepage is equal to about 30% to 40% of the water diverted at EBID canal headings.

Since EBID's average diversion in full-supply years has dropped from 464,000 AF/Y to 312,000 AF/Y, this represents a decrease in canal seepage recharge of 46,000 AF/Y to 61,000 AF/Y; this amount of water previously recharged the aquifer and the impact of that loss is described below.

9.4 Groundwater Budget in Mesilla and Rincon Basins

The change in allocation procedures associated with the 2008 OA have led to a decrease of aquifer recharge (from canal seepage) and an increase in irrigation well pumping. These factors have caused a substantial change in the water budget of the Rincon and Mesilla aquifer system. I estimate, based on my experience modeling the Rincon and Mesilla aquifer system, that these factors combine to negatively impact the aquifer's water budget by well over 100,000 AF in each full-supply year (corresponding to a decrease in canal-seepage recharge of about 50,000 AF/Y and an increase in irrigation well pumping of more than 50,000 AF/Y).

A water budget of an aquifer can, in some ways, be compared to a person's financial budget. The decrease in aquifer recharge is comparable to a decrease in salary, while the increase in groundwater pumping is comparable to an increase in rent.

Based on my experience modeling the Rincon and Mesilla aquifer systems, before 2006 the aquifer budget of the Rincon and Mesilla basins was positive in full-supply years (more recharge than pumping) and negative in low-supply years (more pumping than recharge). Large amount of recharge from canal seepage and on-farm return flow (deep percolation) in full-supply years far exceeded groundwater pumping, allowing the aquifer to recover after periods of low supply, and supplying water to drains.[110] However, the introduction of D3 Allocation, and the adoption of the 2008 OA, has reduced the aquifer budget in full-supply years by more than 100,000 AF, greatly reducing the opportunity for aquifer recovery after drought.

Under the 2008 OA, it is possible that even in full-supply years groundwater pumping in the Rincon and Mesilla Basins will exceed the recharge to these basins. As a result, the aquifer system cannot recover in the full-supply years that follow times of drought. There is evidence that this has, in fact, occurred. The groundwater level plots shown in Section 9.5 show that since D3 Allocation was implemented in 2006 groundwater levels no longer rebound in full-supply years.

The equivalent financial comparison would be if a person's rent and other expenses always exceed their income. If that happens, their bank account would show a continual decrease. In the case of the Rio Grande aquifer system, groundwater levels will continue to decrease under current Project operations conditions.

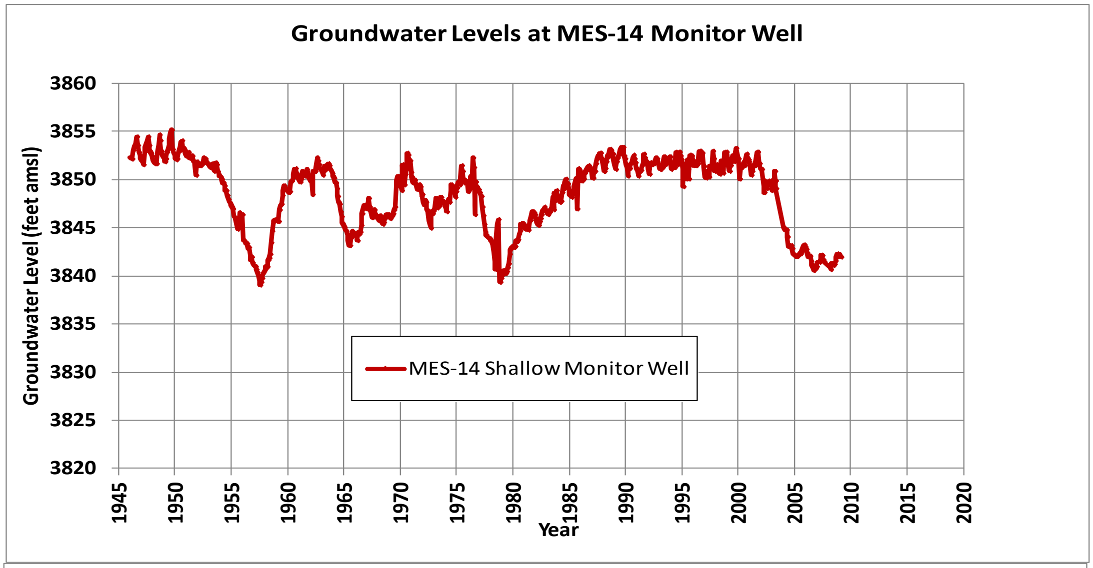
[110] S.S. Papadopulos & Associates, Inc., Summary Documentation of the Calibrated Groundwater Flow Model for the Lower Rio Grande Basin, LRG_2007.

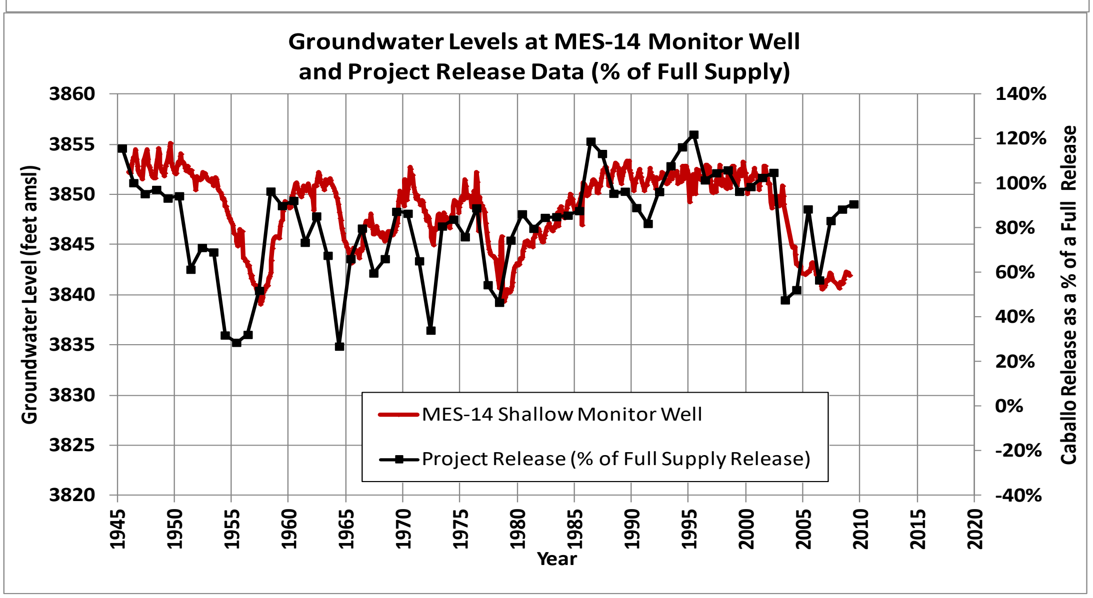
9.5 GROUNDWATER LEVELS IN MESILLA BASIN

As demonstrated in Figures 9.1 and 9.3, the historical response of groundwater levels in the 1950s, 1960s, and 1970s to changing Project water supply was that during times of low Project release, groundwater levels declined, and when the Project released full-supply amounts, groundwater levels would recover. The data I analyze herein suggest that the water budget of the Mesilla Valley aquifer has been changed by D3 Allocation. Now even when the Project has a full supply, groundwater pumping in the Mesilla Basin, by both New Mexico and Texas, may exceed the recharge to the aquifer, so that groundwater levels cannot recover following drought.

This response can be observed during the variable supply conditions of the 1950s, 1960s and 1970s as change in groundwater levels tracking Project releases. During the extended full-supply period of the 1980s and 1990s, groundwater levels recovered, and remained high until the first year of reduced supply in 2003. Groundwater levels dropped in 2003 and 2004, responding to low-supply conditions. Project releases in 2007 through 2009 were relatively high, exceeding 80% of a full-supply release, but groundwater levels do not recover from the lower levels they had reached in 2004.

Figure 9.1. Groundwater Levels at EBID Shallow Monitor Well, 1945-2009. Upper Plot: Historical Groundwater Levels; Lower Plot: Groundwater Levels plotted with Project Release % of a Full-Supply Release (763,842 AF)[111]





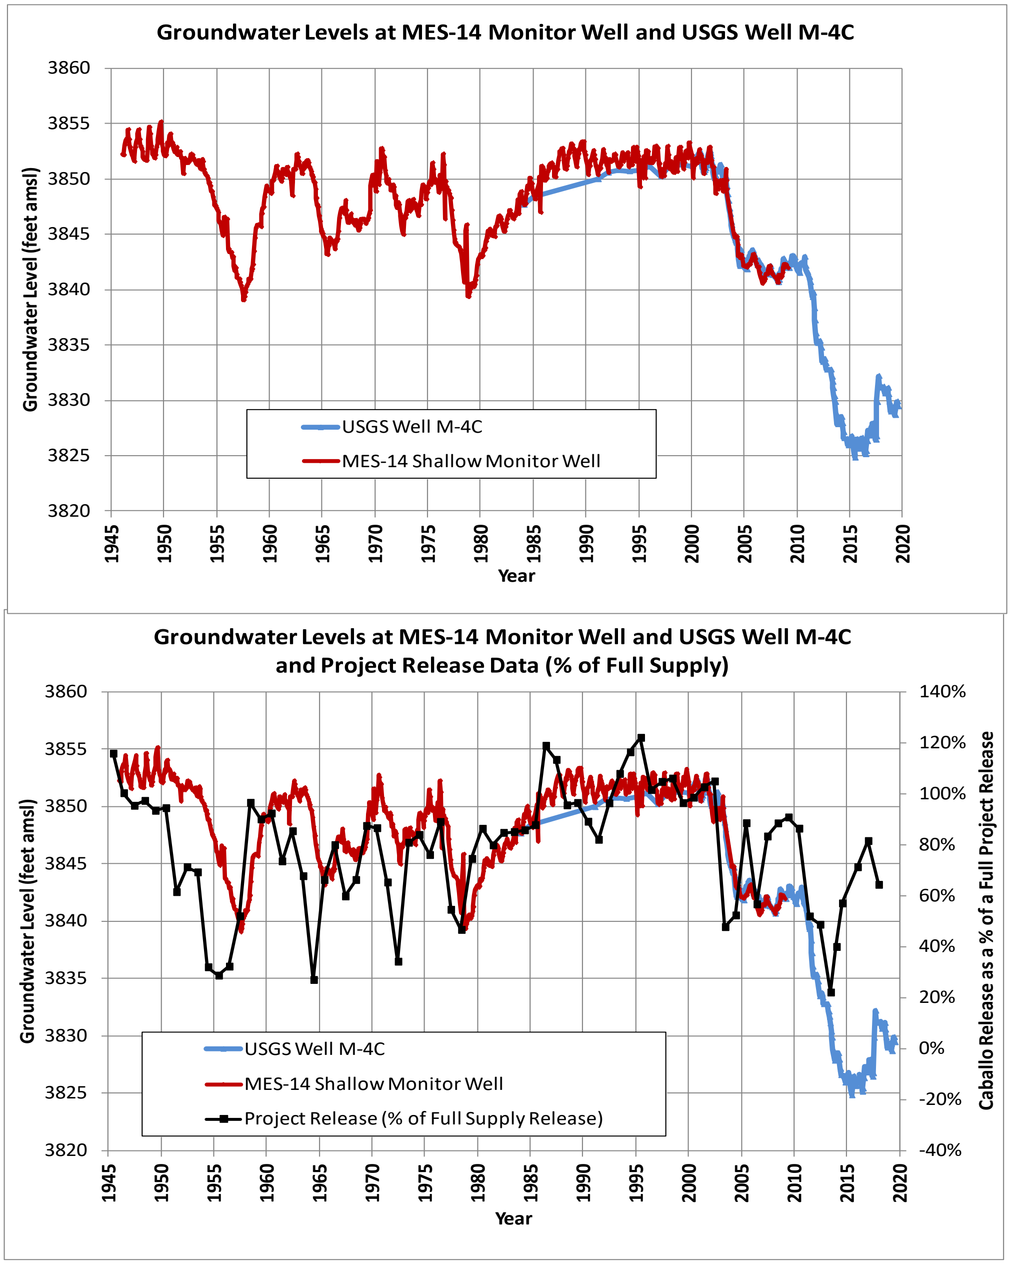
[111] Figure 9.1 is a water level plot from a Reclamation/EBID shallow groundwater monitor well (MES-14 (T24S R02E Section 09.433)) in the central Mesilla Valley, located south of Las Cruces (location indicated in Figure 9.2). This well was plugged in 2009, which is the end of the period of record. The lower graph in Figure 9.1 shows this groundwater level data plotted together with the annual Project release from Caballo, expressed as a percentage of a full-supply release (763, 842 AF).

Figure 9.2. Location Map for Shallow Monitor Wells/Piezometers MES-14 and M-4C (wells referenced in Figures 9.1 and 9.3)

While MES-14 (the well used for the Figure 9.1 data) was taken out of service in 2009, it is located very close to a shallow USGS monitor well: M-4C, which can be used to extend its record.[112] In Figure 9.3 I have combined the data from these monitor wells with Project release data, as before, including data through 2018. Data from both monitor wells shows the same response to low supply conditions in 2003 and 2004, and both show a failure to recover in 2007-2009. Groundwater levels in the USGS well, M-4C, remain low in 2010, despite a relatively high release from Caballo. In 2011, 2012 and 2013, Project releases are below 50%, and groundwater levels drop even more, below the levels observed in 2004. Higher releases in 2016 and 2017 correspond with some level of groundwater recovery, but levels still remain below the lows of 2004, and far below the groundwater levels obtaining in full-supply years prior to D3 Allocation.

[112] The M-4C USGS well has a shorter period of record, having been installed in the early 1980s, but it continues to be used as monitor well today. When the data from these two wells (MES-14 and M-4C) are plotted together, the groundwater levels coincide during the period of overlap, indicating that both wells provide compatible data.

Figure 9.3. Groundwater Levels at EBID Shallow Monitor Wells. Upper Plot: Historical Groundwater Levels; Lower Plot: Groundwater Levels plotted with Project Release % of a Full-Supply Release (763,800 AF)



The wells plotted in Figure 9.3 (MES-14 and M-4C) provide one of the most complete, long-term, high-quality sets of groundwater level data available for the LRG. These wells are located in an area of heavy agricultural water use, where the highest levels of observed groundwater level decline have occurred. Groundwater level data from a number of other Mesilla Valley wells show a similar trend, although the magnitude of groundwater level declines may be smaller. That is, groundwater levels track Project releases until about 2005, and then groundwater levels drop in response to low supply releases but do not recover in subsequent years of near-full supply release.

These data (and data from other monitor wells in the Mesilla Valley) suggest that the water budget of the Mesilla Valley aquifer has been changed by D3 Allocation. Now even when the Project has a full supply, groundwater pumping in the Mesilla Basin, by both New Mexico and Texas, exceeds the recharge to the aquifer so that groundwater levels cannot recover following drought.

In some areas of the Mesilla Valley, monitor wells show a much more muted response to Project Supply conditions, both historically and in recent years. These wells are generally at the northern end of the Mesilla Valley, or west of the Rio Grande, separated from the largest parts of the irrigated lands. The main agricultural area of the Mesilla Valley, from near the town of Dona Ana in the north to the town Mesquite in the south, show a strong response to low supply conditions, and a lack of any groundwater level recovery after 2006 and the implementation of D3 Allocation.

Data from some of the monitor wells in the Rincon Valley show similar trends to those plotted in Figures 9.1 and 9.3 but most Rincon Valley monitor wells show much smaller responses both to past low supply conditions, and to recent variations in supply. The different level of groundwater level response in the Rincon may relate to differences in water use or a difference in aquifer properties.

9.6 Effects of 2008 OA on Surface Water

9.6.1 Rio Grande Seepage

Recent declines in groundwater levels in the Rincon and Mesilla Valleys can impact the flows in the Rio Grande itself. In general, where groundwater levels are extremely shallow, groundwater may discharge into a river (sometimes in the form of springs), creating a "gaining reach" in that river. See, e.g., Figure 3.3. If those groundwater levels decline, the process reverses and results in seepage losses from the river into the groundwater. Further groundwater declines will increase seepage losses from the river, although it is likely that at some point the seepage rate reaches a maximum value, and does not increase further even if groundwater levels continue to decline.

The Rio Grande in the Rincon and Mesilla Valleys has historically been a losing reach, meaning water seeps from the river into the groundwater, although some sub-reaches have been observed to gain water. The southernmost reach of the Rio Grande in the Mesilla Valley, south of Canutillo, has historically been a gaining reach, probably because the aquifer system itself becomes very thin near the El Paso Narrows, and groundwater that had been flowing south at depth is forced upward toward the surface.

USGS seepage studies of the Rio Grande show that seepage losses in the Rio Grande have increased in recent years, and the length of the gaining reach has decreased.[113] This increase in Rio Grande seepage

[113] Briody, A.C., Robertson, A.J. and N. Thomas. *Seepage Investigation of the Rio Grande from below Leasburg Dam, Leasburg, NM, to above American Dam, El Paso, Texas*, 2015. USGS SIR 2016-5011.

makes it more difficult to transport Project water to the lower end of the Project, reducing Project performance, and reducing the Diversion Ratio. The changes in the groundwater budget in the Rincon and Mesilla basins caused by D3 Allocation, and the resulting declines in groundwater levels is most likely contributing to this increase in river losses, and resulting decrease in Project performance.

9.6.2 Drain Flows

The declining groundwater levels in the Rincon and Mesilla Valleys also negatively impact the flows in Project drains. LRG drains were constructed in order to intersect the groundwater table and convey excess groundwater away to the Rio Grande. (*See* Sections 3.3, 5.2 and Appendix C.) As groundwater levels have declined, drain flows have decreased, and in some cases stopped altogether. All of the drains in the Rincon Valley have been largely dry since 2003. Some drains in the Mesilla Valley are also dry, and others have been flowing at greatly reduced levels in recent years. Similar conditions with respect to drain flow obtain in the El Paso Valley, where large amount of municipal groundwater pumping, combined with irrigation well pumping have reduced groundwater levels and depleted drain flows. (*See* Appendix C.) This decrease in drain flow makes it necessary to release more water from storage to fill orders in the lower end of the Project, reducing Project performance, and reducing the Project Diversion Ratio from which the EBID allocation is derived under the 2008 OA.

9.7 Effect of 2008 OA on Project Performance

The net effect of the 2008 OA is to reduce the supply of Project water within EBID, leading to a decrease in aquifer recharge, and to increase in the amounts of groundwater pumping necessary to supply Project lands. These changes negatively impact the aquifer system in the Rincon and Mesilla basins, leading to a decline in groundwater levels, increased losses from the Rio Grande, and decreased drain flows. As a result, increasing amounts of water must be released from Caballo in order to fulfill orders for Project water in the lower end of the Project, thus reducing Project performance and reducing the Project Diversion Ratio.

This reduction in Diversion Ratio then causes a further reduction in EBID's allocation under D3 Allocation. In effect, D3 Allocation and the 2008 OA have created a "vicious cycle", in which the response to reduced Project performance (i.e. reductions in EBID's allocation) causes further degradation of Project performance.

10 ACRONYMS AND GLOSSARY

<u>Note:</u> This Glossary and Acronyms appendix is intended solely as an aid and reference for the purpose of understanding the complex terms contained in this Report and is not intended to have a separate legal effect.

ACRONYMS

AF	Acre foot
AF/acre OR AF/A	Acre feet per acre
BOR	U. S. Bureau of Reclamation
COE	U.S. Army Corps of Engineers
EBID	Elephant Butte Irrigation District
EBR	Elephant Butte Reservoir
EP#1	El Paso County Water Improvement District #1
EPA	U.S. Environmental Protection Agency
EPCWID	El Paso County Water Improvement District #1
EPWU	El Paso Water Utility
ET	Evapotranspiration
GIS	Geographic Information Systems
HCCRD	Hudspeth County Conservation and Reclamation District #1
IBWC	International Boundary and Water Commission
ISC	(New Mexico) Interstate Stream Commission
Juarez	Juarez Valley Irrigation District (Mexico)
LRG	Lower Rio Grande River (for NM, this is the Rio Grande below Elephant Butte; for TX, this is the Rio Grande much further south near the Gulf of Mexico)
LUTA	Land Use Trend Analysis
MRG	Middle Rio Grande
MRGCD	Middle Rio Grande Conservancy District
NEXRAD	NEXt Generation Weather RADar System
NMISC	New Mexico Interstate Stream Commission
NMOSE	New Mexico Office of the State Engineer
NRCS	Natural Resources Conservation Service
OSE	(New Mexico) Office of the State Engineer
RGC	Rio Grande Compact
RGCC	Rio Grande Compact Commission
RGP	Rio Grande Project
TEQCEQ	Texas Commission on Environmental Quality Commission

URG	Upper Rio Grande (for NM, this is the Rio Grande above the Otowi Gage; for TX, this is the Rio Grande within the Texas area of the RGP)
URGWOM	Upper Rio Grande Water Operations Model
USBR	U. S. Bureau of Reclamation
USGS	U. S. Geological Survey
WDR	Water Distribution Report

GLOSSARY

57:43 - The historic delivery ratio of Project water to EBID and EPCWID, respectively, from 1915 to 2006.

A

Acre Feet (AF) - A standard volumetric measurement of water (1 acre of area covered in water 1 foot deep); this comprises 325,851 gallons.

Accounting: Compact: A system of post-fact records summarizing and tabulations of the annual credits and debits of Colorado and New Mexico, and releases and spill from Project Storage under the Compact.

Accounting: Project: A system of post-fact records and tabulations of the amount of Project water diverted by EBID and EPCWID in accordance with established procedures.

Acre feet per year (AF/Y) - The flow or diversion of 1 Acre Foot of water over the course of a year; a measurement of the rate of flow of water, and allocation amount or a diversion amount.

Actual Release - The amount of Usable Water released in any calendar year from Project Storage. (Use: COMPACT and PROJECT accounting term.)

Allocation Process- Prospective /advance determination of the amount of water (in AF) each District (and Mexico) is entitled to each year. Note that each year not all water allocated is actually ordered or delivered. (Use: PROJECT allocation term.)

Allotment: The amount of water, in terms of AF/acre, that Reclamation or the Districts determine that each authorized Project acre is entitled to each year.

Annual Allocated Water – The volume of Project water (in AF) that is determined by Reclamation, in consultation with the Districts, to be allocated each calendar year for delivery to EBID and EPCWID, and for delivery to Mexico. (Use: PROJECT allocation term.)

Alluvium - Unconsolidated clay, silt, sand, or gravel deposited by running water in the bed of a stream or on its floodplain.

Aquifer - A saturated water-bearing geologic formation, or group of formations, which stores, transmits, and yields water in sufficient quantity to be a source of supply. See also Santa Fe Group Aquifer.

B

Beneficial Use - Under New Mexico law, the direct use or storage and use of water by man for a beneficial purpose including, but not limited to, agricultural, municipal, commercial, industrial, domestic, livestock, fish and wildlife, and recreational uses. Beneficial use shall be the basis, the measure, and the limit of a water right.

C

Canalization Project - A project authorized by Congress in 1936 and constructed from 1938-43 in the Rincon and Mesilla Valleys consisting of 106 miles of rectified river channel and levees to add and fortify canals for flood protection and for Project use.

Carryover Water – In the 2008 OA, the amount of a District's Annual Allocation that is unused the end of a given calendar year, and carried over into the next year. (Use: PROJECT allocation and accounting term.)

Carryover Water/Carryover Limit - In the 2008 OA, Carryover Water may be accumulated in an account for each District to a maximum of sixty percent (60%) of each District's respective full yearly allocation (or an amount of Actual Carryover Water equal to 232,915 acre-feet for EPCWID and 305,918 for EBID). (Use: PROJECT allocation and accounting term.)

Carryover Water/Carryover Obligation – In the 2008 OA, the amount of Usable Water that is sequestered from the calculation of Current-Year Allocations for the delivery of Carryover Water. The amount of the Carryover Obligation is the total amount of Carryover Water from both Districts, divided by the Diversion Ratio.

Carryover Water/Carryover Transfer – The amount of Water transferred from one District to the other District as a result of the exceedance of the first District's Carryover Limit, or for other reasons. (Use: PROJECT allocation term.)

Charged Diversion – In Rio Grande Project Accounting, the net amount deducted from a District's Allocation representing the delivery and diversion of Project Supply over the course of an irrigation season (or other shorter period, if specified), calculated in accordance with specific Project Accounting rules. Charged Diversion is the net result of all charges and credits associated with a District's diversions and other operations over the course of an irrigation season. As opposed to Actual or Physical Diversion (Use: PROJECT accounting term.)

Cone of Depression - The cone-shaped depression in the groundwater table caused by the drawdown of a pumping well.

Conjunctive Use - Use of a combination of water sources for supply, i.e. use of both surface and groundwater.

Conservation Storage – Water stored in a reservoir during times of high flows to meet authorized purposes during times of lower flows.

Consumptive Irrigation Requirement (CIR) - The amount of applied water needed to support the growth of a healthy crop. Each type of crop may have a different CIR. Note that the CIR is a component of the Farm Delivery Requirement.

Consumptive Use (CU) - That part of water withdrawn from the stream system that is evaporated, transpired, incorporated into products or crops, consumed by humans or livestock, or otherwise removed from the immediate water environment (also referred to as water consumed). As opposed to Return Flow.

Conveyance Loss (AKA Transit Loss) - The amount of water lost between two defined points along a stream, canal, or ditch under natural conditions without interceding diversions or tributary surface water inflow. Conveyance loss can occur through seepage into the subsurface, evaporation and transpiration from vegetation.

Credits and Debits: Compact - The excess, or shortage, of surface water actually delivered by one state to another, compared to the obligation according to the Compact. (Use: COMPACT accounting term.)

Credits and Charges: Project - Positive or negative adjustments to the accounting of a District's diversions in determining a District's Charged Diversions, that is: how much of its allocation that District has been delivered. (Use: PROJECT accounting term.)

Credits and Debits/Accrued Credits - The amounts by which the sum of all Annual Credits exceeds the sum of all Annual Debits over any common time period. (Use: COMPACT accounting term.)

Credits and Debits/Annual Credits or Debits - The amounts by which actual deliveries in any calendar year exceed (or fall below) scheduled deliveries. (Use: COMPACT accounting term.)

Credits and Debits/Credit/Debit Balance - The end-of-the- year balance of credits and debits accrued under the Rio Grande Compact. (Use: COMPACT accounting term.)

Credits and Debits/Credit Water - That amount of water in Project Storage which is equal to the Accrued Credit of Colorado or New Mexico, or both. (Use: COMPACT accounting term.)

Current-Year Allocation- The amount of water annually allocated to a District under the 2008 Operating Agreement, exclusive of Carryover Water or Carryover Transfer. As opposed to Total Allocation which includes both Current-Year Allocation and Carryover Water. (Use: Project allocation term.)

D

D-1 Equation or Curve - The correlation between releases from Project Storage and delivery to farms in the Districts (and to the heading of the Acequia Madre for delivery to Mexico). The correlation was based on historical Rio Grande Project data for the period of 1951 through 1978. The D-1 Curve is now used primarily to determine the allocation to Mexico. (USE: PROJECT allocation term.)

D-2 Equation or Curve - The correlation between releases from Project Storage with corresponding annual deliveries to Rio Grande Project diversions from the Rio Grande for EBID, EPCWID, and Mexico. The correlation was based on historical Rio Grande Project data for the period of 1951 through 1978. The D2 Curve is now used primarily to determine allocation to EPCWID. (USE: PROJECT allocation term.)

D-3 Allocation Method or Procedure - A Project Allocation method first implemented in 2006, and adopted by the 2008 OA, which calculates Mexico's allocation using the D1 Curve, EPCWID's allocation using the D2 Curve, and allocates the remainder of Project Supply to EBID. (USE: PROJECT allocation term.)

Debit Storage - Water retained in storage in reservoirs constructed after 1937 in Colorado above Lobatos and in reservoirs constructed after 1929 in New Mexico equal to or less than the Accrued Debits of either state, respectively**.** (Use: COMPACT accounting term.)

Delivery: Compact - Amount of water delivered on an annual basis under the Compact as crossing the Colorado-New Mexico stateline and/or the change in volumetric content within Elephant Butte Reservoir plus the amount of water released from the reservoir downstream. (USE: COMPACT accounting term.)

Delivery: Project - The deliveries of Project water to canal headings (including water already at the canal) and the delivery of canal water to farmers. Before 1978, Reclamation made delivery both to canal headings and to farmers. Since 1978, Reclamation makes delivery to canal headings, while EBID and EPCWID make the final delivery to the farmers. (USE: PROJECT accounting term.)

Depletion - Net rate of water use consumed from a stream or groundwater aquifer for agricultural, domestic, riparian use, or evaporation from open water surfaces. Water gets "depleted."

Discharge – The flow of water, typically from one conveyance to another, or from groundwater into a surface water body.

District - In the Rio Grande Project, either EBID or EPCWID. See Irrigation District.

Diversion, Actual Diversion or Physical Diversion- The physical removal of surface water from a channel. This can be done by a dam or headgate or other means of "diverting" water from the channel. It also means the act of bringing water under control by means of a well, pump, or other device for delivery and distribution for use.

Diversion Ratio – A new term developed for D3 Allocation and the 2008 OA. The Diversion Ratio is equal to the ratio of Charged Diversions (including the Mexican diversion) and the Release from Caballo. The Diversion Ratio is used in the determination of the annual allocation to EBID. (USE: PROJECT accounting term.)

Drain, Drainage - Channels installed to intercept the water table in a shallow aquifer, removing excess groundwater and lowering the water table. In the LRG, the drains were installed after early Project irrigation return flows overloaded the aquifer, "subbing out" farm fields. LRG drains historically discharged large amounts of Project return flow throughout the Project, and that water used to comprise a significant amount of Project supply.

E

Effective Precipitation / Rainfall - Precipitation available for use by plants; the portion of the rainfall event that does not flow overland into an arroyo or stream, infiltrate to the water table and contribute to aquifer recharge or become lost to immediate evaporation from soils.

Effluent - Treated municipal wastewater.

Elevation - Physical height of a spot above mean sea level. For instance, water levels in reservoirs are often based on their elevation – that is, height above sea level. AKA Stage.

Elephant Butte Effective Index Supply (AKA Elephant Butte Scheduled Delivery) - The delivery obligation at Elephant Butte Reservoir according to the Compact. The value of this delivery obligation is determined based on inflow conditions at the Otowi Gage. USE: COMPACT accounting term.)

Engineer Advisor (EA) - Each State's technical advisor to its Compact Commissioner.

Ephemeral Flow - Water flow in a stream channel that occurs only after precipitation.

Ephemeral Tributaries - Rivers or streams that only flow during certain times of the year or under certain hydrologic conditions (versus perennial tributaries).

Evaporation (E) - The physical process by which a liquid or solid is transformed to the gaseous state which, in irrigation, usually is restricted to the change of water from liquid to gas. Water is lost to the atmosphere as a result of this process.

Evapotranspiration (ET) - The combined processes of evaporation and plant transpiration through which liquid water is converted to water vapor and lost to the atmosphere.

F

Farm Delivery Requirement (FDR) - The amount of water that must be delivered to a farm so that the CIR can be met. To account for farm losses including the deep percolation of return flow, this amount will be higher than the actual CIR requirement.

Full-Supply Conditions – Historically, the Rio Grande Project was considered to have a full supply when the annual amount of Usable Water available to the Project was sufficient to deliver 3.024 AF/A to Project Lands, plus 60,000 AF to Mexico at International Dam. Full-supply conditions largely obtained prior to 1951, pertained intermittently from 1951 through 1978, pertained from 1979 through 2002, and have occasionally occurred from 2003 until the present time. Since the adoption of the D3 Allocation method in 2006, Full-Supply Conditions can be defined either based on the annual amount of Usable Water available to the Project, or based on the Current-Year Allocation to EPCWID.

G

Gage / Gaging Stations - A surface water instrument station or structure that measures Stage (Elevation) of the water surface or flow. Within the Project, the USGS and the IBWC have gaging stations to monitor the Rio Grande level and flow rate.

Gains - Increases in the water supply within a system or "reach" of a river. For example, gains to streamflow may occur due to precipitation, snowmelt, groundwater discharge, wastewater discharge, or agricultural return flow. Roughly the opposite of Seepage.

Groundwater - Water occurring within underground geologic units of sand, gravel, fractured rock, etc. It is reached for use through drilling wells.

Groundwater Model - A computer program and input files that simulate groundwater flow and groundwater levels.

H

Head gate or Heading - The structure through which water is delivered to a canal or to a farm.

Hudspeth or HCCRD - The irrigation district located directly downstream of EPCWID. Hudspeth is not a Project beneficiary, but it receives and buys water from the Project. Many EPCWID farmers own land in Hudspeth as well, and the irrigation systems of the two districts are closely integrated.

Hydraulically Connected - A condition in which groundwater or surface water moves relatively easily between aquifers that are in direct contact, or between groundwater and a surface water body.

Hydrology - The branch of science concerned with the properties of the earth's water, and especially its movement in relation to land. The study of groundwater and its relationship to geology, the flow of surface water in rivers and conveyances, and the interaction between groundwater and surface water.

Hydrogeology - The study of groundwater and its relationship to geology.

Hydrograph - A graph showing the Stage (or Elevation), flow, velocity or other characteristics of water with respect to time. A stream hydrograph commonly shows the elevation or water flow; a groundwater hydrograph shows the water level.

Hydrologic Budget / Balance - Accounting of the inflow to, outflow from, and storage in a hydrologic unit such as a drainage basin, aquifer, soil zone, lake or reservoir; the relationship between evaporation, precipitation, runoff, consumptive use and the change in water storage, expressed by the hydrologic equation.

Hydrologic Cycle - The complete cycle that water can pass through, beginning as atmospheric water vapor, turning into precipitation and falling to the earth's surface, moving into aquifers or surface water, and then returning to the atmosphere via evapotranspiration.

I

Infiltration - The downward entry of water through the soil surface into the soil or into an aquifer.

Instream Use - The use of water that does not require withdrawal or diversion from its natural watercourse; for example, the use of water for navigation, recreation, and support of fish and wildlife.

Inter-district Contract - The contract between EBID and EPCWID executed in 1938 establishing, among other things, the agreed 57/43 division of water between the Districts.

Irrigation District - A legal entity, with definite geographic boundaries, created by statute to develop and manage large irrigation projects. In the Project, the two Districts are EBID and EPCWID.

Irrigation Water Requirements (WR) - The quantity of applied irrigation water that is required for various uses, particularly evapotranspiration (CIR, FDR, PDR).

J

Junior Appropriator - The holder of a surface or groundwater right that was acquired subsequent in time to other water rights (Senior Appropriator) on the same stream or aquifer.

M

Mainstem - The principal watercourse in a water basin system. The Rio Grande River is the mainstem of the Rio Grande River Basin.

N

Native Water - Surface water originating in the Rio Grande basin. In the Rio Grande stream system, San Juan Chama is not Native Water.

Non-Allocated Water – From the 2008 OA, Project water diverted from the Rio Grande by EBID or EPCWID that is not charged by Reclamation against any allocation account. (USE: PROJECT allocation term.) Compare to Annual Allowed / Allocated Water.

Non-Consumptive - That part of water withdrawn that is not evaporated, transpired, incorporated into products or crops, consumed by humans or livestock, or otherwise removed from the immediate water environment environment and which eventually returns to the aquifer or stream. It can include carriage water, end up as tail water, deep percolation, or operational waste.

O

Operating Agreement of 2008 (2008 OA) - The Operating Agreement for the Rio Grande Project entered into by the United State of America, by and through the Burreau of Reclamation, Elephant Butte Irrigation District, and El Paso County Water Improvement District No. 1 on March 10, 2008.

Operations Manual - The Rio Grande Project Water Accounting and Operations Manual created by Reclamation, EBID, and EPCWID that contains information regarding the methods, equations, and procedures used by EBID, EPCWID, and Reclamation to account for all water charges and operating procedures for the Rio Grande Project as required by the 2008 OA, and as periodically amended.

Order - A request to Reclamation by a District for the delivery of a quantity of Project water to the District's delivery and accounting stations at a specific flow rate (cubic feet per second) and at a specified delivery time and day. Or a request by a Farmer for delivery of a certain amount of water at the farm head gate. (USE: PROJECT Accounting and Operations term.)

Otowi Gage - The gage at Otowi on the Rio Grande, north of Santa Fe, which measures flow at that point and from which the delivery obligations of New Mexico to Elephant Butte Reservoir are determined. (USE: COMPACT accounting term.)

Otowi Index Supply - The recorded flow of the Rio Grande at Otowi Gage, adjusted for storage in reservoirs in New Mexico constructed after 1929 and for Trans-mountain Diversions. (USE: COMPACT accounting term.)

P

Perennial Tributaries - Rivers or streams that flow continuously throughout the year (versus Ephemeral Tributaries).

Permeability - The property of a material to transmit fluids (water) through its pores when subjected to pressure or a difference in Head.

Phreatophyte - A plant with roots that generally extend downward to the water table and customarily utilizes water from the capillary fringe. Phreatophytes are commonly referred to as "water-loving" plants and are common in riparian habitats.

Piezometer – A device, often consisting of pipe casing perforated near the terminal point only, or a well which is screened only over a specific depth interval, which indicates the water-pressure hydraulic head at a "point" in an aquifer.

Porosity - The ratio of void volume within the bulk volume of a material. Porosity determines the capacity of a rock formation to absorb and store groundwater.

Primary Irrigation Season - The period of a year when water is being released from Caballo Reservoir for irrigation purposes (generally early spring through about September). (USE: PROJECT accounting term.)

Priority Date - The seniority date or placement of a water right in perspective of its relative standing to other water rights within a common stream system or aquifer. This method of determining water rights is specific to the western United States (see Junior and Senior Appropriator).

Project Storage - The combined capacity of Elephant Butte Reservoir and all other reservoirs actually available for storage of Usable Water below Elephant Butte and above the first diversion to land of the Rio Grande Project, but not more than a total of 2,638,860 AF. (USE: COMPACT accounting term; PROJECT allocation term.)

Project Supply- Water that is delivered or available for delivery to Project beneficiaries, derived from several sources including Usable Water released from Project Storage, Drain flows, Return Flows, Tributary inflow, and Effluent. (USE: PROJECT allocation term.)

R

Reach - The geographic area of a river between any two points.

Recharge - The replenishment of groundwater in an aquifer. Recharge can occur from the infiltration of precipitation, seepage from a stream or irrigation conveyance, or seepage of the unconsumed part of the water applied to cropland.

Rectification Project - A project in the late 1930s-early 1940s in the El Paso Valley to straighten and fortify the Rio Grande river channel and clearly define the border with Mexico.

Release - The water released from Project Storage express either in terms of a flow rate (cubic feet per second) or a volumetric amount (acre-feet).

Relinquishment - The administrative process by which one state gives up part of its Accrued Credits, allowing that water to become Usable Water available to the Project, in exchange for the benefit of storing water upstream in reservoirs constructed after 1929 when the storage prohibition of Article VII of the Compact is in effect. (USE: COMPACT accounting term.)

Return Flow - That portion of water returning to the river or groundwater after diversion into irrigation canals, including tail water from farms, drainflow or applied irrigation water seeping past the root zone to groundwater. As opposed to Consumptive Use.

Rio Grande Compact or the Compact (RGC) - The interstate river compact that was ratified by the States of Colorado, New Mexico and Texas, approved by the United States Congress and signed by the President in 1939 (53 Stat. 785) to equitably apportion waters in the Rio Grande Basin from its headwaters in Colorado to Fort Quitman, Texas.

Rio Grande Compact Commission or the Commission (RGCC) - The agency created by the Rio Grande Compact for its administration thereof. It is comprised of one voting representative from each of the States of Colorado, New Mexico, and Texas. The United States is represented by one non-voting federal representative who acts as Chairman of the Commission.

Rio Grande Project or the Project (RGP) - The facilities, works, and appurtenant lands authorized by an Act of Congress on February 25, 1905, 33 Stat. 814 in compliance with the Reclamation Act of 1902, 32 Stat. 390. The major facilities and works include Elephant Butte Dam and Reservoir, Caballo Dam and Reservoir, a power generation plant, and six diversion dams (Percha, Leasburg, Mesilla, American, International, and Riverside) on the Rio Grande in New Mexico and Texas serving lands and service area authorized by the 1905 Act.

Riparian - Relating to or situated on the banks of a river.

Root Zone - The layer of soil that plant roots readily penetrate and in which the predominant root activity and water extraction occurs.

S

San Juan-Chama Project Water (SJC Water) - Transmountain surface water from the Colorado River system delivered through a series of diversion works and tunnels to the Rio Chama and thence to the Rio Grande. (USE: COMPACT accounting term.)

Santa Fe Group Aquifer System - A deep complex of unconsolidated alluvial sediments along the Rio Grande that form an aquifer that is hydraulically connected with the Rio Grande.

Seepage - The loss of water through the wetted perimeter beneath a reservoir, lake, ditch, canal or other open-channel water body. Roughly the opposite of Gains.

Senior Appropriator - The owner of a surface water right whose right was acquired earlier or prior to other right holders (Junior Appropriators) on the same stream.

Spill Year - A year during which there is flow over the spillway at the Elephant Butte Reservoir

Stage - Physical height of a spot above mean sea level. For instance, water levels in reservoirs are often based on their stage – that is, height above sea level AKA Elevation.

Storage - Either 1) the amount of water in a reservoir, or 2) the amount of water existing in the interstices of a geologic medium as part of a groundwater system.

Stream Connected Aquifer - An aquifer with hydraulic connection with a surface water system.

Surface Water- Water that is available on top of ground, versus groundwater.

T

Tail Water - Excess surface water flowing off a field under cultivation or excess water at the bottom of an irrigation system.

Transfer Contracts - The contracts executed between Reclamation / EBID (Feb. 15. 1979) and Reclamation / EPCWID (March 14, 1980) after the Districts had paid off their loans to the federal government, transferring certain Project infrastructure and responsibilities to the Districts.

Transit Loss - See Conveyance Loss.

Trans-Mountain Diversions - Water imported into the drainage system of the Rio Grande from a drainage system outside of the Rio Grande Basin (i.e., San Juan-Chama Project water) (USE: COMPACT accounting term.)

Transpiration (T) - The process by which water in plants is transferred as water vapor to the atmosphere.

Tributary - Any stream which naturally contributes to the flow of the Rio Grande.

U

Usable Water - All water, exclusive of Credit Water and San Juan-Chama water, which is in Project Storage. Usable Water is available for release in accordance with irrigation demands, including deliveries to Mexico. (USE: COMPACT accounting term; PROJECT allocation term.)

W

Waste - Water diverted into Project conveyances then returned to the river through wasteways.

Wasteway - A conveyance for the specific purpose of dumping water from irrigation conveyances back into a river. As opposed to canals and lateral whose purpose is to convey water to fields and other use points.

Water Balance / Water Budget - A mathematical construction that shows the amount of water leaving and entering a given watershed or aquifer (Inflow versus outflow).

Water Distribution Report (WDR) - Reports prepared by Reclamation which tabulate diversion and deliveries by “Project”, “valley”, or “unit”; these are the only accounting records of Project Deliveries prior to 1979.

Water Supply - The amount of water potentially available for use within a study area; this must account for both the hydrologic supply and the legal limitations imposed by State law and water allocation agreements such as the Rio Grande Compact.

Water Table - A fluctuating demarcation line between the unsaturated (vadose) zone and the saturated zone that forms the upper layer of an aquifer. It may rise or fall, depending upon precipitation, recharge, and withdrawals.

Well Permit - The granting of permission by the government (in New Mexico, the Office of the State Engineer) allowing the construction of a groundwater well and the application of water to beneficial use.

Margaret (Peggy) Barroll, Ph.D.
Senior Water Resource Hydrologist

Professional Resume

Peggy Barroll
691 East Zia Rd
Santa Fe, NM 8750

Phone: (505) 660 8079
pbarroll@gmail.com

Education:

Ph.D. Geophysics, with concentration in groundwater hydrology, 1989, New Mexico Tech, Socorro, New Mexico. Dissertation: "Analysis of the Socorro Hydrothermal System, Central New Mexico"
M.S. Geophysics, 1984, New Mexico Tech, Socorro, New Mexico
B.A. Physics, Honors, 1980, Swarthmore College, Swarthmore Pennsylvania

Employment:

Fall 2017 to Current:	Balleau Groundwater Inc. and West Consultants Inc. -- Senior Water Resource Hydrologist
1991 – 2017:	New Mexico Office of the State Engineer -- Senior Water Resource Hydrologist
1988-1991:	D.B. Stephens and Associates -- Hydrologist (part-time)

Relevant Expertise:

1) **Computer model development and effective model use for scientific evaluation of hydrogeologic systems**
    a. New Mexico Administration: Lower Rio Grande Basin
        i. Principal scientist in the development of multiple MODFLOW groundwater models for the Lower Rio Grande (LRG) aquifers
            1. Development of farm budgets and groundwater pumping inputs for these groundwater models
            2. Committee member of modeling experts for 2007 LRG Groundwater Model
        ii. Completed in depth analysis of irrigation water demand and water use through
            1. Analysis of well meter data
            2. Calculation of irrigation well pumping for periods prior to well metering

      iii. Provided hydrogeologic consultation to developers of models to simulate Rio Grande Project operations
      iv. Provided hydrogeologic consultation to developers of salinity models
      v. Created compilations of hydrologic data: groundwater pumping, groundwater levels, surface water flows, etc.
      vi. Testifying Expert in the Consumptive Irrigation Requirement Determination in the Lower Rio Grande adjudication
         1. Prepared technical exhibits for Adjudication Court related to irrigation water use
   b. New Mexico Administrative Middle Rio Grande Basin
      i. Principal scientist in the revision of the pre-existing USGS Middle Rio Grande groundwater MODFLOW model for determination of impairment in Office of the State Engineer (OSE) water right application proceedings
      ii. Collaborated with the United States Geological Survey (USGS) in development of updated groundwater MODFLOW model of Middle Rio Grande Basin
   c. Taos Valley
      i. Principal scientist for the OSE in the development and refinement of the Taos Valley MODFLOW groundwater model
      ii. Collaborated with multi-agency Technical Committee (Federal, State and local representatives) on the creation and calibration of the Taos Valley MODFLOW groundwater model and associated processing tools
      iii. Technically sound consultation and work product for assistance in the Taos adjudication settlement negotiations
   d. Pecos River Basin
      i. Principal scientist for the OSE in the development, calibration, application and update of the Carlsbad Area Groundwater MODFLOW model and associated creation of preprocessing software necessary to initiate model runs
      ii. Senior scientist for the OSE collaborating in the development, application and update of the Roswell-Artesian Basin Groundwater MODFLOW model
      iii. Senior scientist for the OSE collaborating in the development of RiverWare model of the Pecos River
      iv. Senior scientist for the OSE in the development, support and technical management the Pecos Decision Support System (PDSS). The PDSS is comprised of four independent models, the Carlsbad Area Groundwater MODFLOW model, the Roswell-Artesian Basin Groundwater MODFLOW model, the Pecos River RiverWare Model, and a water balance model of the Pecos River from Carlsbad, NM to the New Mexico-Texas state line. The PDSS was developed to inform negotiators of the Pecos River Settlement Agreement of the impacts of various proposals for New Mexico's compliance with the United States Supreme Court's Amended Decree from Original Action No. 65

2) Groundwater resources development, management and protection

   a. Lower Rio Grande

i. Analysis of Rio Grande Project Operations, historical and present, within New Mexico and Texas
ii. Utilized the application of models to provide the SE information on historic and proposed Lower Rio Grande water management issues
iii. Provided technically sound consultation and work product in the development of administrative guidelines, and proposed rules for the Lower Rio Grande within the OSE's jurisdiction
iv. As the Principal scientist, provided technical evaluation and input on District Specific Rules developed under the OSE's framework rule set for the State of New Mexico's Active Water Resource Management
v. Engaged with stakeholders from the Lower Rio Grande region on the development of rules for alternative administration of water rights in the OSE's jurisdiction and provided multiple presentations on the 2008 Operating Agreement and associated Operations Manuals

b. Middle Rio Grande
   i. Development of State Engineer Water Right Application Guidelines for the Middle Rio Grande Administrative area
   ii. Guideline technical basis stemmed from groundwater water modeling
   iii. Determined Critical Management Areas where groundwater pumping is constrained to ensure limits of aquifer drawdown

c. Miscellaneous assignments as Principal scientist for New Mexico Office of the State Engineer
   i. Hydrologic assessments for pending water right applications.
   ii. Hydrologic assessments for adjudications, subdivision water availability determinations
   iii. Technically sound consultation and work product for SE consideration in water resource management and supervision
   iv. Technically sound consultation and work product for the Office of the State Engineer litigation activities, including interrogatory questions and responses, technical memoranda, exhibits and expert reports, written and oral testimony

APPENDIX A

HISTORICAL ALLOCATION AND DIVERSION DATA

TABLE OF CONTENTS

TABLE OF FIGURES

TABLE OF TABLES

APPENDIX A - HISTORICAL ALLOCATION AND DIVERSION DATA

This Appendix presents historical Project allocation and diversion data in order to document the changes in the distribution of Project water between the Districts associated with the 2008 OA. My analyses of the raw data as set forth in this Appendix underlies other analyses and conclusions throughout this Report. The back-up raw data for this Appendix is provided with this Report in the form of WDRs, District accounting workbooks, scanned allocation spreadsheets, scanned accounting summaries, and random allocation data sources. The data sets analyzed herein are divided into three periods:

- 1931 – 1978: Unified Project Operations under Reclamation
- 1979 – 2005: D1/D2 Allocation of Project Supply to Districts
- 2006 – 2018: D3 Allocation with Carryover, 2008 OA Allocation to Districts

For convenience, key data from this Appendix are compiled by the author as Total Allocation and Delivery of Project Water to Districts and Mexico, 1930-2018, produced contemporaneously.

1 1931-1978: PROJECT ALLOTMENT, DIVERSION AND DELIVERY DATA

In this section Reclamation allotment, diversion and farm delivery data from the period 1931[1] through 1978 is summarized in tables and graphical form. During this time period (and prior to this time) Reclamation treated the Project as one entity, allotting water to all Project acreage in terms of acre-feet per acre ("AF/A"), diverting water at Project canal headings and delivering water to Project farmers.

1.1 1931-1978 PROJECT ALLOTMENT DATA

As set forth above, prior to 1979, Reclamation allotted water to all Project farms on an equal AF/A basis. The resulting allocation shares were thus equal to the shares authorized acreage: ~57% to EBID and ~43% to EPCWID (the 57:43 split).

Before 1940, it appears that Reclamation did not set a limiting allotment for Project lands. Project Histories from the 1940's indicate that in some years Reclamation was concerned about water shortages, and set a limiting allotment, although during the 1940s these limiting allotments were lifted at some point during the irrigation season. Starting in 1951, limiting allotments were set, and while these allotments were modified as water supply conditions changed, they remained in force throughout the irrigation season. Table A.1 and Figure A.1 provides Reclamation allotment data extracted from the Project Histories for various years, and from Reclamation's "Project Annual Operating Plan 1984 Operations, 1985 Outlook."[2]

[1] 1931 is the beginning of a relatively complete sequence of legible Project delivery data.

[2] *Annual Operating Plan*: *1984 Operations, 1985 Outlook*, Bureau of Reclamation, Rio Grande Project, 1985.

Figure A.1. Project Allotments Set by Reclamation 1951-1978

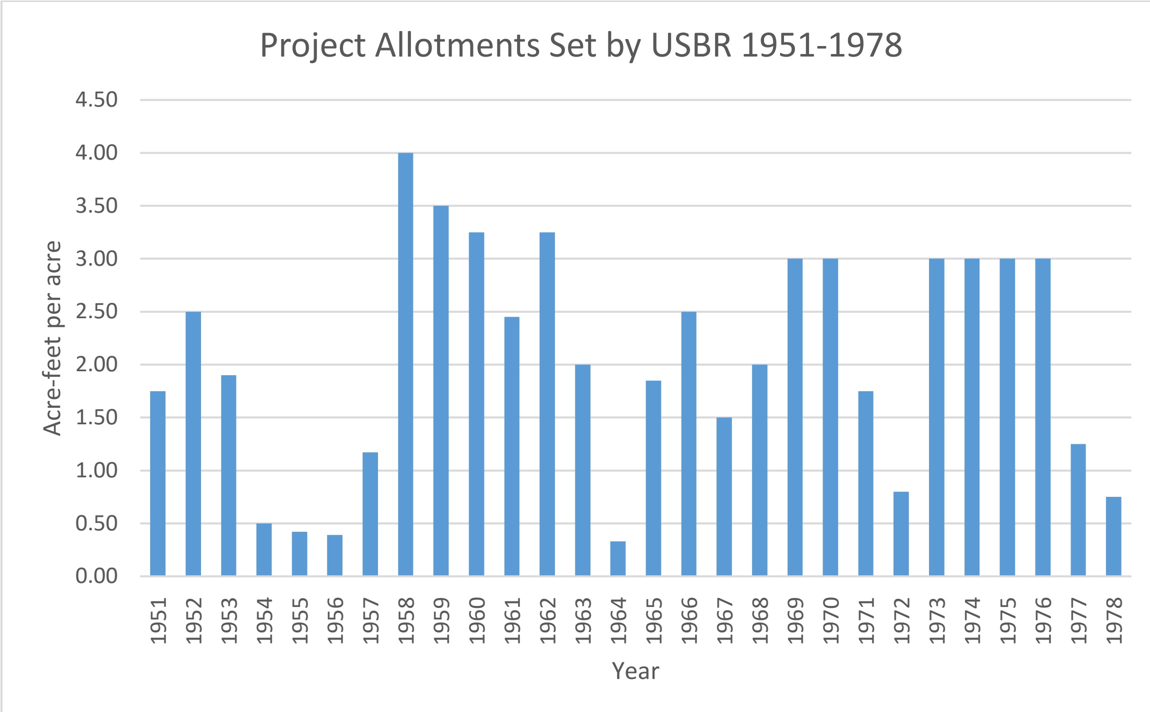

Table A.1. Project Allotments Set by Reclamation 1951-1978

Historical USBR Allotments to RGP Lands (NLA = No Limiting Allotment Set)		
	Initial Allotment to Project Lands	Final Allotment to Project Lands/EBID Lands
1940	NLA	NLA
1941	2.00	NLA
1942	NLA	NLA
1943	NLA	NLA
1944	NLA	NLA
1945	NLA	NLA
1946	NLA	NLA

1977	1.00	1.25
1978	0.25	0.75

1.2 1931-1978 District Diversion Data

Diversion and farm delivery data for the Project prior to 1979 is available from Project Water Distribution Reports (WDRs). During this time, diversions at canal headings were not reported on a District basis. Instead, diversions were reported by "Unit" (Rincon Valley Unit, Leasburg Unit and Mesilla Unit) or "Valley" (Mesilla Valley and El Paso Valley), with the diversions tabulated in the Mesilla Unit and Mesilla Valley supplying both EBID and EPCWID lands. An example of one of these reports is provided as Figure A.2.

Figure A.2. Water Distribution Report (WDR) for the Mesilla Unit, 1958:

[1] Diversion amount exclusive of waste at head gates for sand sluicing, etc.
[2] Reservoirs connected with distributing system only.
[3] Diversions plus inflow from reservoirs and other sources less delivery to reservoirs.
[4] Measured at
[5] Measured at

I calculated the amounts diverted by each District based on data from Reclamation Unit and Valley WDRs. Net Diversions for each unit are calculated by subtracting El Paso Valley Carriage (if any) from the Diverted from Stream values. EBID's diversion is calculated as the sum of the Net Diversion from the Rincon and Leasburg units, plus 80% of the Mesilla Unit Net Diversion, plus diversions at through Percha Private Lateral, plus water pumped from EBID District wells (1976-1978). EPCWID's diversion is calculated as the sum of the El Paso Valley Diverted from Stream values, plus 20% of the Mesilla Unit Net Diversion. The resulting calculated District diversions are provided in Table A.2.

Table A.2. District Diversions 1931 - 1978

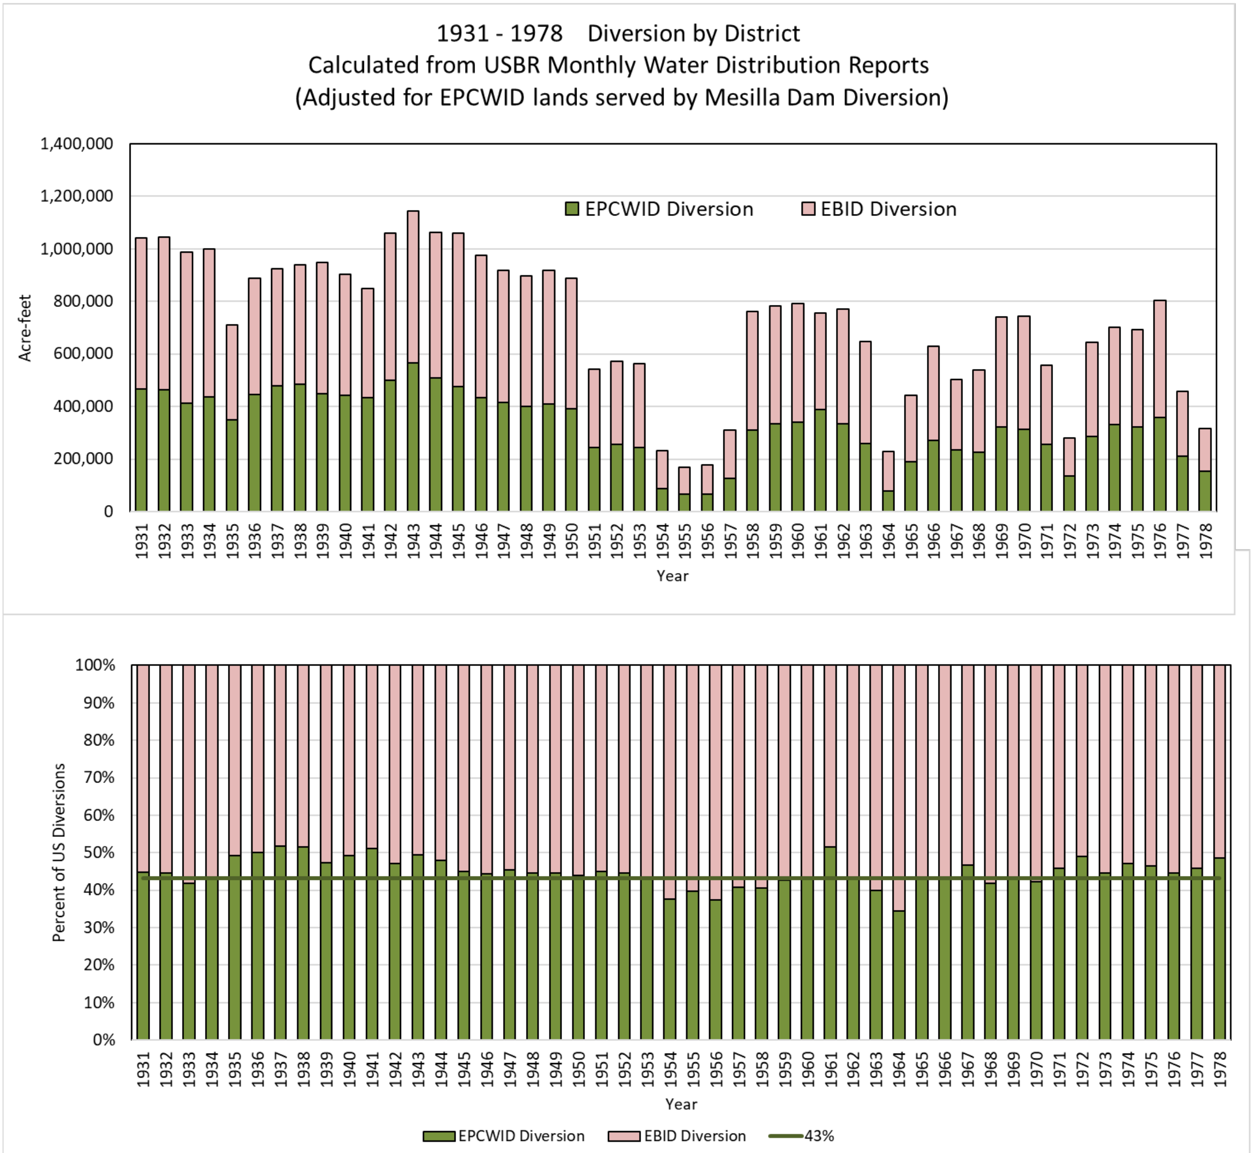
Average 1931-1978	392,506	54.5%	327,138	45.5%
Average 1951-1978	308,753	56.2%	240,702	43.8%

Figure A.3 is a graphical representation of the data from Table A.2, both in terms of AF diverted by each District, and in terms of the percentage share diverted by each District. A line denoting the 57:43 split between EBID and EPCWID is shown for reference.

Figure A.3. District Diversions 1931 - 1978



1.3 1931-1978 District Farm Delivery Data

Farm delivery data (or "Charged to Farms" entries) from Project WDRs for the Project Units and Valleys has been similarly adjusted to obtain estimated District farm deliveries. I have assigned farm delivery data from the Mesilla Unit to EBID and EPCWID based on the amount of irrigated acreage belonging to each District within the Mesilla Unit: 80% to EBID and 20% to EPCWID. The resulting farm delivery data is provided in Table A.3 and Figure A.4.

Table A.3. Farm Delivery Data from Project WDR forms, adjusted for EPCWID lands in Mesilla Unit

Year	EBID Farm Delivery		EPCWID Farm Delivery

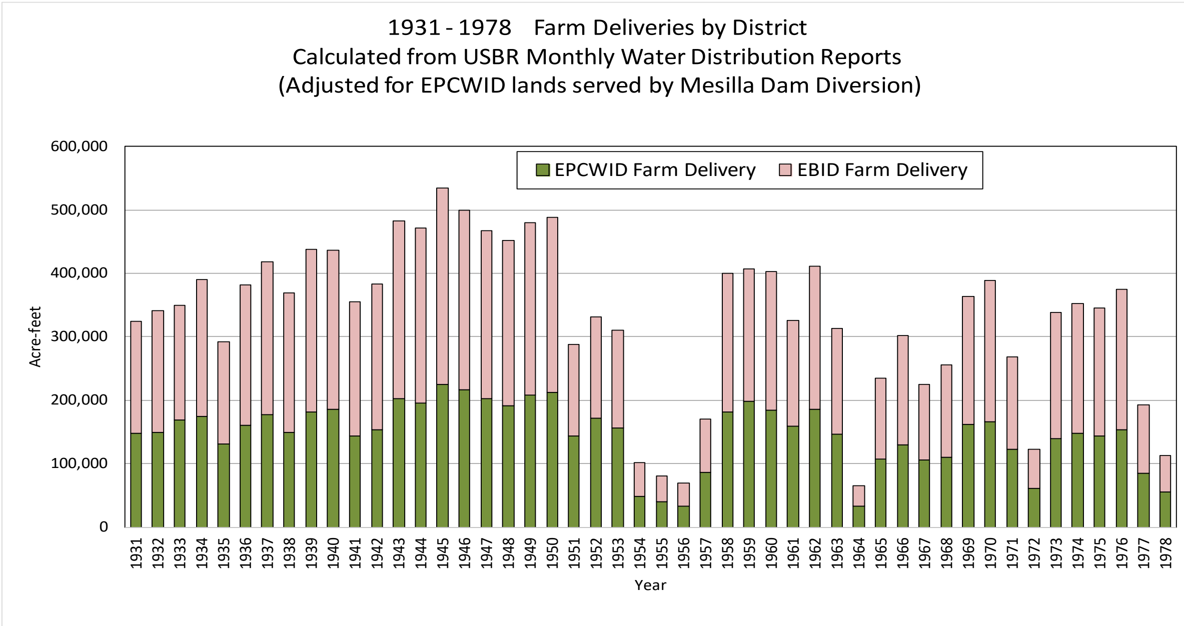
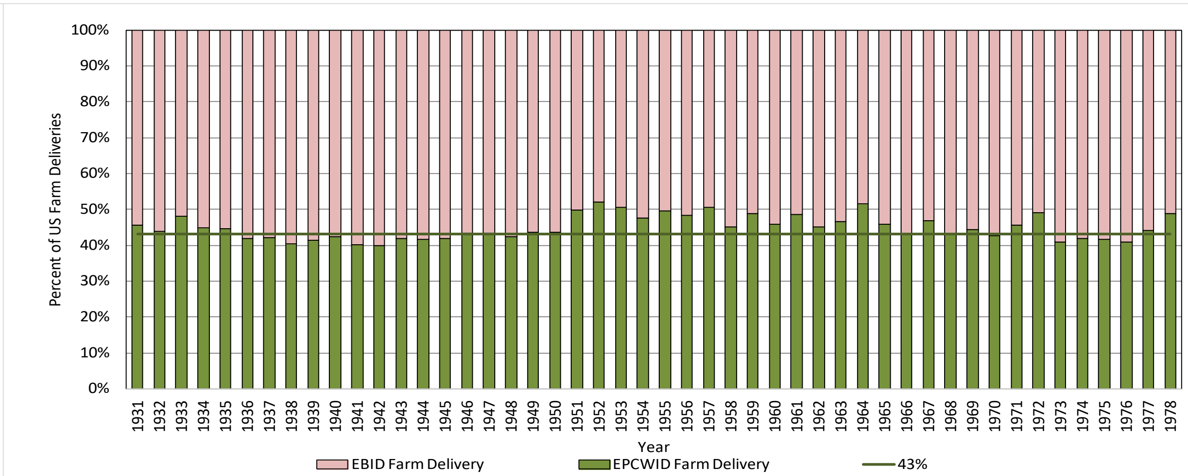
Figure A.4. Farm Delivery Data from Project WDR forms, adjusted for EPCWID lands in Mesilla Unit





2 1979 – 2005: District Allocation Data

This section provides Project allocation, diversion and delivery data for the period 1979 through 2005. Starting in 1979, Reclamation allocated water (on a volumetric basis, in terms of acre-feet (AF)) to the Districts for diversion at canal headings. The Districts were then responsible for delivering this water to their farmers.

2.1 1979 – 2005 District Allocation Data

There was some variation in the allocation process over this period of time. During the early 1980s the D2 method was under development, and different draft versions of this method were created. In approximately 1990, Reclamation adopted the Project Water Supply Allocation Procedures[3] document ("WSAP"), and followed the procedures documented therein. The Project had a full supply every year from 1979 through 2002, and therefore EBID, EPCWID and Mexico were each allocated a full supply (although in the early part of this period, there were changes in what constituted a full supply). In 2003 and 2004, the Project has a very limited supply. Rather than implement the D2 Curve procedures for determining allocation, Reclamation implemented an ad hoc procedure, allocating an amount equal to the Usable Supply in storage, and increasing the allocation only when inflows allowed.

Throughout this time period, the allocation process involved dividing the U.S. share of Project Supply 88/155 and 67/155 between EBID and EPCWID respectively (57:43). In 2003 and 2004, EPCWID's allocation included an addition of 12,127 AF and 13,025 AF (respectively) for the ACE Credit.

Note that from 1979 forward, Reclamation no longer determined the allotment of water to farms (that is, the amount each Project acre was entitled to order, in terms of acre-feet per acre (AF/A)). Instead, each District would issue an allotment to its own farmers. EBID's allotment process is based on the annual allocation from Reclamation, and a full-supply allotment is 3.0 AF/A.[4] ECPWID's allotment process may include both its allocation from Reclamation and assorted other sources of water considered to be "non-Project water."[5] A full supply allotment for EPCWID appears to be 4.0 AF/A[6] based upon language in the Implementing Third-Party Contract between EPWU, EPCWID and US, as well as my general understanding.

This allocation data is compiled in Table A.4 and is plotted in Figure A.5.

2.2 1979-2005 District Charged Diversion (Post-1978 Accounting Data)

Starting in 1979, Reclamation implemented accounting procedures designed to allow diversion amounts to be assigned to each District, incorporating a complex scheme of charges and credits. This accounting method is described in the 1985 Draft Operating Agreement and this description appears to have formed the basis for the current accounting methods as documented in the Operations Manuals associated with the 2008 OA. In Table A.5 below, the total charged diversions for each District and Mexico (Mexico's diversion is still measured as the gaged discharge into Acequia Madre) are provided. Table A.6 provides the distribution of the charged diversions between the Districts. The data in Tables A.5 and A.6 is plotted in Figure A.6.

WDRs continued to be generated for the Project, but no longer by Unit or Valley. Instead, a WDR was generated for each District and one for the Project as a whole. The values in the District WDRs are not the same as the charged diversions generated using the new Project accounting reflecting a discrepancy between the D2 Curve and Post-1978 Accounting, which is discussed more fully in Appendix E.

Table A.5. Total Charged Diversions for Each District and Mexico (1979-2005)

Project Release, Charged Diversion of Project Water by Districts, and Mexican Delivery 1979 - 2005				
	Release from Caballo	EBID Charged Diveersions	EPCWID Charged Diveersions	Mexican Delivery

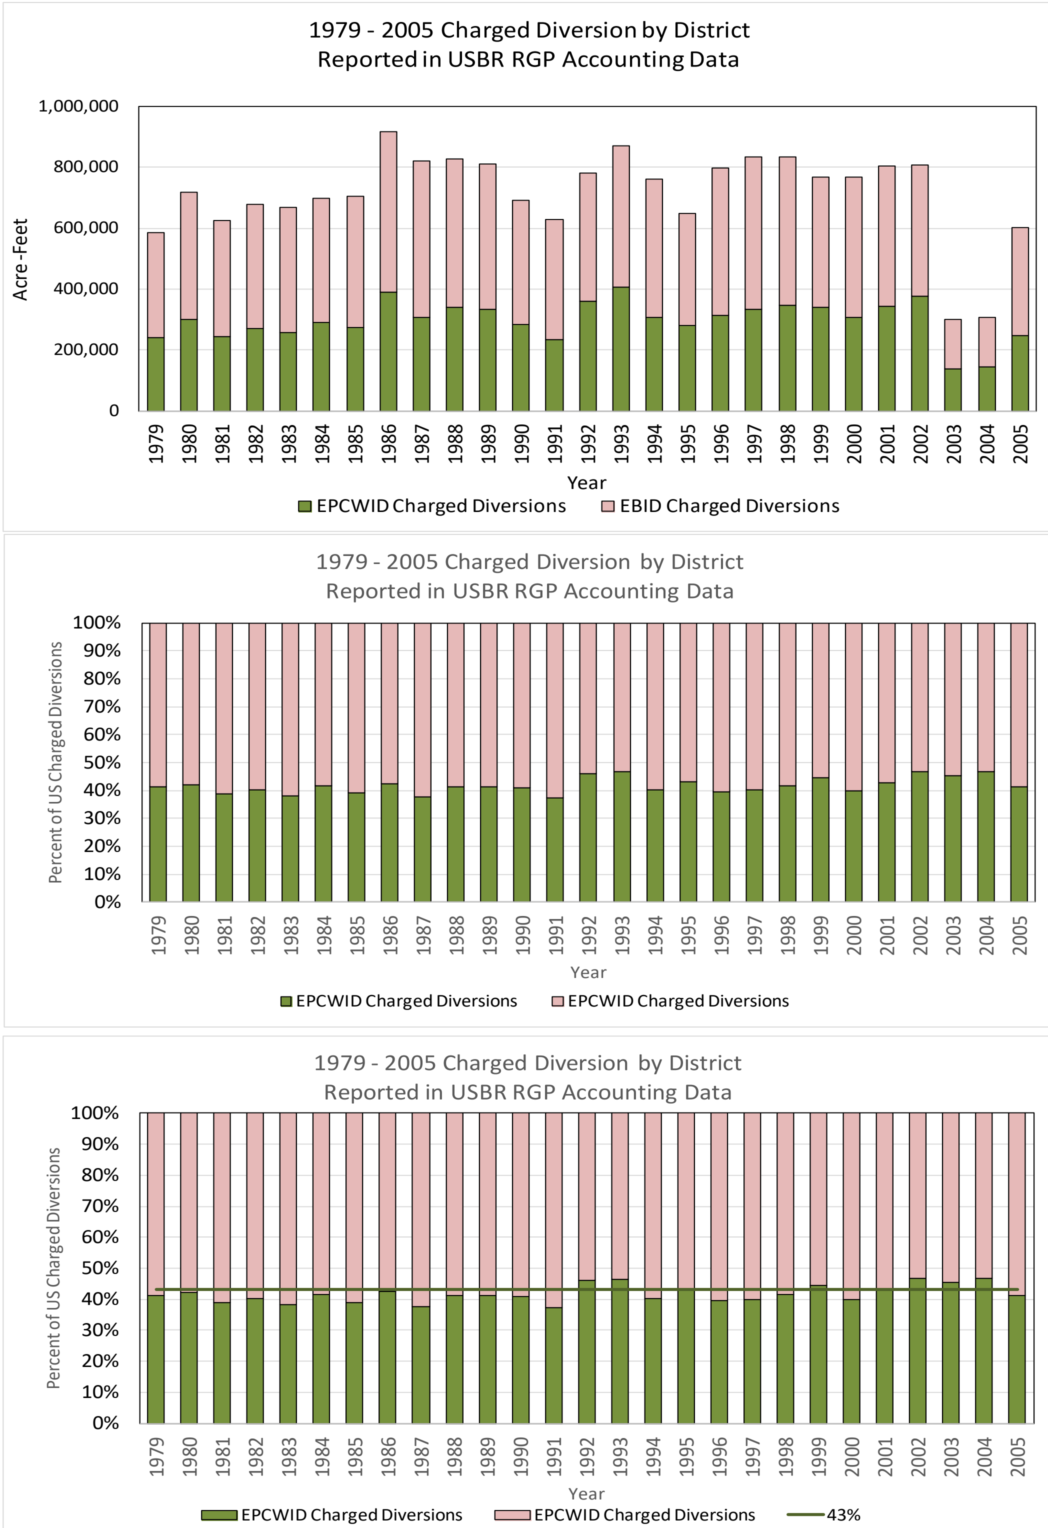
Figure A.6. Charged Diversions of Project Water to Districts (1979-2005)



2.3 1979 – 2005 EBID Allotment to Farmers

Starting in 1979, Reclamation allocated water to the Districts on a volumetric basis (acre-feet (AF)), and then the Districts allotted water to their farmers in terms of acre-feet per acre (AF/A). Table A.7 is a compilation of EBID allotment data from the period 1979 through 2005. I do not have a comparable set of allotment data for EPCWID.

Figure A.7. Reported Deliveries to Districts' Farm Headgates and EPWU (1979-2005)

2.5 1979 – 2005 Comparison of Allocation and Charged Diversions

I have compared each District's charged diversions to its total allocation during the time period 1979 through 2005. This data is tabulated and Table A.9, and plotted in Figure A.8. High-flow spill years during the 1980s have been omitted; due to very high flow conditions obtaining at that time, uncharged non-Project diversions may have occurred.

Table A.9. Comparison of District Allocation and Charged Diversions, 1979-2005

Comparison of Allocation and Charged Diversions 1979 - 2005 (Omitting 1986, 1987 and 1988, due to high-flow conditions)

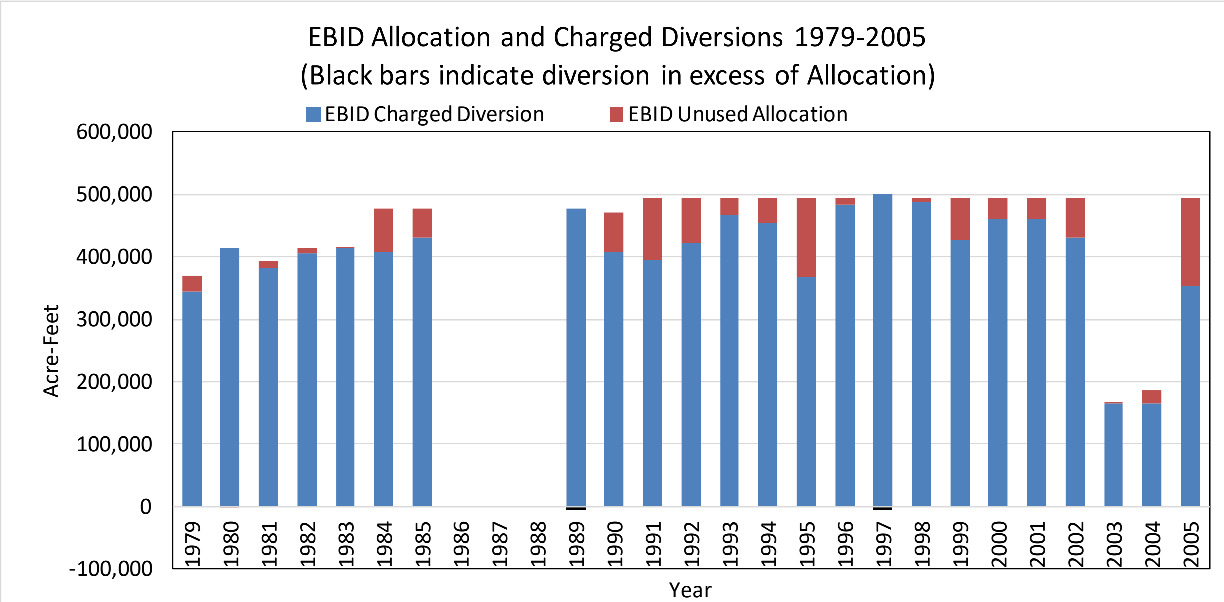
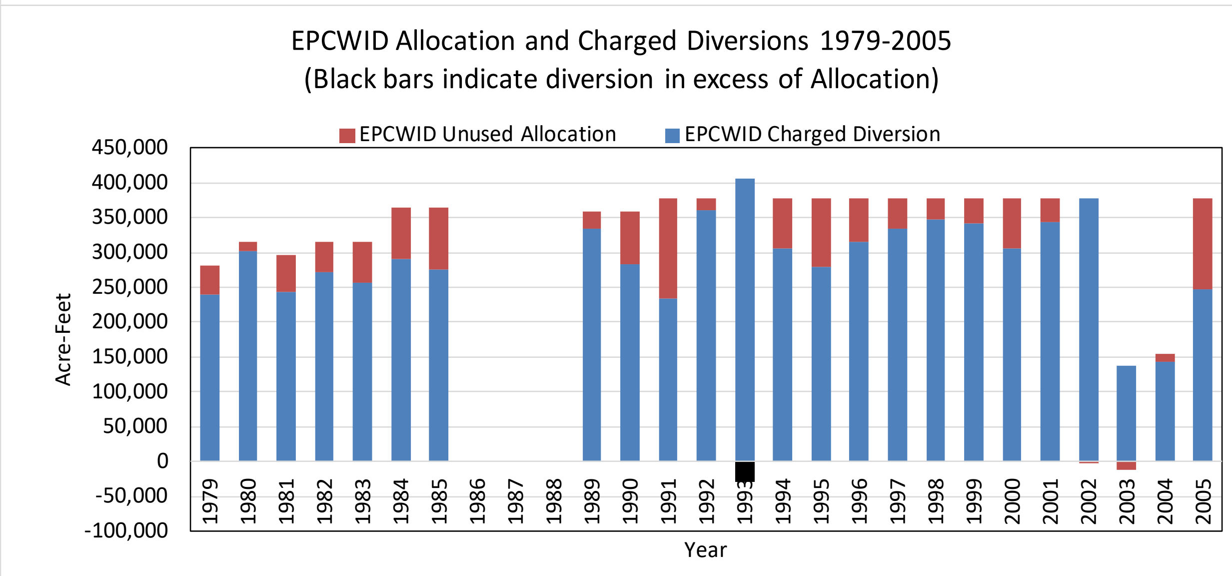
Figure A.8. Comparison of District Allocation and Charged Diversions, 1979-2005





3 2006-2018: ALLOCATION AND ACCOUNTING DATA

This section provides tabulations and graphs summarizing annual Project allocation and charged diversions under D3 Allocation and the 2008 OA, for the time period 2006 through 2018.

3.1 2006-2018 ALLOCATION DATA

I have compiled allocation data from 2006 forward from a variety of Reclamation sources, including final Project allocation spreadsheets provided by Reclamation to the Compact Commission, Project allocation spreadsheets obtained from Allocation Committee members, Reclamation presentations obtained from the Project website, and Project accounting summary data provided to New Mexico by Reclamation staff.

Table A.10 is a summary of Current-Year Allocations, including ACE Credits, for EBID and EPCWID. This data does not include allocation carried over from the previous year by either District. Figure A.9 is graphical representation of this data.

Table A.10. Current-Year Allocation to Districts (2006-2018)

Current-Year Project Allocation to Districts 2006 -2018 (D3 Allocation)							
	EBID	EBID % of US Share	EPCWID	EPCWID ACE Credit	EPCWID (Including ACE Credit)	EPCWID % of US Share
Year	AF		AF	AF	AF	
2006	211,385	47%	227,146	14,511	241,657	53%

US_MSJ_00000739

3.2 2006-2018 Charged Diversions to Districts

District Charged Diversions (also described as Allocation Charges or Allotment) are summarized in Table A.10 and presented in graphical form in Figure A.11, together with the gaged diversion by Mexico at Acequia Madre. I extracted annual charged diversion data for the Districts from final Reclamation accounting spreadsheets for each year from 2010 through 2018, and from accounting data summaries provided by Reclamation for earlier years.

Table A.12. Charged Districts' Diversions and Delivery to Mexico (2006-2018)

Table A.12. Charged Districts Diversions and Delivery to Mexico 2006 - 2018 (D3 Allocation)

PROJECT OPERATIONS: RELATIONSHIP BETWEEN CABALLO RELEASES, ORDERS, AND INSTREAM WATER SUPPLY

TABLE OF CONTENTS

TABLE OF FIGURES

APPENDIX B - PROJECT OPERATIONS: RELATIONSHIP BETWEEN CABALLO RELEASES, ORDERS, AND INSTREAM WATER SUPPLY

This Appendix describes the current and historical procedures used to determine Caballo releases, and provides a description of a spreadsheet I developed to simulate this procedure. I demonstrate that in full-supply years the amount of water delivered to Texas is controlled by EPCWID orders for water and not by the variation in drain flows or losses in the Rincon or Mesilla Valleys upstream in New Mexico.

The procedures reviewed and relied upon are:

1) Project Order and Release procedures from the 1943 Rio Grande Project History,

2) Project Water Order description and forms from the 1985 Draft Operating Agreement, and

3) forms and description in the 2012 Operations Manual associated with the 2008 OA.

1 PROJECT ORDER AND CABALLO RELEASE PROCEDURE DESCRIBED IN THE 1943 PROJECT HISTORY

The 1943 Project History has a long section titled "Rio Grande Project – Daily Reports of Operation Divisions."[1] This Project History section provides detailed descriptions of how Reclamation ditchriders and water masters compiled and tabulated Farm Orders and translated those Farm Orders into the amount of diversion required at each main canal heading (the main canal headings discussed in this appendix are Arrey, Leasburg, Eastside, Westside, Franklin, and Riverside).

Once the necessary diversion amounts at main canal headings were determined, they were sent to the Project office where the calculation of the required Caballo release was performed by Reclamation staff. This calculation was based on the required main canal heading diversions, with adjustments made to:

- increase the release by the amount of estimated transmission loss, and
- decrease the release for the amounts of drain and waste inflows above the main canal diversion headings (i.e. an adjustment for instream flow between Caballo and the main canal headings).

These adjustments were based on observations along the Rio Grande between Caballo and Riverside Dam. Figure B1 shows a sample calculation from the 1943 Project History.

[1] RGPH 1943, pp. 53-65.

Figure B.1. Sample Calculation of Necessary Caballo Release from 1943 Project History

Desired at El Paso (El Paso Valley order and Mexican Canal)	1,111	second	feet

Drainage flow to river from Mesilla Division	-425	"	"
Subtotal	626	"	"
Add estimate of transmission losses between Mesilla Dam and El Paso (This will vary during year from 20 CFS minimum to 85 CFS maximum)	+85	"	"
Necessary flow below Mesilla Dam	711	"	"
Add East Side and West Side Order	+800	"	"
Subtract drain flow Leasburg Division	-19	"	"
Add estimate of losses Leasburg to Mesilla (This will vary from 20 CFS minimum to 60 CFS maximum)	+ 40	"	"
Subtotal	1,532	"	"
Necessary flow below Leasburg Dam			
Add Leasburg Canal Order	+565	"	"
Subtract drainage flow to river from Rincon Valley	-80	"	"
Subtract estimated waste from Rincon Valley	35	"	"
Add estimate of river losses Caballo Dam to Leasburg Dam (This will vary from 40 to 70 CFS)	40	"	"
Add order for Arrey Canal	250		
Total necessary release from Caballo Dam	2,272	Second	Feet

2 Caballo Release Procedure Described in 1985 Draft Operating Agreement

Figure B.2 is a copy of the Project Water Order Form from the 1985 Draft Operating Agreement. The form has a section for the orders from the "Upper Valley" (above Courchesne), and a section for the "Lower El Paso Valley." As sometimes used historically, and throughout this Appendix, the Upper Valley is the part of the Project that is upstream of Courchesne, which includes the Rincon and Mesilla Valleys. The Lower Valley consists of the part of the Project that is below Rio Courchesne in the El Paso Valley.

On the order form, below the Lower El Paso Valley section, there is a section titled "Total Project Order" in which all orders are summed along with the water needed for Mexico. This form calculates the Release from Caballo based on the Total Water Ordered, minus (or "Less") the amount of "Drain Water to River," plus "River Loss." Thus, the Caballo Release was calculated based on orders, then adjusted upward if necessary to account for river losses, and downward to account for usable flows already in the Rio Grande.

3 CABALLO RELEASE PROCEDURE DESCRIBED IN 2008 OPERATING AGREEMENT

Figure B.3 is an image of an Excel spreadsheet I have created based on the Rio Grande Project Internet-Based Order Sheet provided in the 2012 Operations Manual of the 2008 OA (using data from the "Current" columns).[2] On the left hand side of Figure B3, the column labeled "Orders" shows the amounts (in cfs) ordered at each main canal heading from the Reclamation Order Form under "Current" (for the purpose of this Appendix, the sub-orders within the Eastside and Westside main canal headings from El Paso Water Utility have been omitted for simplicity; this does not impact the analysis). In accordance with Reclamation's Order Form, these orders are organized by Upper Valley and Lower Valley.

In the column labeled "Gains/Losses" are the Rio Grande gains or losses copied from the Reclamation Order Sheet. As indicated in the 2012 Operations Manual, and from numerous discussions with Reclamation and EBID personnel, the gains refer to any net gain to the specified reach of the Rio Grande from groundwater, from drain flows and from any other source of water that can be used by Project beneficiaries. Similarly, losses refer any net loss to seepage or evaporation occurring in a specified reach. The reaches for which gains/losses are tabulated in the Order form are:

1) The reach from Caballo Dam to Leasburg Dam ("above Leasburg"),
2) The reach from Leasburg Dam to Mesilla Dam ("Leasburg/Mesilla"), and
3) The reach from Mesilla Dam to American Dam ("Mesilla/American").

On the right hand side of Figure B.3, in the column labeled "Estimated Flow in the Rio Grande," the values from the Reclamation Order Sheet are entered. The difference between the "Estimated Flow" in the Rio Grande at each location is equal to the net effect of gains, losses and diversion of orders in the intervening reach.

[2] 2012 Operations Manual, p. 6

Lower Valley	Riverside	485			
	EPWU	141			
	Mexico	177			
	Total Lower Valley Orders	963			
	plus Mexico				

Development of a spreadsheet to simulate the Caballo Release Procedure

I then created a functional Excel spreadsheet which simulates the procedures discussed above, where the Caballo release is calculated from the data (Orders and Gains), ensuring that the flow at American Dam equals the Lower Valley Orders plus the Mexican Delivery. Functions were added to the Excel spreadsheet as follows:

1) Estimated Flow at American Dam was set equal to the total Lower Valley Orders plus Mexico.
2) Estimated Flow Below Mesilla Dam was set equal to the Estimated Flow at American Dam, minus the amount of Bypass from WW32 (this is provided as a negative number, so Excel adds it to the Estimated Flow at American Dam).
3) Estimated Flow below Leasburg Dam was set equal to the Estimated Flow below Mesilla Dam plus (assumed diversion of) the Eastside and Westside Canal orders, minus any gains (or plus any losses) in the Leasburg/Mesilla reach.

4) Estimated Flow Below Percha Dam are set equal to the Estimated Flow below Leasburg Dam plus (assumed diversion of) the order at Leasburg Canal, minus any gains (or plus any losses) in the reach above Leasburg.
5) Caballo Release set equal to the Estimated Flow below Percha Dam, plus (assumed diversion of) the order at Arrey Canal.

When these functions are activated in Excel to calculate the values in the right-hand column, these resulting values of Estimated Flow in the Rio Grande were identical to those in the Figure B.2, replicating the results in the sample Order Sheet provided in the 2012 Operations Manual. This means that the Order Sheet is designed to calculate the Release from Caballo so that resulting Flow at American Dam equals the sum of the Lower Valley Orders plus the water required for the Mexican Delivery. American Dam is 1.5 miles downstream from the gage at Rio Grande at El Paso, also known as the Courchesne gage, with no Project diversion or return structures in between, so the estimated Flow at American Dam is roughly equivalent to the flow at Rio Grande at Courchesne gage.

The result is a simplified but functional spreadsheet of a Project Order Sheet, which has been tested against the Order Sheet provided in the 2012 Operations Manual as set forth above.

With this simplified spreadsheet Order Sheet, I performed a test to change the Gain/Loss to the Rio Grande between Leasburg Dam and Mesilla Dam and between Mesilla Dam and American Dam in order to test the effect of a range of gains or losses to the river. I added a gain of 30 cfs to the Rio Grande in each of these subreaches; this change represents an increase in drain flow (or other net increase in instream flows) in the Mesilla Valley. The result of this change is shown in Figure B4. The increase in total gains by 60 cfs resulted in a decrease in Caballo release of 60 cfs.

Note that in this test case, the flow “At American Dam” does not change and equals the amount of water required for Lower Valley Orders and the required Mexican Delivery. That is, the flow to EPCWID at El Paso does not change; only the Release from Caballo changes.

These results numerically demonstrate that, based on long standing Caballo Release Procedures, increasing the amount of drain flow in the Rio Grande system above Rio Grande at El Paso would not necessarily increase the flow at Rio Grande at El Paso. Instead, during the irrigation season the flow at Rio Grande at El Paso is controlled by the amount of water ordered by EPCWID and required for Mexico.

It is possible for years in which the Project does not have a full supply, increased instream flow (drain flow, etc.) between Caballo and Courchesne could result in additional water available for allocation, and thus higher allocations, and perhaps higher orders. Therefore, in years in which the Project does not have a full supply available, an increase in instream flow could result in increased flows at El Paso. However, in full-supply years, EPCWID would have been allocated a full supply, and would have ordered the water needed to supply the orders of its water users, unconstrained by supply limitations. Under such conditions, increased instream flow between Caballo and Courchesne would result in reduced releases from Caballo necessary to meet those orders. During full-supply years, I conclude that increases in instream flow (drain flow, etc.) between Caballo and El Paso would not lead to a direct increase in the flow at El Paso during the irrigation season. Instead, increases in instream flow in such years would lead to reduced releases from Caballo, which could translate to increased water availability in future low-supply years, unless that water was spilled from the reservoir before such time occurred.

APPENDIX C

CHANGES IN PROJECT DIVERSION AND CONVEYANCE IN THE EL PASO VALLEY AND ASSOCIATED PROJECT IMPACTS

TABLE OF CONTENTS

Table of Figures

Table of Tables

Appendix C

Changes in Project Diversion and Conveyance in the El Paso Valley and Associated Project Impacts

This Appendix will demonstrate that return flow from El Paso Valley drains was historically an important part of Project Supply. Significant changes in the El Paso Valley, including dramatic infrastructure changes as well as changes in groundwater conditions due to groundwater pumping in the Hueco Bolson by Texas and Mexico, and the effects of drought, have substantially reduced this source of Project Supply. Notably, Post-1978 Accounting[1] does not have a term to account for diversion of El Paso Valley drain flows; therefore, this historical source of Project Supply is not counted even if EPCWID continues to divert these waters.

In this Appendix I will first describe the infrastructure changes, then I will quantify the decrease in El Paso Valley drain flows as a source of Project Supply.

1 Description of the El Paso Valley Diversion and Conveyance Systems and Changes Thereto

Water discharged from a system of drains in the El Paso Valley has historically provided irrigation water to Project lands and to Hudspeth County ("HCCRD"), which is not a Project beneficiary. Drains collect seepage and excess water from the river, from conveyance structures, and from irrigated lands, and returns or discharges that water to the Project system for further delivery and use. Diversion structures in the El Paso Valley have changed considerably through the history of Project and add complexity to any understanding of how the drainage system initially worked and was relied upon as an important source of Project Supply, and the current situation where drainage serves as a negligible source of Project Supply or aquifer recharge.

The El Paso Valley drains can be divided into two groups: those discharging into the Rio Grande (or Project conveyances) above the town of Fabens, Texas (Drains Above Fabens), which is about two-thirds of the way down the El Paso Valley, and those discharging into the Rio Grande (or Project or HCCRD conveyances) below the town of Fabens (Drains Below Fabens).[2] This method of description will be used in this Appendix.

---

[1] In approximately 1979 Reclamation implemented a new Project accounting system which determines the charged diversions (AKA allocation charges) for each District ("Post-1978 Accounting"); *see* Appendix D for a detailed discussion.

2 Starting in the early 1920s through 1983, Reclamation records subdivide the El Paso Valley drains in to "Above Fabens" and "Below Fabens," and identify cases in which the gaged flow of a tributary gage are included in the flow gaged in the combined drain downstream.

1.1 EARLY DIVERSION AND CONVEYANCE IN THE EL PASO VALLEY

Before the Rectification of the Rio Grande in 1938:

- Water was diverted from the Rio Grande at International (or Mexican) Dam into both Acequia Madre (for Mexico) and Franklin Canal (to supply U.S. Project lands (that is, the Districts)).
- Water was also diverted from the Rio Grande at Riverside Dam, to supply lands within EPCWID.
- Water supplying Project lands was also diverted from the Rio Grande at the Tornillo Canal heading, at the town of Fabens.
- Two other small U.S. diversions downstream of the International Dam are mentioned in Rio Grande Project Histories: Hansen and Guadalupe (little information is available about these diversions and I believe them to be of negligible import).

The Drains Above Fabens include the River Drain, its main tributary the Middle Drain, and the Mesa, Cuadrilla, and Fabens Intercepting Drains. Before 1938, these drains discharged into the Rio Grande, and water from these drains would then be diverted at the Tornillo Canal heading. This configuration is illustrated in Plate 21 of the Joint Investigation; an excerpt from this plate is included as Figure C.1.[3] The important conveyances in this area are more clearly illustrated in a Reclamation map from the papers of Raymond Hill[4] apparently created at the time of the Joint Investigation, included herein as Figure C.2.

Tornillo Canal at Fabens was completed in 1925. It was described In the Project Histories as "*the means to collect a large amount of recovered and developed water of the Project*"[5] and as the site of "*collection and diversion of irrigation water and return flow.*"[6] That is, return flow was plentiful enough at this location that it required a means to move it back into directed Project use.

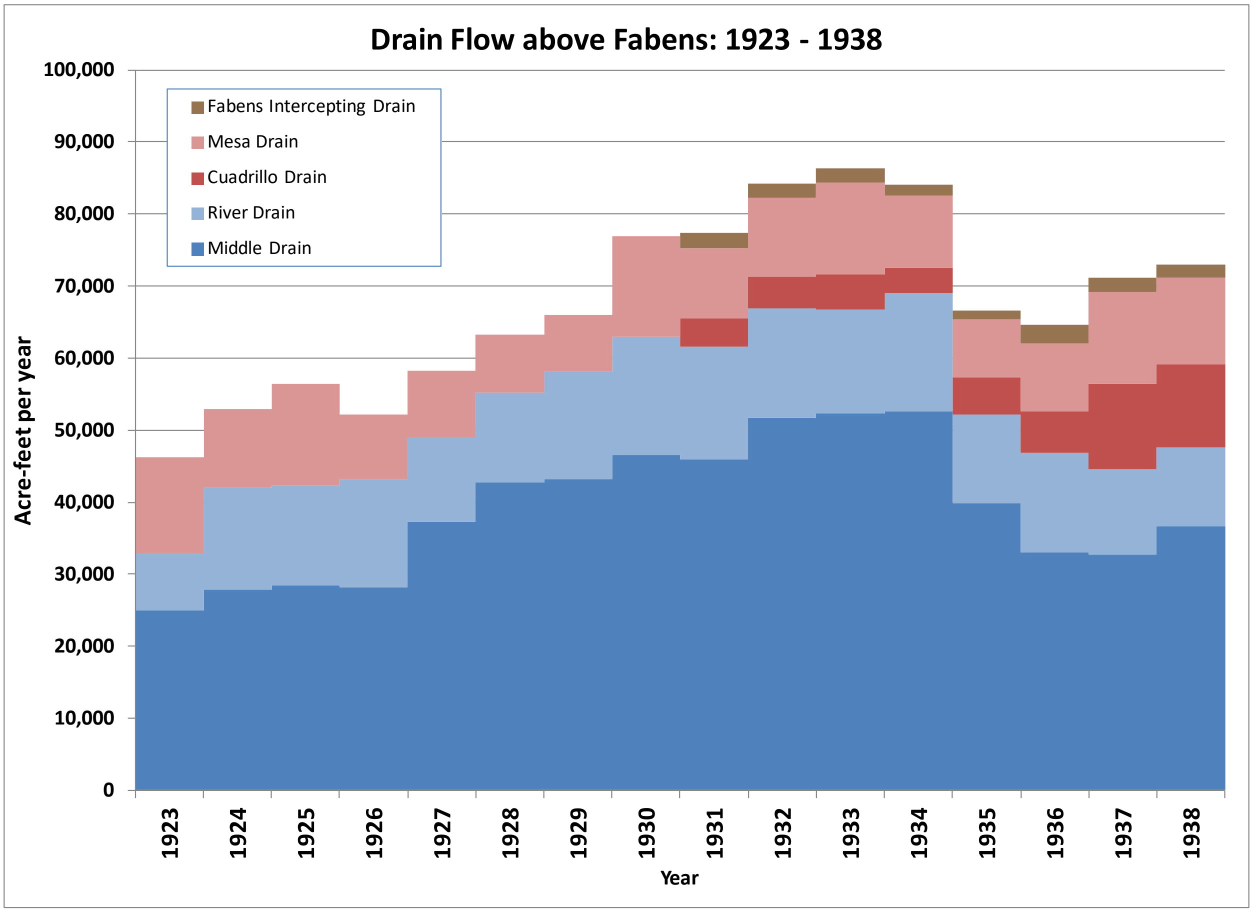
In Figure C.3, I plotted the discharge data from the Drains Above Fabens from the time period before the Rio Grande Rectification.[7] These data show that during the 1930s between 60,000 AF/Y and 80,000 AF/Y of drain flow was available for diversion at the Tornillo heading for further delivery to EPCWID lands.

<u>Figure C.3. Gaged Discharge of El Paso Valley Drains Above Fabens</u>



[7] Reclamation Drainage Data Reports, 1923-1938.

1.2 Significant Changes to the Infrastructure of the El Paso Valley

In 1938 two major changes structural changes occurred in the El Paso Valley: completion of the American Dam, and the realignment of the Rio Grande near Fabens. Another impactful infrastructure change was the construction of the American Canal Extension ("ACE") in 1998.

1.2.1 Construction of the American Dam and American Canal

The American Dam and American Canal were completed in 1938, allowing the US to divert water for the Project above International Dam.[8] Starting in 1938, American Canal delivered water to EPCWID's Franklin Canal heading, which previously had been supplied by the International Dam. In addition, much of the water diverted at American Dam was wasted back to the Rio Grande at locations below International Dam, for delivery to Riverside Dam further downstream. This reconfiguration is illustrated in the schematic in Figure C.4.

The 1938 Project History describes the operations in this area as follows:

> *The manner of operation of the American Dam and Canal is that the water allotted to Mexico is passed through the dam into the old river channel, while the remaining total flow of the river is carried through the American Canal to the Franklin Canal settling basin. The net diversion for the Franklin is made several miles below the settling basin after sluicing operations have returned to the river all of the water not desired for the Franklin Canal net diversions. This water returned to the river, of course, is for later diversion by Riverside Canal... Incidentally, the old International Diversion Dam, which formerly served both the Franklin Canal and the Acequia Madre is now only used by the Acequia Madre, since under the new setup the diversion for the Franklin Canal is now made at the American Dam.*[9]

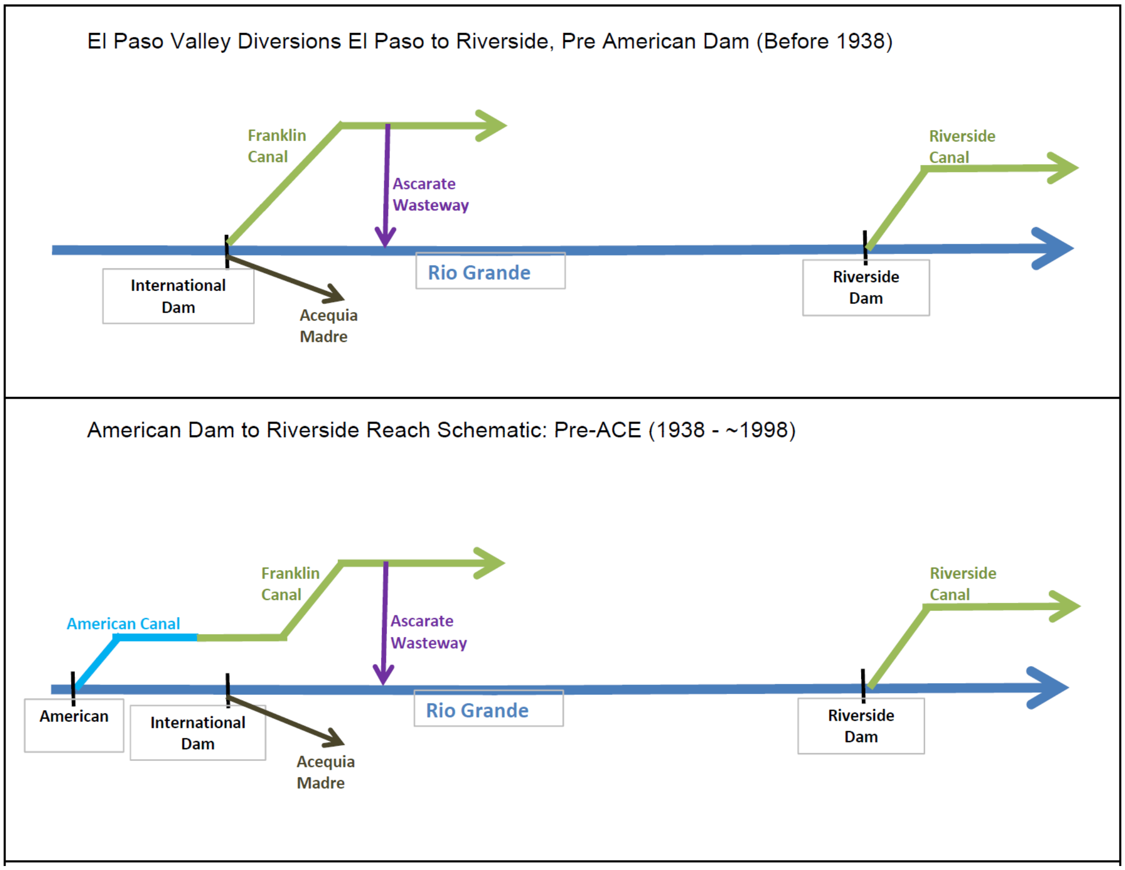
[9] RGPH 1938, p. 31/312.

Figure C.4. Schematic of El Paso Valley Conveyance Reconfiguration above Riverside in 1938



1.2.2 Realignment of the Rio Grande

Prior to Rectification, the bed of the Rio Grande had passed through the town of Fabens where water, including discharge from several El Paso Valley drains, was diverted into the Tornillo Canal. Rectification moved the bed of the Rio Grande approximately 3 miles south to coincide with the international border, causing Fabens to be divorced from the river.[10] This move effectively disconnected the Project heading at Tornillo from the Rio Grande and constituted a significant change in the course of the river in the Fabens area, as illustrated in Figure C.5 showing the major changes in the position of the Rio Grande in the El Paso Valley since 1903.

[10] RGPH 1938.

Figure C.5. Major Changes in the Position of the Rio Grande, 1903 to Present[11]

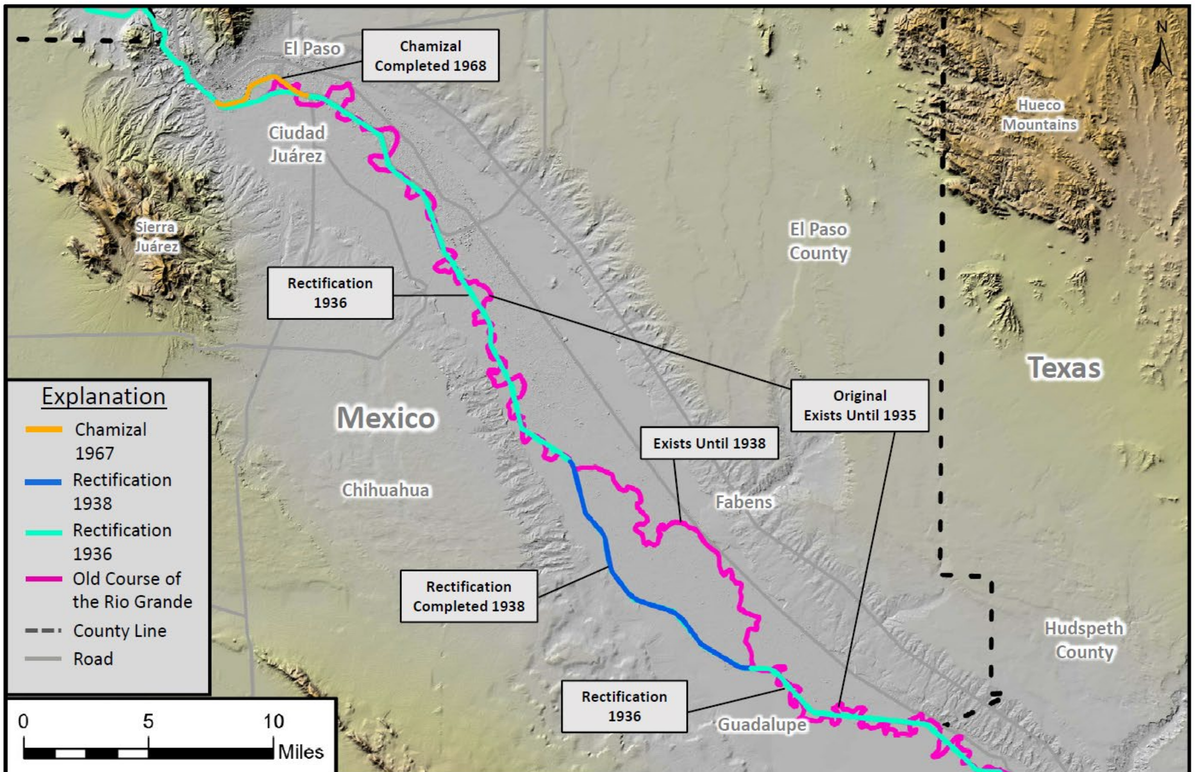


Figure 4.5a – Major changes in the position of the Rio Grande, 1903 to present.

McDonald Morrissey Associates, LLC Ground Water Hydrologists

Confidential Draft - Privileged Pursuant to Rule 26 of the Federal Rules of Civil Procedure: Prepared for Litigation

This realignment is described in the 1938 Project History: "*The river channel was relocated on July 1, 1938 … the old river channel … had run along the north and east side of the San Elizario Island through the town of Fabens … as a result of this change the old river was used merely as a feeder for the Hansen and Tornillo Canals after July 1*."[12]

In the years that followed, Reclamation used the now-dry bed of the Rio Grande above Fabens as a feeder for the Tornillo Canal, and then built an extension of the Riverside Canal along the old river bed to convey water to the Tornillo heading.[13] Reclamation also constructed the Fabens Waste Drain south of Fabens, to collect discharge from the Drains Above Fabens, and the Fabens Waste Channel along the course of the old river bed below Fabens, to convey waste and drain waters to HCCRD.

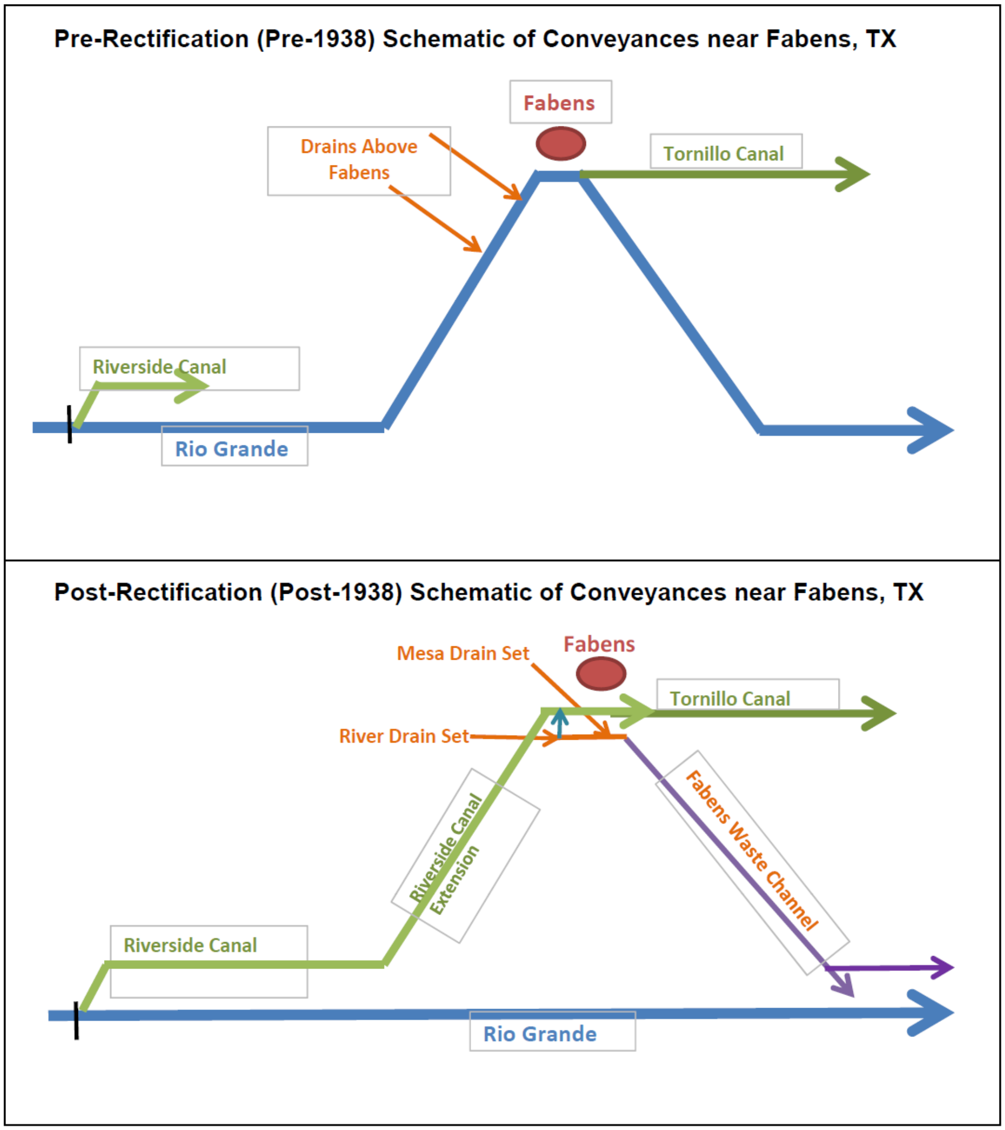
[12] RGPH 1938.

[13] RGPH,1939, 1940, 1941 (Chapter II Construction).

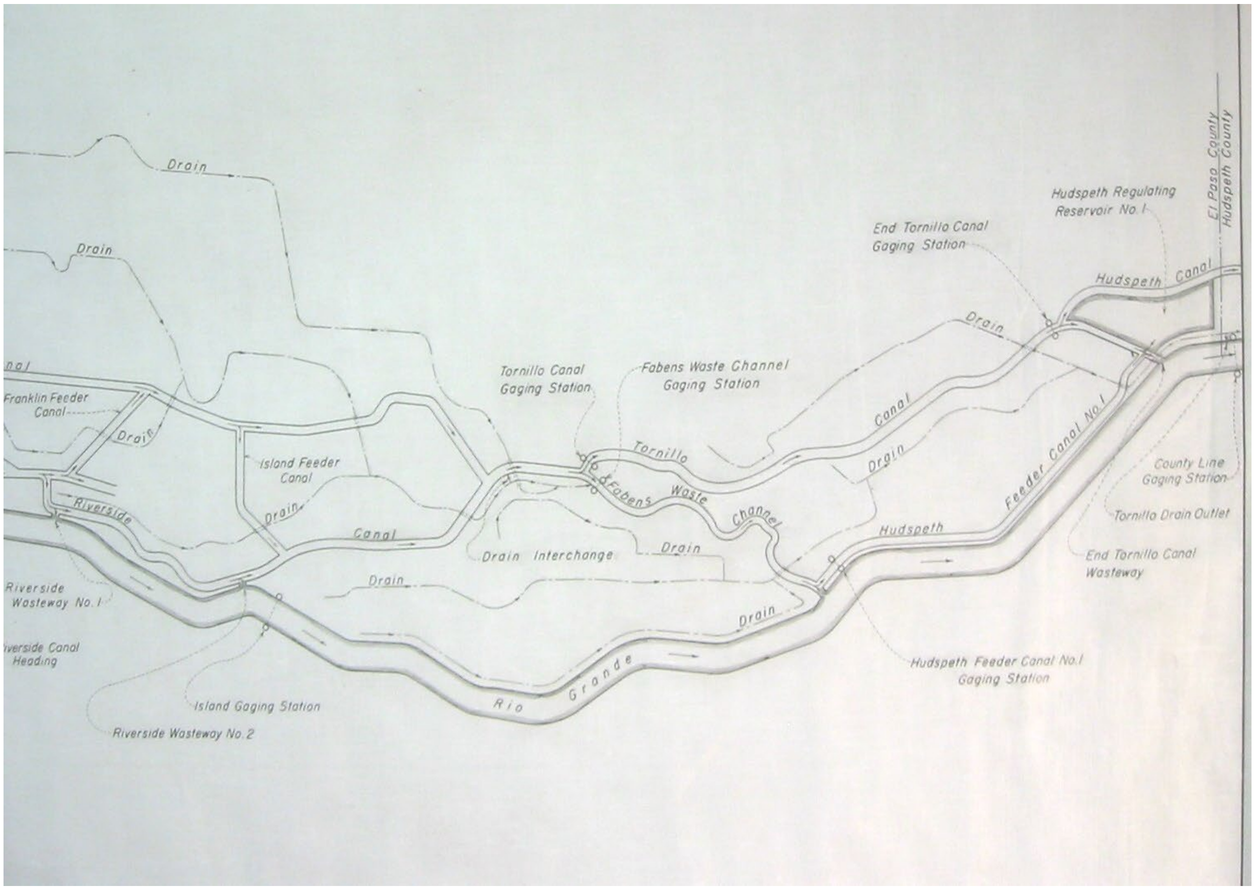
The pre-existing Tornillo Canal now received water from the new Riverside Canal Extension. This change in conveyances is illustrated in Figure C.6 (created by author), and the later configuration is illustrated by Reclamation in Figure C.7, showing the extended Riverside Canal and the heading of the Tornillo Canal.[14]

Figure C.6. Schematic of 1938 Change in Conveyances near Fabens, TX



[14] Cortez, F., PPT: U.S. Bureau of Reclamation / Rio Grande Project, 2003 (PPT named: TCEQ_BOR_PP_121103.ppt,), Slide 30.

Figure C.7. Reclamation Project Map, Fabens Area, Post-Rectification



As a result of these significant infrastructure modifications, starting in 1938 the main Project diversions in the El Paso Valley changed to:

- The Franklin Canal which now diverted water from the American Canal, and
- Riverside Dam which continued to divert water from the Rio Grande to supply the EPCWID lands it had already supplied, and to deliver water to the now land-locked Tornillo heading.

Reclamation's reconstruction of Project conveyances following Rectification did segregate the discharge from the Drains Above Fabens by conveying this water under the Riverside Canal Extension to the Fabens Waste Drain. Specifically:

- Water from Mesa Drain, Cuadrillo Drain, and the Fabens Intercepting Drain was routed directly to the Fabens Waste Channel for delivery to HCCRD.
- The River Drain, however, was configured so that water from this drain could be diverted into the Riverside Canal Extension above the Tornillo heading. As a result, the flows of the River Drain and the flows of its main tributary, the Middle Drain (which discharges into the River Drain below the River Drain gage) were available for diversion at the Tornillo heading, and evidence

(as described below) demonstrates that a "Drain to Canal" diversion formed part of Project Supply.

Contemporaneous Project documents state that one of the benefits of the Rio Grande Rectification to the Project was that poor-quality drain flow could be segregated out of Project Supply at Fabens. A 1937 letter by Fiock (then manager of the Project) states:

> "*Probably most outstanding in the way of advantages accruing to the irrigation project through the removal of the river to the international boundary line would be the possibility of keeping irrigation water for the lower end of the project separated from drain water at Fabens, thus holding the salt content to a safe dilution…"*[15]

A 1940 letter by Fiock states:

> "*The first and most important item of this work was the separation of the irrigation and drain water in the vicinity of Fabens, that is, carrying the drain discharge from the valley above Fabens under the canal and returning to the old river bed below the Tornillo Canal heading.*"[16]

Despite these clear statements, when the drain system near Fabens was reconstructed after the realignment of the Rio Grande ***only some*** of the drains were routed directly into the Waste Drain and to the Waste Canal for conveyance to HCCRD. The River Drain was plumbed differently so that water from the River Drain (which included the flow from its main tributary the Middle Drain) could be conveyed to the Tornillo heading.

The fact that Reclamation treated these two drain systems differently indicates that Reclamation preferred to continue using water from the River Drains within the Project, but not the water from the other drains which it sent to HCCRD, presumably because of water quality issues.

The connection of the drain system to the canal and waste system is illustrated in schematics obtained from Reclamation.[17] The schematic at Figure C.8 shows that the River Drain is connected to the Riverside Extension by means of a feature labeled "Drain to Canal." Based on my field inspection, this connection appears to be a subterranean tunnel between the two conveyances, which are parallel and close together at that location. Figure C.9 is a diagram I drew based on my observations of the Project conveyance system near Fabens.

RIVER BUDGET FOR THE RIO GRANDE 113

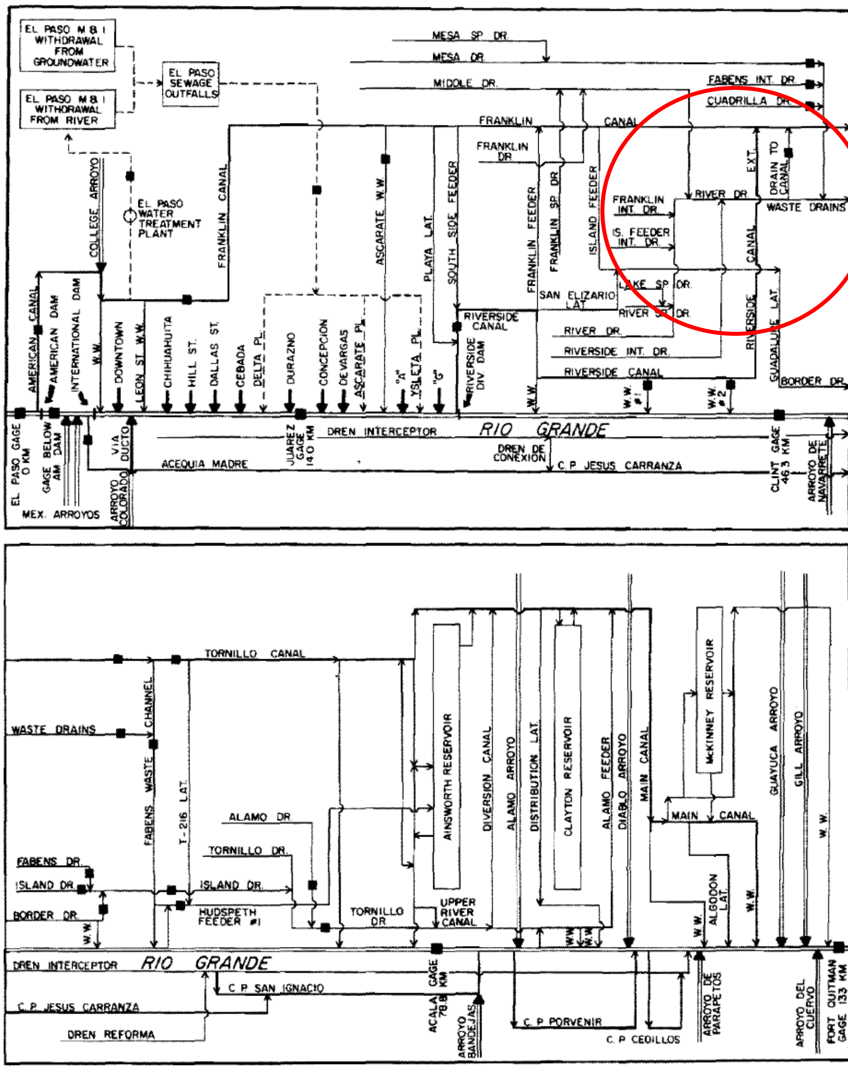

Figure 3. Schematic diagrams of present-day inflows and outflows to the Rio Grande and routing of river water through the El Paso–Juarez Valley. The bottom diagram is a continuation of the upper diagram. Solid boxes represent gages; solid triangles represent arroyo inflows to river; bold arrows represent urban runoff inflows to river; dashed arrows represent El Paso sewage inflows to river; other arrows represent irrigation transfers.

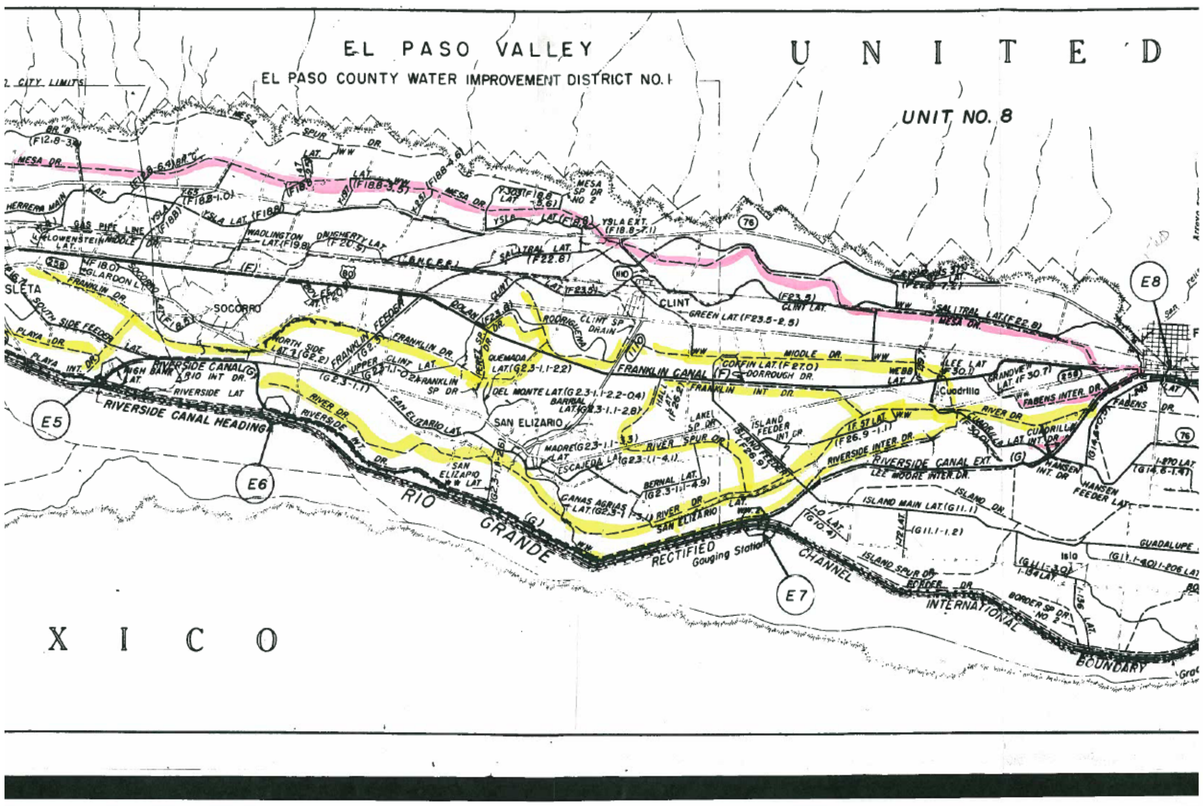
[18] Marston, R.A. and Lloyd, W.J., *River Budget for the Rio Grande, El Paso-Juarez Valley*, Journal of Arid Environments, (1985) 8, 109-119, September 30, 1983.

Figure C.11 is an excerpt from a strip map of the Project's El Paso Valley area from the 1985 Draft Operating Agreement and illustrates the two different sets of Drains Above Fabens. I modified this map by highlighting the River Drain and its tributaries in yellow, and the other Drains Above Fabens in pink. Figure C.11 clearly illustrates the large source area of the River and Middle Drain system.

Figure C.11. Excerpt of Reclamation Project strip map of the El Paso Valley



1.2.3 Construction of the American Canal Extension

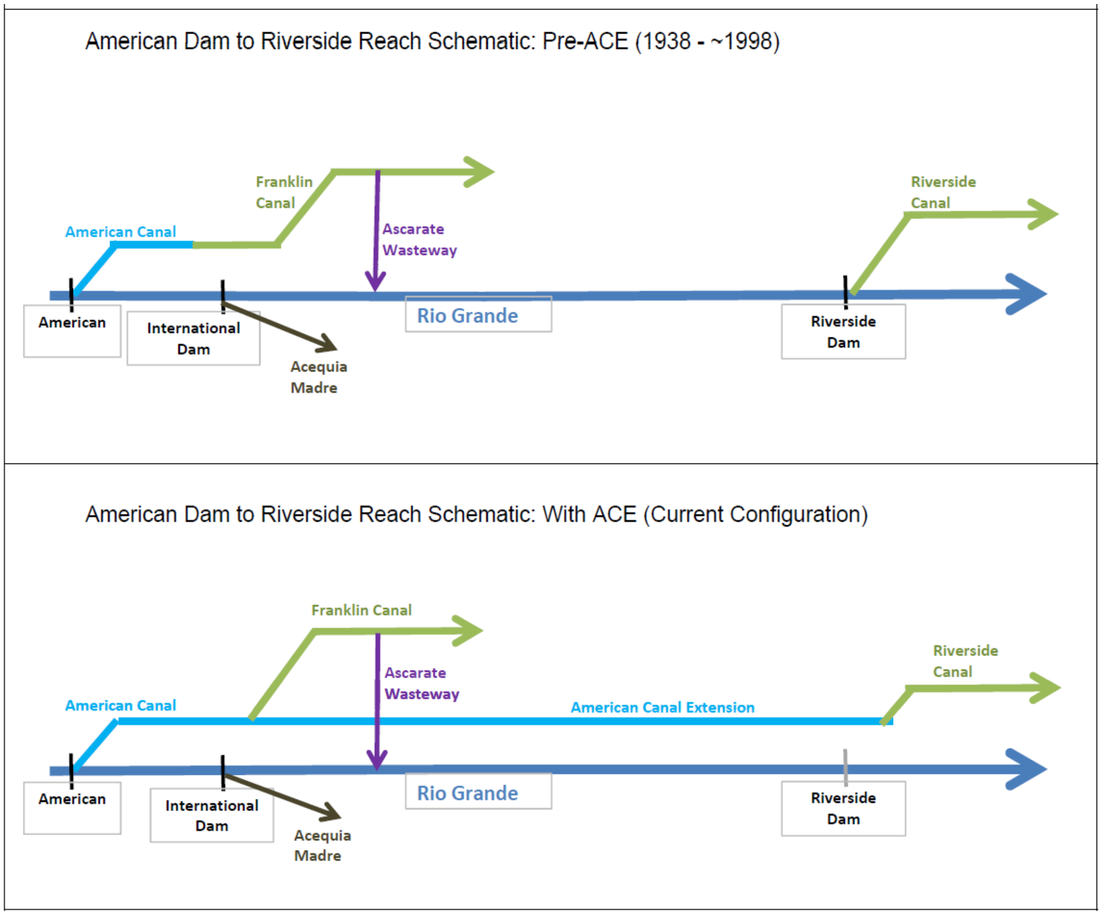
In 1987 Riverside Dam was damaged by high flows. Following the failure of Riverside Dam, the Riverside Canal was supplied by a temporary coffer dam installed by EPCWID near the location of Riverside Dam until the completion of the American Canal Extension ("ACE") in 1998.[19] With the completion of the ACE, Project water could be diverted at American Dam to supply both Franklin and Riverside Canals, with water conveyed to the Riverside Canal heading through the newly built ACE instead of through the bed of Rio Grande. This is shown in schematic form in Figure C.12 (drawn by the author), and also in Figure C.13, a Project diagram obtained from Reclamation.[20]

---

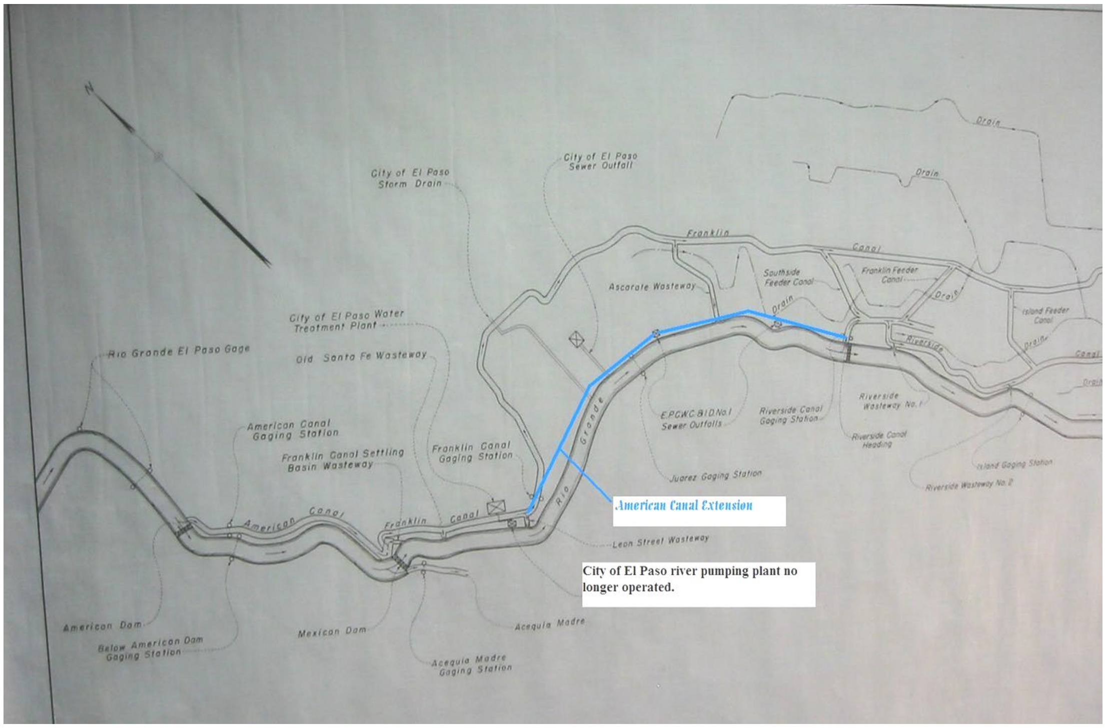
[19] 2001 Final Environmental Assessment for "Replacement of the Old American Canal" Located in El Paso, Texas. prepared for U.S. IBWC by ENCON International, Inc., December 6, 2001 (2001 FEIS).

[20] Cortez, F., PPT: U.S. Bureau of Reclamation / Rio Grande Project, 2003 (PPT named: TCEQ_BOR_PP_121103.ppt,), Slide 29.

Figure C.12. Schematic of Project: American Dam to Riverside, before and after completion of the American Canal Extension (ACE)



<u>Figure C.13. Reclamation Illustration of Project from Courchesne Gage to Riverside Dam, showing planned location of ACE</u>



The impact on Project operations of the ACE is improve the conveyance efficiency of the Project in the El Paso Valley, but at the same time recharge to the groundwater system in the El Paso Valley has been decreased because of less seepage from ACE and other concrete-lined canals, and less seepage from the bed of the Rio Grande.

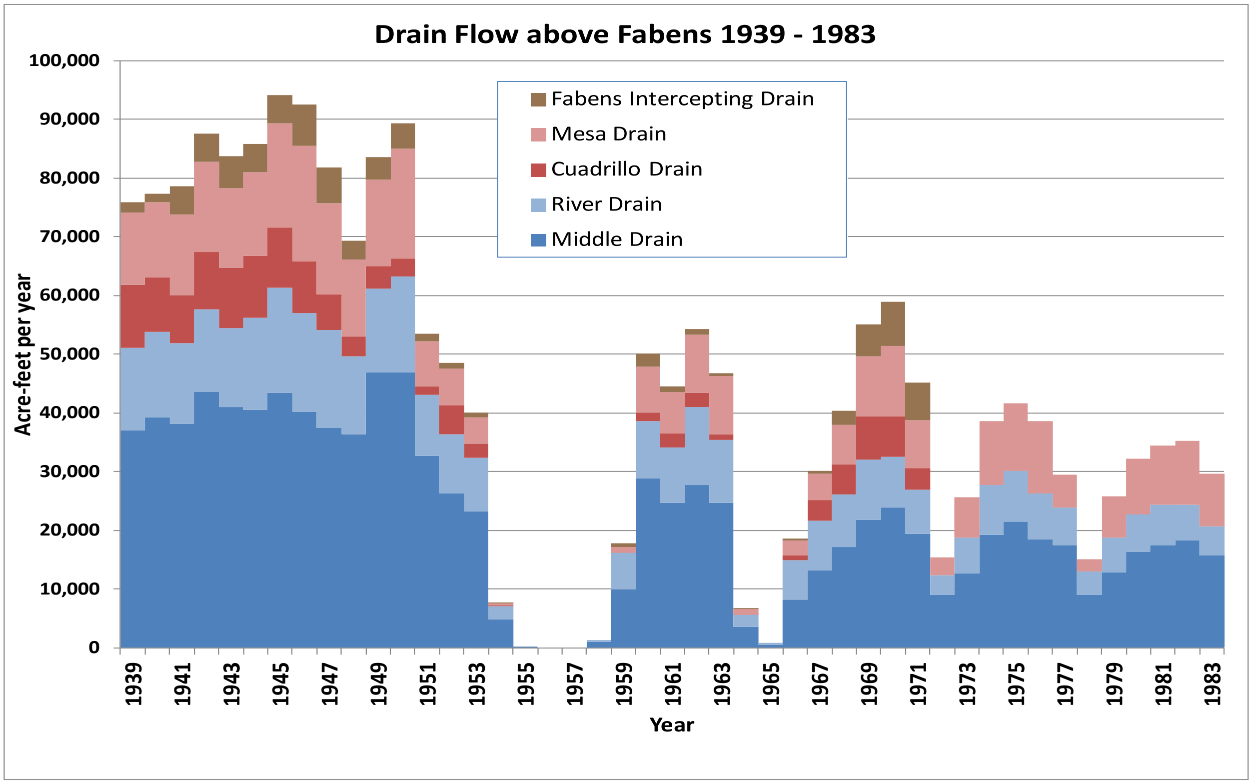
2 QUANTIFICATION OF THE IMPACTS OF EL PASO VALLEY INFRASTRUCTURE CHANGES

I have conducted a great deal of research to determine what, if any, these El Paso Valley infrastructure changes have had on Project operations and Project Supply. The results follow.

2.1 Drain Flow Availability

I plotted discharge data from the Drains Above Fabens from the time period 1939 through 1983 (post-Rectification) in Figure C.14.[21] The blue bars, representing drain flow from the River and Middle drains, would have been available to supply to the Riverside Canal Extension. Comparison of the bar charts in Figures C.3 and C.14 show a substantial decrease in El Paso Valley drain flows starting during the drought of the 1950s and continuing through the rest of the period of record. (I am not aware of any post-1983 discharge records for these El Paso Valley drains).

Figure C.14. Gaged Discharge of El Paso Valley Drains Above Fabens, 1939-1983



---

21 Compiled from Reclamation Drainage Data Reports, 1923-1983.

What this plotted data clearly shows is that drain flows in the El Paso Valley have decreased substantially since extensive groundwater pumping for irrigation in the El Paso Valley began during the 1950s. Municipal groundwater pumping by both El Paso and Juarez also increased during this time.

2.2 Drain to Canal Diversion Records

The diversion from the River Drain into the Riverside Canal Extension was historically gaged, and this diversion data is available from a number of sources:

1) Reclamation Drainage Data reports from the years 1945 through 1982 include notations of the annual totals of Drain to Canal diversions, typically denoted as the amount "diverted from River Drain to Riverside Ext. – Tornillo Canal." An example excerpt from one of the Drainage Data Reports is in Figure C.15a.[22]
2) The "Report on Annual Flow Data" (circa 1956) from the New Mexico College of Agriculture and Mechanical Arts (now New Mexico State University or NMSU) includes a table of "Drain Water Diverted at Fabens" that is populated with data from 1945 through 1955.[23] This table is in Figure C.15b.
3) NMSU's 2003 compilation of Project flow data included a large set of scanned Reclamation data sheets that include annual discharge data reports for Drain to Canal at Fabens for the years 1945 through 1983.[24] An example of one of these annual discharge reports is in Figure C.15c.

U.S. GOVERNMENT PRINTING OFFICE 6—7984

Where these data sets overlap, they are consistent with each other. I created a summary of the data from these sources as tabulated in Table C.1. The average annual reported Drain to Canal diversion over the period of record is 9,850 AF/Y. While this diversion is significant, it is far less than the 60,000 AF/Y to 80,000 AF/Y of Drain Flow above Fabens available for diversion at Tornillo heading at the time of the Joint Investigation.

Table C.1. Tabulation of the Annual Diversions from the River Drain into Riverside Extension

1962	12,212		1982	155
1963	17,470		1983	0
1964	2,758			

This summary table demonstrates the large amount of diverted El Paso Valley drain flow through the 1940s, the dramatic decrease in such diversions during the drought of the 1950s, the resumption of significant amounts of diverted El Paso Valley drain flows through most of the 1960s, and the sporadic and decreasing amounts of diverted El Paso Valley drain flows after about 1972. I have no information on available or diverted amounts of El Paso Valley drain flows after 1983 but believe, based on my observations and my understanding of groundwater conditions caused by recent years of low surface water supply, urbanization, reductions in recharge caused by canal lining and Texas and Mexico pumping, there is little drain water available in the El Paso Valley.

2.3 El Paso Valley Drain Flows as a Source of Project Supply

As reflected in the findings of the Joint Investigation, diverted El Paso Valley drain flow accounted for a significant portion of Project water deliveries in the early years of the Project. In fact, the Joint Investigation noted that some 35% of water diverted to EPCWID at Franklin Canal was composed of "drain flow and seepage," while a full 57.7% of water diverted at Tornillo was composed of "drain flow and seepage."[25] The difference between these two numbers: 35% and 57%, represents the amount of El Paso Valley drain flow diverted at Tornillo that would not have been available further upstream at Franklin, meaning that between these two points the Project received considerable drain flow for Project use.

Prior to Rio Grande Rectification, the discharge of all the Drains Above Fabens was available at Tornillo heading for diversion and was thus available to the Project.

After Rectification, there is evidence from Reclamation records that the Drain to Canal diversion of El Paso Valley drain flow formed part of Project Supply. The only comprehensive tabulations of Project diversions prior to 1979 are the Project Water Diversion Records (WDRs). The WDRs provide annual tabulation of water distribution for the Project as a whole, and for various subdivision of the Project, including the El Paso Valley. The data set from which the D2 Curve was derived (see Appendices A and E) included annual Project-wide diversion data from these WDRs for the period 1951 through 1978, which included the severe drought years of the 1950s.

Some of the pre-1979 WDRs available for the El Paso Valley indicate that the diversions tabulated on the forms are the result of a calculation involving various diversions and wasteway discharges. Figure C.16 is a sample WDR for the El Paso Valley for 1951 extracted from the Project History (Reclamation Form 7-322). The notations on the back of this sheet indicate that the El Paso Valley diversion is calculated from the diversions into Franklin and Riverside canals plus Drain to Canal.[26] This indicates that El Paso Valley drain flows diverted at the Drain to Canal conveyance were part of Project Supply after the Rio Grande Rectification. Another source of this data is in the 1956 New Mexico Agriculture and Mechanical Arts "Report on Annual Flow Data."[27] The tabulation of "El Paso – Diversions", which is consistent with the WDR El Paso Valley Diversions, has a description field which reads: "Includes drain water diverted at Fabens."

---

[25] Joint Investigation, Part I, page 100, Table 90.

[26] Other terms are then subtracted including Ascarate waste way discharge, which at that time would have been rediverted at the Riverside Dam, discharge from Riverside waste ways #1 and #2, and Playa Lateral waste to Riverside Canal.

The inclusion of Drain to Canal diversion in Reclamation's Project WDRs indicates that El Paso Valley drain flow formed part of the data set calculated to derive the D2 Curve.[28] The average amount of Drain to Canal diversion during the D2 Period (1951 – 1978) is 8,400 AF/Y.

2.4 Current Accounting for and Diversion of El Paso Valley Drain Flows

The Post-1978 Accounting rules and procedures as set forth in the 1985 Draft Project Operating Agreement are similar to those described in the 2008 Operations Manual, which is operative today. In neither the 1985 Draft Operating Agreement nor the 2008 Operations Manual is there any term for "Drain to Canal" nor any term representing the diversion of El Paso Valley drain flow, nor any term representing a diversion at Tornillo, meaning these drain flows have not been counted as Project Supply since at least 1979 through today, although before that time records reflect these drain flows were counted. Field visits by myself and other New Mexico experts indicate that the Canal to Drain diversion structure remains in place. During my recent visits there has been no flow in the River Drain at that location, which probably results from recent low-supply Project conditions and high levels of groundwater pumping in the Hueco Bolson (the Rio Grande groundwater basin below Courchesne). Given the current Project accounting, even if such flow existed and were diverted, this diversion would not be charged to EPCWID.

3 Conclusions

Based upon the data and analysis provided below, I conclude the following:

- El Paso Valley drain flows have historically been available for diversion at the Tornillo heading for Project Supply.
- Prior to the 1938 Rectification of the Rio Grande, drain flow from all the El Paso Valley Drains Above Fabens (including the River Drain system, and the Mesa, Cuadrillo and Fabens Intercepting Drains) were discharged into the Rio Grande and were available for diversion at Tornillo heading. The total discharge of these drains ranged from 60,000 AF to 85,000 AF during the 1930s
- Tornillo heading was intended to collect and then deliver Project return flows, including drain flow.
- The Rio Grande Joint Investigation indicates that El Paso Valley drain flows were a significant source of the water diverted at the Tornillo heading during the period 1930-1936.
- Following the 1938 Rectification, water was diverted from the River Drain into the Riverside Canal Extension for delivery to the Tornillo heading. Drain flow from the Mesa, Cuadrillo and Fabens Intercepting Drains was conveyed directly to the Fabens Waste Drain and Waste Channel for delivery to HDDRC.
- The reported amounts of water diverted from the River Drain into the Riverside Canal Extension from 1945 through 1983 period of record ranged from zero to 38,000 AF/Y.

[28] See Appendix E for a discussion of the other diversion terms in Figure C.16.

- The flows in the Drains Above Fabens declined significantly during the 1950s drought from what they had been previously. The recorded flows in the Drains Above Fabens remained relatively low throughout the remainder of the period of record (until 1983). It is likely that the relatively low flows in these drains since the early 1950s is caused by a number of factors including low supply, urbanization and increased irrigation and municipal groundwater pumping in the Hueco Bolson.
- Recent field visits by me and other New Mexico staff and experts indicate that a structure to divert water from the River Drain to Riverside Canal Extension is still in place.
- My analysis of current Project accounting procedures indicates that when there is water in the River Drain, and when that water is diverted, that diversion will not be charged to EPCWID.

APPENDIX D
PROJECT ALLOCATION AND ACCOUNTING

In this Appendix, I discuss in detail and provide support for the facts and conclusions summarized in Section 6 of the Report.

1 PROJECT ALLOCATION AND PROJECT ACCOUNTING 1979-2005

1.1 D1/D2 ALLOCATION

Beginning in 1979, and as a result of the Districts and Reclamation executing the Transfer Contracts, Reclamation significantly changed its delivery operations. Heretofore, Reclamation had allotted water to farmers on a pro-rata basis by acreage, and delivered water to farmers at their individual farm head gates. To effect the mandates of the Transfer Contracts, Reclamation instead agreed to allocate water to the Districts and deliver this water to EBID and EPCWID canal headings; the Districts then to oversee delivery of the water to individual Project beneficiaries.

The Transfer Contracts contain language requiring that "[a] detailed operating plan will be concluded between the United States and the District setting forth procedures for water delivery and accounting."[1] Reclamation was charged with developing a means of allocating water to the Districts, instead of to farmers, that would maintain the equities of the Project. Accordingly, during the 1980s Reclamation performed analysis of historical water distribution data and developed the "D1 Curve" and the "D2 Curve", which are linear regression fits of Project water distribution data from 1951-1978. Figures D.1 and D.2 were obtained from Reclamation,[2] and reflect the D1 and D2 Curves. These Curves form the basis of the "D1/D2 Allocation."

Note that significant although largely unmeasured groundwater pumping was known to have occurred throughout the Project during the D2 Period (1951 – 1978). Reclamation reports (and other sources) indicate that farmers in EBID and EPCWID pumped large amounts of groundwater during years of low Project supply during this period (*see* Report section 4). Increased groundwater pumping, combined with the drought conditions that gave rise to increased pumping, caused decreased drain flows in the Rincon, Mesilla and El Paso Valleys during this time period, and probably increased seepage losses from the Rio Grande as well. Project water distribution data from that period would have reflected these hydrologic effects.

In 1985 Reclamation released its 1985 Draft Operating Agreement, including an early version of the D1/D2 Allocation method, and documentation of an accounting system that describes how the Districts' diversions would be accounted, or charged, against their allocations. A cover letter addressed to the New Mexico State Engineer indicates that the 1985 Draft Operating Agreement "has been implemented

[1] Transfer Contracts, section 6, paragraph d.

[2] Cortez, F., PPT: U.S. Bureau of Reclamation / Rio Grande Project, 2003 (PPT named: TCEQ_BOR_PP_121103.ppt), provided to the New Mexico ISC March 2005.

in 1985."[3] Thereafter, Reclamation produced a document for the Project entitled "Annual Operating Plan, Actual Operations 1984, Forecast Operations 1985"[4] which documented the implementation of the allocation and accounting described in the 1985 Draft Operating Agreement.

Reclamation officially documented the D1/D2 Allocation method (with a modified version of the D2 curve) in its Water Supply Allocation Procedures ("WSAP") document. The WSAP was provided to NM State Engineer Office staff by F. Cortez of Reclamation's El Paso Office in 2005. The WSAP document presents the D1 and D2 Curves which have been used for allocation since 1991,[5] and are incorporated into the 2008 OA.

The D1/D2 Allocation method explicitly divided the U.S. share of Project supply 88/155 (57%) to EBID and 67/155 (43%) to EPCWID, on an annual basis, in keeping with earlier agreements and historical practice. The new method and system further retained the historic practice of including any unused allocation from one season as part of pool of water available for allocation to the Districts and Mexico the next year.

In general, the D1 Curve was (and still is) used to determine Mexico's share of Project Supply, and the D2 Curve was used to determine the total amount of Project Supply available for allocation to both the Districts from Project Storage.

- The D1 Curve was derived from a plot of the annual delivery to U.S. farms plus the delivery to Mexico at Acequia Madre versus the annual release of Project water from Caballo. The farm delivery data in the D1 data set are equal to the reported farm deliveries from Reclamation's annual Water Distribution Reports (WDRs), and thus presumably originated from those reports (Appendix E to this Report describes the D1 data set).
- The D2 Curve was derived from a plot Project Net Supply plus the delivery to Mexico at Acequia Madre versus the annual release of Project water from Caballo. The Project Net Supply data are equal to the reported "Net Supply" or "Diverted from Stream" values from Reclamation's annual WDRs, and thus presumably originated from these reports (Appendix E to this Report describes the D2 data set).

In Figure D.3 I have plotted the D2 data provided in the WSAP report, together with a linear regression of that data (calculated in Excel), which is identical to the D2 Curve presented in the WSAP report. In Figure D.4 I illustrate how the amount water allocated by the D2 Curve is distributed among Mexico, EBID and EPCWID under D1/D2 Allocation.

The D2 Curve is used to calculate the total amount of water available for diversion by the Districts and Mexico at canal headings (or Project Supply), based on the amount of Usable Water in storage available

[3] Letter 1985 0129 from R.K. Patterson, USBR, to Steve Reynolds, New Mexico State Engineer, RE Implementation of 1985 Draft Operating Agreement.

[4] Annual Operating Plan: 1984 Operations, 1985 Outlook, Bureau of Reclamation, Rio Grande Project, 1985.

[5] Full-Supply Allocation amounts for the year 1991-2002 and 2005 are consistent with the D2 Curve in the WSAP document.

for release. Historically, the total amount of water thus calculated was then divided up between Mexico, EBID and EPWCID. Mexico's allocation (determined using the D1 Curve) was first subtracted from the total Usable Water available for diversion, and the remainder was split 57:43 between EBID and EPCWID respectively. This division between the Districts is based upon each District's proportion of the Project authorized acreage as set forth in the 1938 Inter-district Contract and applied historically.

The D2 Curve is, in effect, a measure of the Project performance, or Project delivery efficiency, during the 1951 through 1978 period. It describes how much water the Project delivered to canal heading for a given amount released from Project Storage.

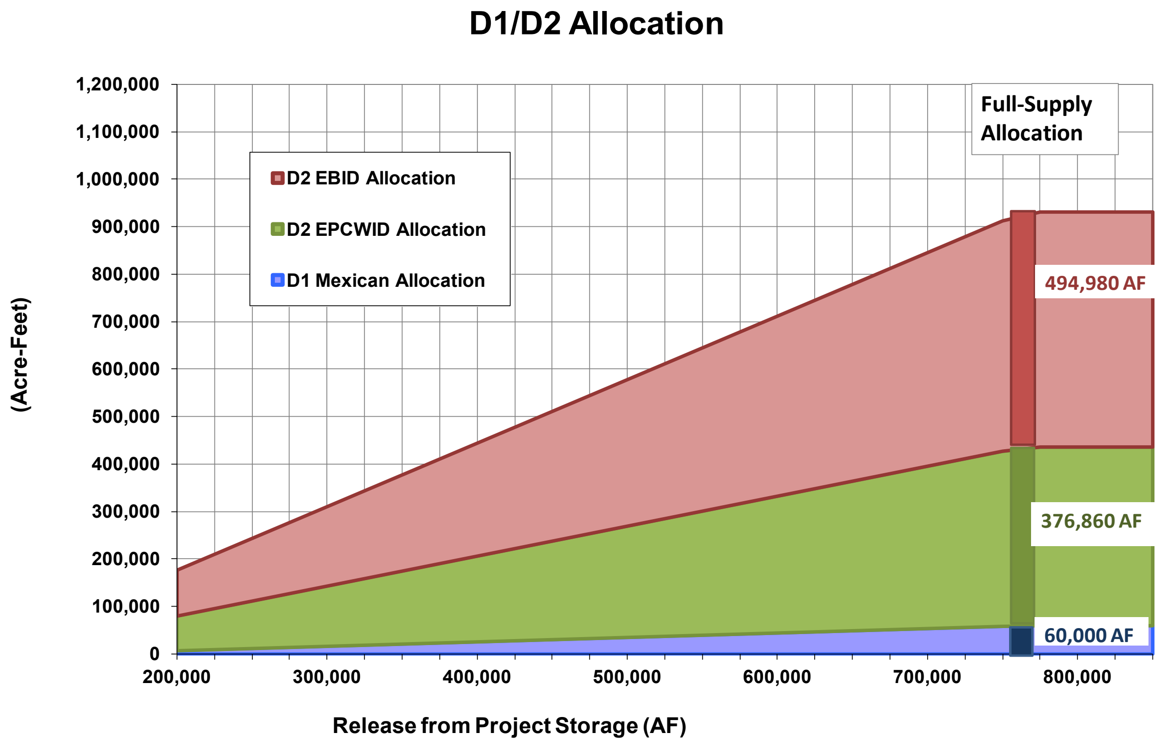
Figure D.4. Illustration of D1/D2 Allocation among Districts and Mexico



The D1/D2 analysis provided in the WSAP document determines full-supply allocation[8] amounts for Mexico, EBID and EPCWID as shown in Table D.1. These amounts differ from the full-supply allocations amounts provided in the 1985 Draft Operating Agreement which were based on somewhat different D2 Curve, and also from the reported allocations for full-supply years from 1979 - 1990, suggesting that the allocation method had not been completely finalized until 1990.

The D1/D2 analysis in the WSAP determined that a release from reservoir storage of 763,842 AF would provide a full supply to the Districts and Mexico.

[8] A "full-supply" allocation is the amount each District is allocated in a year during which the Project experiences a full supply of water, and was defined based on the canal heading diversions necessary to deliver a normal supply of 3.024 AF/A to all District lands.

Table D.1. D1/D2 Rio Grande Project Allocations for Full Water Supply from WSAP

Allocations for a Full Water Supply[1] (acre-feet)						
Release Requirement[2]	Net Diversions at Headings[3]	Mexico Allocation	EBID Allocation	EBID Percentage[4]	EPCWID Allocation	EPCWID Percentage[4]
763,842	931,841	60,000	494,979	56.77%	376,860	43.23%

1. Full water supply is 468,700 acre-feet to farm head gates of US lands (3.024 AF/A for 155,000 authorized acres) and 60,000 acre-feet to Mexico at the International Dam
2. Release from Caballo Reservoir necessary to meet full water supply at diversion headings
3. Net Diversion at Headings determined from Curve D2 (includes US and Mexico)
4. Percentage is based upon the net amount remaining to U.S., after deducting Mexico's allocation

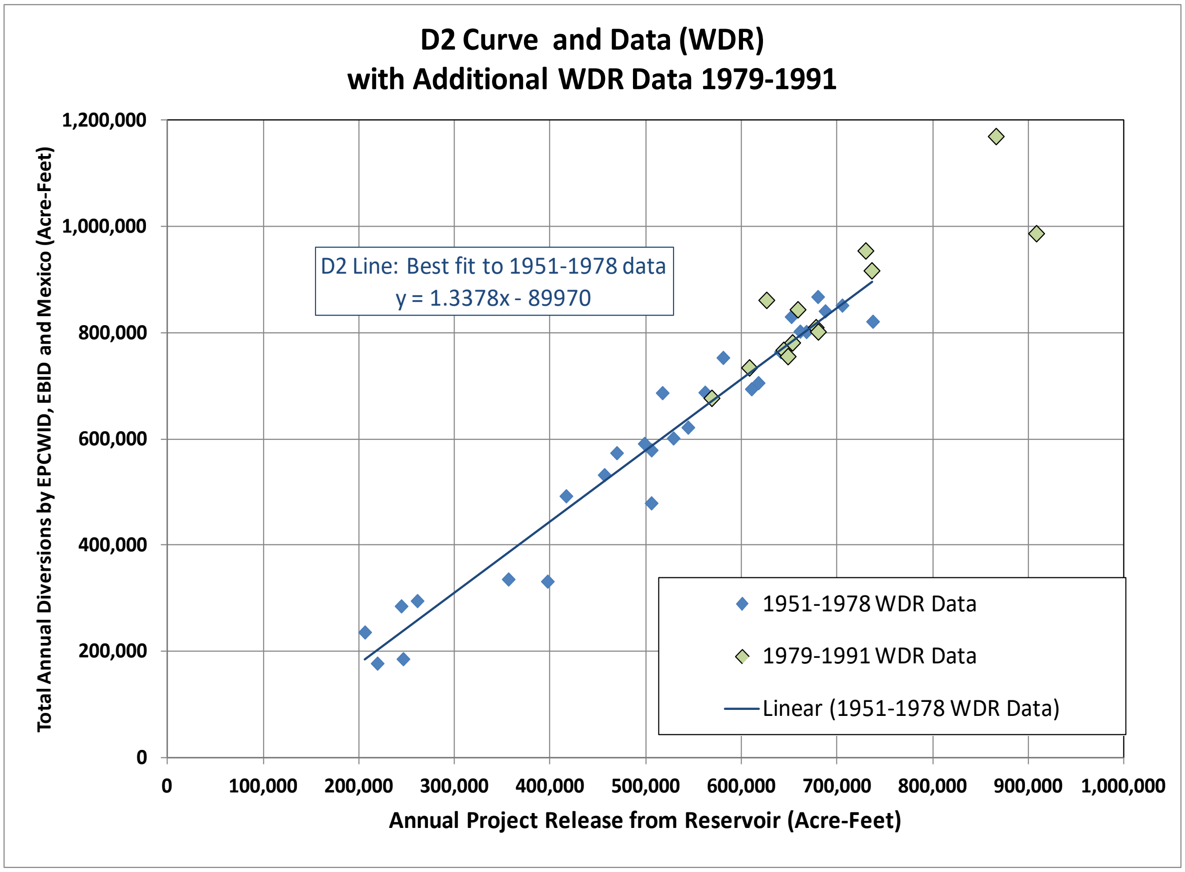
Full-supply conditions obtained for 24 years, from 1979 up to and including 2002. During this period, each District was allocated a full supply, but it was unusual for either District to divert all of the water allocated to it.

During the water-short years of 2003 and 2004, Reclamation employed an ad hoc allocation method in which the allocation to EBID and EPCWID was based upon the historic 57:43 division of an amount based on the Usable Water in storage, without reference to the D2 Curve. This change recognized the fact under the conditions existing at that time, an allocation made using the D2 Curve would be greater than the amount that could actually be delivered.

Project record keeping changed over the 1979 – 2005 period. It is my understanding that Reclamation continued to report this data through 1991 with some changes in format,[9] but starting in 1992 or 1993 more of the responsibility for cropping and water distribution reports fell to the Districts, and it is likely that the Districts were responsible for the data on these forms starting at that time. Figure D.6 is a plot of the D2 Curve and the D2 data set (with additional total diversion data from these other WDR sources from 1979 through 1991).

[9] Until 1978, this data was collected on "Monthly Water Distribution" form 7-322. From 1979 – 1981 this type of data appears on computer printout titled "Monthly Water Distribution and Operation and Maintenance Costs." Starting in 1982, this data was reported on "Crop Production and Water Utilization Data" form 7-2045 (3-79).

Figure D.6. D2 Curve and D2 Data (WDR), with additional 1979 – 1991 data from Project WDR sheets



The WDR diversion data from 1979 through 1991 are well aligned with the D2 Curve suggesting that Project performance during this period was consistent with the Project performance during the 1951 through 1978 period. That is, the D2 Curve was a good predictor for water available to be diverted at the main canal headings through 1991, as tabulated by Reclamation on WDR forms.

1.2 Post-1978 Accounting

Once Reclamation began allocating and delivering water to the Districts in 1979, it needed a system for assigning Project diversions to each District so that each District's diversions could be charged against its allocation. I am not aware of any description available of the accounting Reclamation used for this purpose until the 1985 Draft Operating Agreement; however, the available accounting data from 1979 through 1985 suggests that the general accounting methodology described in the 1985 Draft Operating Agreement was used starting in 1979. This accounting system has been modified since it was first documented in the 1985 Draft Operating Agreement, but to a large degree this same accounting system is in place today and will be referred to here as "Post-1978 Accounting."

Post-1978 Accounting is described here based on the 1985 Draft Operating Agreement. The significant changes made to the accounting process as part of the 2008 OA will be described in a later section.

In general, Post-1978 Accounting is based on the amounts diverted at Project diversion headings:

- EBID diversions from the Rio Grande at the Arrey, Leasburg, and Eastside and Westside canal headings, plus a number of minor diversions.
- EPCWID diversions at the Franklin and Riverside canal headings (which currently divert water from the American Canal), two diversion headings for the El Paso Water Utility ("EPWU"), and a number of other minor diversion locations.

An important feature of Post-1978 Accounting is a process for dealing with the diversions at Mesilla Dam to the Eastside and Westside Canals, which supply lands in both EBID and in EPCWID. Post-1978 Accounting assigns charges to EPCWID, and credits to EBID, for deliveries of Project water to EPCWID lands in the Mesilla Basin.

In addition, there is a provision in the 1985 Draft Operating Agreement called "Early Water Order by One District" for the case when one District starts ordering water earlier in the year than the other District. During such a time, charges are based on the release from Caballo "plus drain and sewage effluent," if that amount is greater than the amounts diverted at the District's diversion headings.[10] This provision is similar to current Project accounting practices applied when only one District is ordering water.

Post-1978 Accounting includes a number of credits, not part of the prior accounting method, which reduce the amount of each District's total charged diversions. These credits will be discussed in more detail in Section 3 of this Appendix.

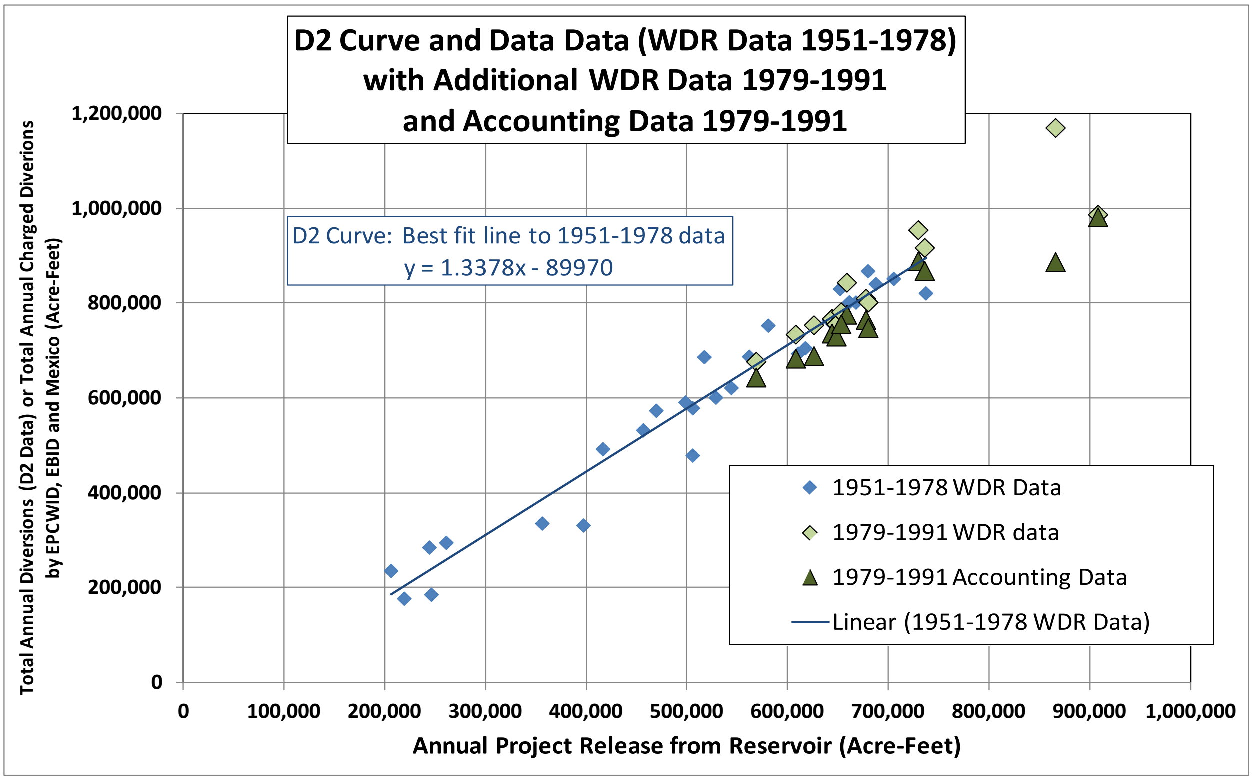
The 1985 Draft Operating Agreement included a description of the process by which the Districts order water and the process for calculating charges and credits, including a statement that "*All diversions made by the Districts during the nonirrigation season utilizing return flow waters shall not be charged against the Districts' respective allocations.*"[11] Only limited information is available regarding the early application of Post-1978 Accounting, and it is uncertain to what extent non-irrigation season diversions were included in the calculation of charged diversion during this time.

Accounting data in the form of charged diversions (or allocation charges) are available for each District starting in 1979 (at least in summary form). In Figure D.7 I have combined the total annual charged diversions for the Districts with the Mexican diversion, and plotted this data from 1979 through 1991 together with the D2 Curve, the D2 data set, and the WDR data from 1979 through 1991.

[10] 1985 Draft Operating Agreement, p 13.

[11] 2008 Operations Manual, p.3.

Figure D.7. D2 Curve and D2 Data (1951-1978), with Additional WDR Data (1979 – 1991), and Accounting Data (1979 – 1991)



Data in Figure D.7 indicate that charged diversions from Project Accounting are systematically lower than data from the WDR reports for the same years. This indicates that Project accounting data are systematically different than the WDR data. This suggests that the accounting process itself is responsible for part of the negative departure from the D2 Curve.

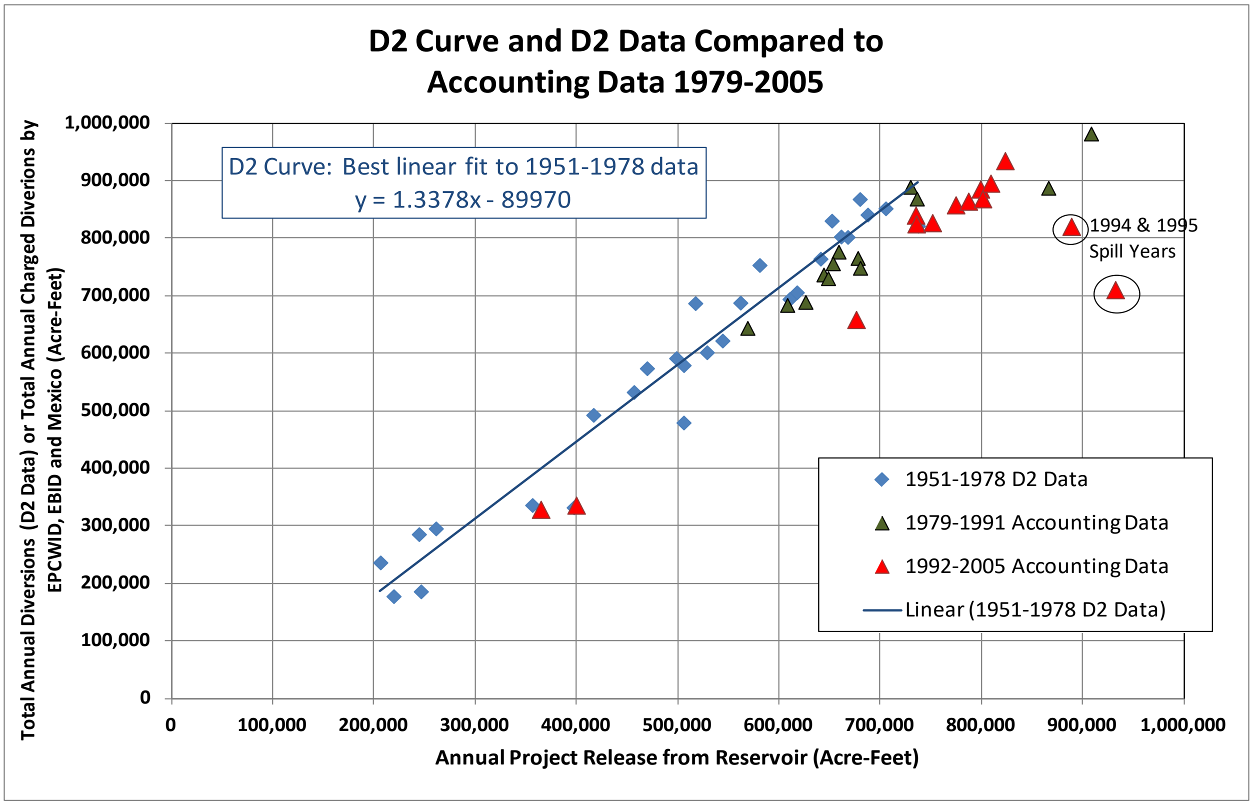
The practical effect of a negative departure from the D2 Curve is that more water will have to released from Caballo to deliver a given amount of charged diversions to the District and Mexico than the D2 Curve would predict.

In recent years, negative departures from the D2 Curve are interpreted by Reclamation as evidence that the performance of the Rio Grande Project has deteriorated since the D2 Period (1951 – 1978).[12] This view is reflected in D3 Allocation (discussed below), which reduces total allocation to account for this negative departure, and "charges" EBID for that entire amount, assuming the discrepancy is all associated with the actions of New Mexico and its citizens, and not taking into account the effect of changes in accounting.

[12] Continued Implementation of the 2008 Operating Agreement for the Rio Grande Project, New Mexico and Texas, Final Environmental Impact Statement, Bureau of Reclamation, September 30, 2016.

In Figure D.8, I have plotted Project accounting data from 1979 through 2005 together with the D2 Curve and associated D2 data. The accounting data consists of annual total Charged Diversions from EBID and EPCWID, combined with the gaged Mexican Diversion at Acequia Madre.

Figure D.8. D2 Curve and D2 data plotted together with 1979 – 2005 Charged Diversions as reported by Reclamation, calculated using Post -1979 Accounting



The 1979-2005 Charged Diversions in Figure D.8 are systematically lower than the D2 Curve. This means that in these years, the total amount of allocation that was delivered to Project headings and Mexico was less than what would be predicted by the D2 Curve, and therefore less than what was allocated under D1/D2 Allocation. This result suggests that Reclamation may have allocated more water than it could have actually delivered as charged diversions in most years since 1979. However, since the Project had a full supply every year between 1979 and 2002, and neither District ordered the full amount allocated to it, there were no resulting operational problems.

I conclude that D1/D2 Allocation, as applied until 2006, generated higher allocations than could be delivered as charged diversions. However, because in the full-supply years of 1979 through 2002 neither District ordered all of its allocation, this issue did not become apparent. There was enough water available to supply all orders, if not the full amount allocated. The problem did become acute, however, in 2003 when the amount of water available to the Project was far below full supply. This condition led Reclamation to allocate by an ad hoc method, without reference to the D2 Curve in 2003 and 2004.

2 ALLOCATION AND ACCOUNTING 2006 – 2019 (D3 ALLOCATION WITH CARRYOVER)

Considerable controversy arose during the 1990s and early 2000s over Project operations. Litigation between the Districts and Reclamation and New Mexico was occurring in a number of judicial venues. During some of this time there were confidential negotiations concerning Project operations, which included the Districts, Reclamation, and the States. It is my understanding that other negotiations took place during this time frame that only included the Districts and Reclamation.

In the spring of 2006, EBID proposed a new and different allocation method, the D3 Allocation method.[13] New Mexico expressed support for this proposal, with the proviso that "additional study is needed before adoption of a permanent change in Project operations."[14] D3 Allocation was implemented by Reclamation in that same year. At about the same time, EPCWID demanded the ability to "carry over" unused allocation from year to year for its individual use,[15] rather than the historic practice of incorporating that unused allocation into the pool of water available for allocation the next year. EPCWID argued that since it did not use all of the water allocated to it in every year, it should be able to "carry over" the excess, and not have to share it with EBID as part of the following year's allocation process, although this had been the practice for "nearly 100 years."[16]

Reclamation partially implemented carryover of unused allocation in 2006, starting the 2007 allocation for each District with what shall be called "Carryover" equal to one-half of the District's unexpended 2006 allocation.[17] EPCWID filed suit against EBID and Reclamation in US District Court for the Western District of Texas in 2007 as a result of this partial (rather than full) implementation of Carryover.

In 2007 Reclamation published and adopted the 2007 Operating Procedures for the Rio Grande Project.[18] These Operating Procedures included the D3 Allocation method as proposed by EBID, and provisions for Carryover of unused allocation as demanded by EPCWID. Also in 2007 confidential

settlement negotiations took place between the Districts and Reclamation (but not including the states of New Mexico or Texas), that in 2008 resulted in settlement of litigation between those parties.

The 2008 Settlement Agreement[19] associated with the two federal cases among Reclamation, EBID, and EPCWID was executed by the Districts and Reclamation. The 2008 Settlement Agreement included the 2008 Operating Agreement[20] adopting D3 Allocation and Carryover.

The 2008 OA included provision for the development of an Operations Manual[21] to "contain detailed information regarding the methods, equations, and procedures used by EBID, EPCWID and the United States to account for all water charges and operating procedures for the Rio Grande Project." An Operations Manual was adopted in 2008, and has been modified since (2010 and 2012) as new issues arose and additional data analysis warrented.

Under the D3 Allocation method, Mexico and EPCWID are generally allocated water according to the D1 and D2 Curves, as described in the previous section, but EBID's allocation is calculated based on the Project Diversion Ratio, a new term in Project allocation.

The Diversion Ratio is calculated as the ratio of the annual Project Charged Diversions (including Mexico) divided by the annual Project release from Caballo. This term is used to estimate the total amount of allocation that can be delivered to the Districts and Mexico (Project Supply) for a given Project release. In effect, the Diversion Ratio is a measure of current Project delivery efficiency or performance, although it is calculated using charged diversions rather than total actual diversions.

The effect of the Diversion Ratio in the D3 Allocation method is shown in Table D.2. The calculation shown is highly simplified, in that Carryover and ACE Credit are assumed to be zero, but accurately represents the effect of the Diversion Ratio. The example shown is for full-supply conditions. The two columns of data show the resulting D3 Allocation as calculated assuming two different diversion ratios: 1.1 and 1.0. Both calculations provide Mexico and EPCWID are allocated the same amounts: 60,000 AF and 377,000 respectively, as calculated using the D1 and D2 Curves.[22] EBID's allocation is calculated using the diversion ratio, and varies greatly between the two scenarios. EBID is allocated 403,000 AF if the diversion ratio equals 1.1, but only 327,000 AF if the diversion ratio is 1.0.

---

[19] Agreement between the U.S./USBR, EBID, and EPCWID, executed August 15, 2008, settling cases: *EBID and The City of Cruces/Intervenor v. U.S./USBR and EPCWID,* Cause No. CIV 00-1309 JB/KBM in the District Court of New Mexico, and *EPCWID v. U.S./USBR,* Cause No. EP-07-CA-0027-PRM in the Western District of Texas – El Paso Div. ("2008 Settlement Agreement").

[20] 2008 Operating Agreement for the Rio Grande Project, Agreement between Elephant Butte Irrigation District, El Paso County Water Improvement District No, 1, and the United States through the Bureau of Reclamation, signed March 10, 2008.

[21] 2008 OA, Section 1.12.

[22] The D2 calculation for EPCWID is made in accordance with the 2008 OA, in which the D2 Curve has been extended to a release of 790,000 AF.

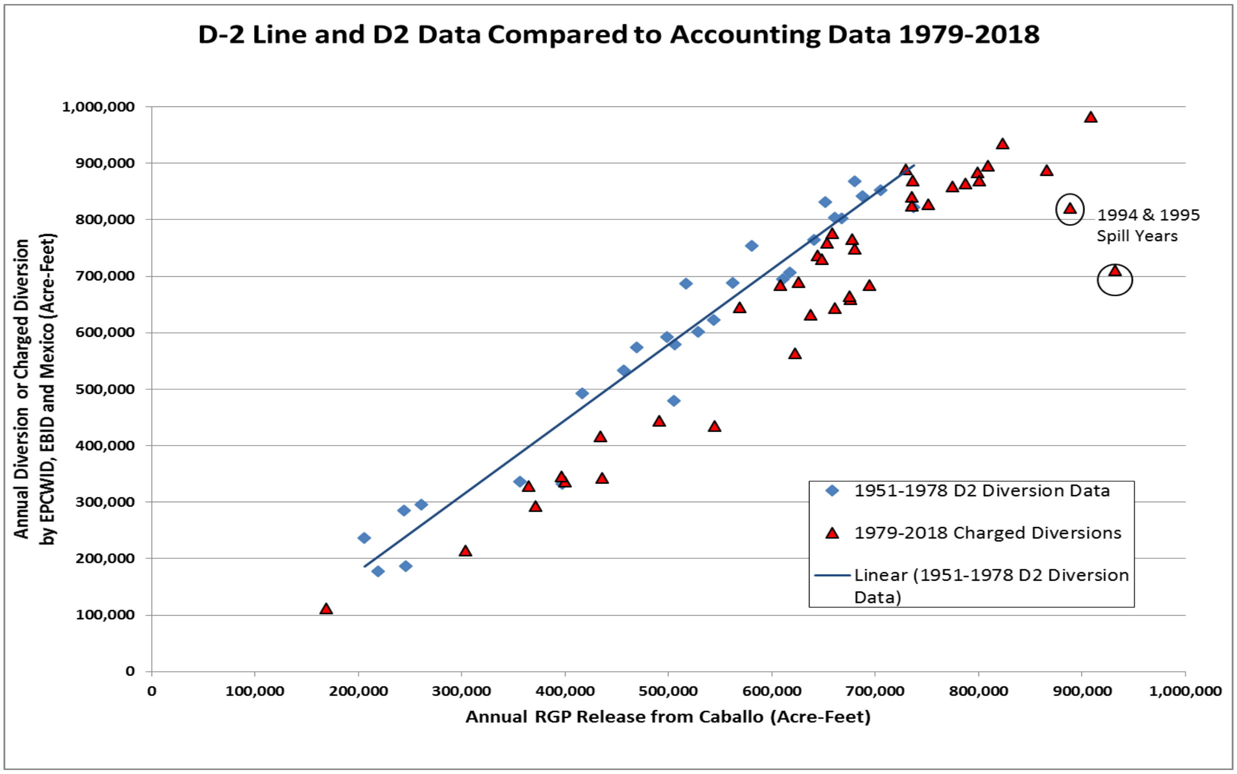
Table D.2. Illustration of the Effect of Variation in the Diversion Ratio (D3 Allocation, Full-Supply)

Illustration of the Effect of Variation in the Diversion Ratio under D3 Allocation. (Values rounded to nearest 1000 AF)		
Diversion Ratio (unitless)	1.1	1.0
Usable Water (AF)	764,000	764,000
Mexican Allocation (AF)	60,000	60,000
EPCWID's Allocation (AF)	377,000	377,000
EBID's Allocation (AF) [(Usable Water x Diversion Ratio) – Mexican Allocation – EPCWID Allocation]	403,000	327,000

Roughly speaking, under the D3 Allocation method, Mexico's D1 Allocation and EPCWID's D2 Allocation are subtracted from the Project Supply (calculated using the Diversion Ratio), and the remainder is allocated to EBID. D3 Allocation has the effect of reducing EBID's allocation by any amount by which the estimated deliverable or actual Charged Diversions falls short of the Net Supply calculated by the D1/D2 Allocation method.

The D3 Allocation is based on a comparison of Project Charged Diversions versus Caballo Release data compared with the D2 Curve. In Figure D.9, I have plotted Project accounting data from 1979 through 2018 together with the D2 Curve and associated D2 data. The accounting data consists of annual total Charged Diversions from EBID and EPCWID, combined with the gaged Mexican Diversion at Acequia Madre.

Figure D.9. D2 Curve and D2 data plotted together with 1979 – 2018 Charged Diversions as reported by Reclamation, calculated using Post -1979 Accounting

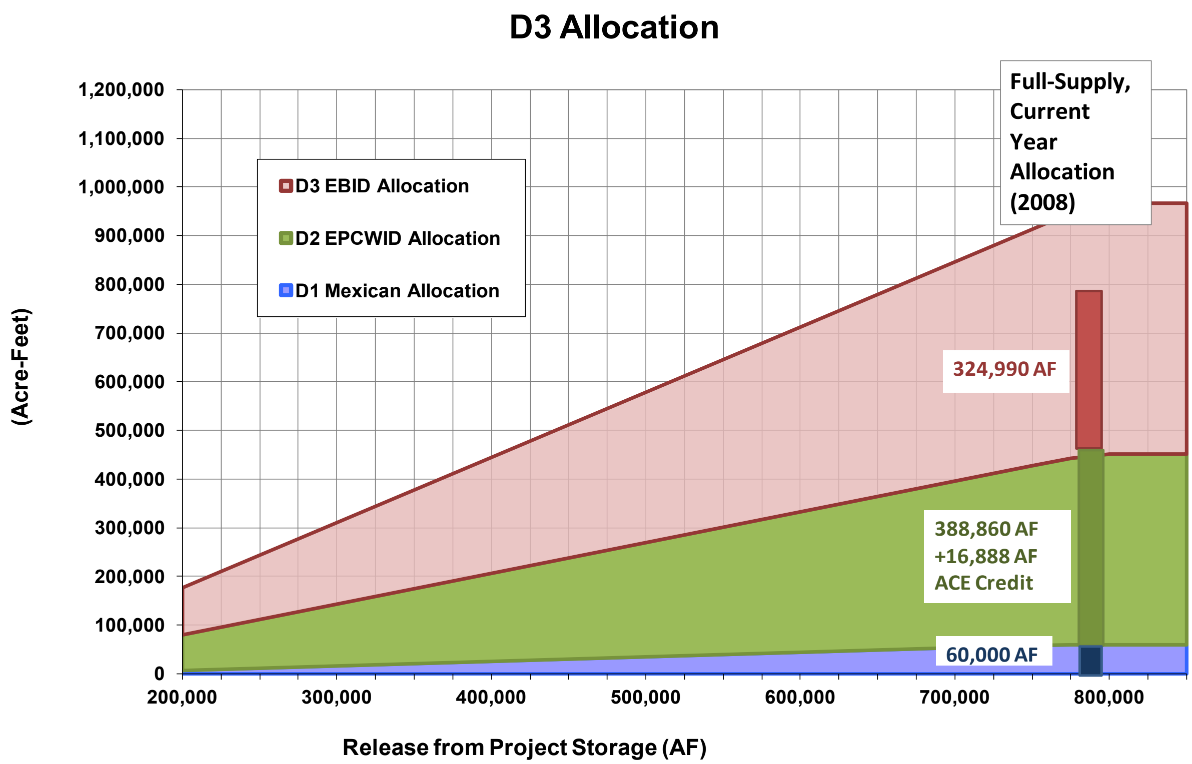


The D3 Allocation method, as applied, uses the Diversion Ratio to reduce the total amount allocated each year to account for deficiencies in Project performance. The total D3 Allocation should, in theory, closely approximate the amount of charged diversions the Project can deliver to canal headings under the hydrologic conditions existing in each year. Mexico's and EPCWID's allocations, however, are still determined using the old D1/D2 method, meaning they suffer no consequences related to changes, or apparent changes, to Project performance. EBID's allocation is reduced to make up the difference; that is, EBID's allocation is reduced by the difference of the total D3 Allocation and the total D1/D2 Allocation, or the negative departure from the D2 Curve.

The import of this negative impact on EBID by D3 Allocation is illustrated for a full supply year (2008) in Figure D.9, which superimposes a bar showing 2008 current-year allocations on top of a D1/D2 Allocation distribution graphic.[23] The effect of D3 Allocation is illustrated by comparing the full-supply allocation bar in Figure D.10 to that of Figure D.4.

[23] The D1/D2 allocation graphic includes the "extension of the D2 curve" included in the 2008 OA, which increases EPCWID's full-supply, current-year allocation from 377,000 AF to 388,000 AF, not including ACE Credit.

Figure D.10. D3 Allocation Illustration with Current-Year Allocation Data from 2008



The D2 Curve, a plot of total water delivered to canal heading versus total release from Caballo, is in effect a historical efficiency or performance relationship for Project delivery. The D3 Allocation method is intended to reduce EBID's allocation to account for all negative departures from the Project's historical performance.[24] As set forth in Section 6 of the Report, Reclamation stated that *"any river system losses in New Mexico that affect the deliveries in EPCWID and Mexico will be replaced from EBID allocated water."*

That is, the D3 Allocation procedure reduces EBID's allocation to account for all negative departures from the D2 Curve (unless multi-year drought conditions apply, in which case the standard for Project performance is eased). The assumption that all negative departures from the D2 Curve are caused by New Mexico is unsupported, and as will be shown in this report, is contradicted by fact.

In sum, D3 Allocation calculates Mexico's allocation using the D1 Curve, EPCWID's allocation using the D2 Curve, and then allocates EBID any water that is left over. New Mexico is only allocated water after EPCWID and Mexico have gotten their full shares.

[24] In theory, EBID's allocation would be increased above its D2 Allocation if Project performance is better than the D2 curve would predict. This occurred only once, in 2011.

2.1 D3 PLUS CARRYOVER ALLOCATION METHOD DESCRIPTION

Project allocation under the 2008 OA is accomplished by the Allocation Committee, which consists of technical representatives from Reclamation, EBID and EPCWID. The Allocation Committee meets before the irrigation season begins, and regularly throughout the irrigation season, to determine the current Diversion Ratio, and update the allocation of water between the Districts and Mexico as necessary.

2008 OA allocation is performed using a spreadsheet with embedded formulas that make allocation calculations. In general, the D3 Allocation method is performed as follows:

1) "Total Usable Water Available for Release" is calculated by subtracting Compact Credit and San Juan-Chama water from the total amount of water in storage in Elephant Butte and Caballo reservoirs. (When allocation is performed during the irrigation season, any water already released from Caballo is also added back in.) A buffer to account for "Reservoir Evaporation/Dead storage" may also be subtracted.
2) Mexico's allocation is calculated using the D1 Curve, based either on the "Total Usable Water Available for Release", or the estimated release from Caballo for the year.
3) Usable Water for Current Year's Allocation is calculated by subtracting the Carryover Obligation (the amount of reservoir water that would be needed to deliver the allocations carried over from the previous year) from the Total Usable Water.
4) EPCWID's current-year allocation is calculated using an adjusted D2 Curve, based on Usable Water for Current Year's Allocation. The D2 adjustments consist of:
    a. A multi-year drought D2 Curve correction factor, lowering the D2 Curve, that is applied during and immediately after extended low-supply conditions, and
    b. An extension to the D2 Curve in high-supply years, so that increasing allocations are calculated up to a newly defined full-supply release of 790,000 AF.
5) EPCWID's current-year allocation is increased by the amount of the American Canal Extension (ACE) credit.
6) The Diversion Ratio is determined, either estimated based on hydrologic conditions (early in the irrigation season), or calculated based on the ratio of charged diversions over Caballo releases to date.
7) The amount of Project Supply (or deliverable allocation) is calculated based on the Diversion Ratio and the estimated release of water for the year.
8) EBID's D3 Allocation is calculated as the Project Supply minus Mexico's D1 allocation and EPCWID's D2 allocation and EPCWID's ACE credit.
9) If EBID's D3 Allocation is greater than what EBID would have been allocated under the D2 Curve, and the supply of Usable Water is less than 600,000 AF, then 43% of that positive departure from the D2 Curve is subtracted from EBID's D3 Allocation and awarded to EPCWID.
10) The amounts resulting from steps 5, 8 (and 9 if applicable) above constitute EBID's and EPCWID's current-year allocations.
11) The total allocation for each District is the sum of each District's current-year allocation plus any Carryover from the prior year.
12) Carryover for the next year is the difference between each District's total allocation and its charged diversions, limited to a maximum of 232,915 AF for EPCWID and 305,918 AF for EBID.

These Carryover limits are based on 60% of each District's full supply allocation. If a District's unused allocation exceeds its Carryover limit, the excess is awarded to the other District.

Under the 2008 OA, a full-supply release is 790,000 AF, and in a full-supply year EPCWID's current-year allocation is 388,192 AF. EBID's allocation always depends on the Diversion Ratio, and so there is no one number that can describe EBID's full-supply, current-year allocation.

Table D.3 provides a simplified version of allocation under the 2008 OA in a full-supply year.

Table D.3. Simplified Allocation Example, D3 Allocation plus Carryover, Full-Supply Year, Amounts rounded to nearest 1000 AF

	Allocation Term	Quantity (AF)	Calculation
A	Total Usable Water Available for Release	1,000,000	
B	EBID Carryover from Previous Year	20,000	
C	EPCWID Carryover from Previous Year	190,000	
D	Total Usable Water Available for Current Year Allocation	790,000	A – B- C
E	Mexican Allocation	60,000	Use D1 Curve

2.2 Post-2008 Changes to Project Allocation Process

The Allocation Committee has made modifications to 2008 OA allocation process since 2008. Three significant changes have been made since 2008:

- A "Multiyear Extreme Drought D2 Correction Factor", introduced in 2012, allows EBID a larger allocation in some low-supply years. The Extreme Drought Factor effectively lowers the D2 Curve in years of successive years of low supply (that is, Caballo releases less than 400,000 AF). The introduction of the Extreme Drought Factor is a recognition that some of the D2 data from the multi-year drought of the 1950s fall below the D2 Curve. The effect of Extreme Drought Factor is to reduce the historical performance target in such years, which reduces EPCWID's allocation and increases EBID's allocation. This term affected Project Allocation in years 2012 through 2016, increasing EBID's allocation, and decreasing EPCWID's.

- An "Estimate End of Season Adjustment of Project Water Due to Evaporation" was added in 2012. The Evaporation Adjustment introduces a cushion into the allocation process by removing some water from the total amount to be allocated in certain years, taking into account that evaporation during the irrigation season may reduce the actual amount of "wet" (or physically available) water available below the amount that might otherwise be allocated. The documentation in the 2008 Operations Manual does not clearly specify when this term will be applied, and how this term is to be calculated. So far, this term has been applied in years 2013, 2014, 2015, 2016 and 2018, and the values applied have range from 5,000 AF to 15,000 AF. This term reduces the chance that the Allocation Committee will allocate more water than can be delivered. In 2011, the year before this Adjustment was introduced, Reclamation had problems delivering all the water it had allocated, and it is likely that this factor was introduced to prevent this situation from arising again. There is no other term in Project allocation or accounting that explicitly accounts for evaporation of Project Supply or of District Carryover accounts.

- Another significant change was introduced in 2011 associated with the calculation of Usable Water Available for Release. Usable Water is a Rio Grande Compact term and is defined as the amount of water in reservoir storage, minus the amount of Compact Credits and omitting imported San Juan-Chama water, as determined by the Rio Grande Compact Commission. In the first years of the 2008 OA allocations, Usable Water was calculated in accordance with the Compact and the amounts of Compact Credit determined by the Compact Commission each March. Starting in 2011, the Project Allocation Committee started to estimate Compact Credits by other methods, reducing the Compact Commission's values for additional evaporation during the irrigation season, thus freeing up more "Usable Water" for Project allocation and release but decreasing New Mexico's Compact Credit Water to its detriment.[25] New Mexico objected forcefully to this change, and it has had repercussions on Compact Accounting that continue to the present time. *See* Estevan Lopez Expert Report, 2019, for a full discussion of this issue.

2.3 Post-2008 Changes to Project Accounting

In addition to changes in allocation, following the adoption of the 2008 OA there have been a number of modifications to the Project accounting process. These changes have taken the form of additional charges against EPCWID's allocation:

- In 2012 a charge for "Upper Valley Pumps" was added to EPCWID's accounting summary. It is my understanding that this term is intended to account for the water pumped by EPCWID District-owned and operated wells in the southern Mesilla Valley. The amounts of water associated with this new charge have been small (less than 500 AF/Y) and in some years this term is omitted from the accounting summary altogether. (There is no term associated with farmer-owned and operated irrigation wells in the Texas part of the Mesilla Valley, which are estimated to pump over 10,000 AF/Y in low-supply years.)

- In 2016 a change was made to EPCWID's accounting summary, labeled "Proposed 2016 CWF Resolution and NWWTP Flow." This charge reappears in 2017, and in 2018 is replaced by a

[25] As a result of this calculation, in 2011 Reclamation released Compact Credit water from Elephant Butte reservoir, leading to New Mexico's lawsuit against Reclamation in August of 2011. *State of New Mexico v U.S. Bureau of Reclamation, et al.,* Case No. 1-11-cv-00691-JB-KK, In the United States District Court, District of New Mexico.

charge for "CWF Technical Memorandum 1/9/2019." It is my understanding that these charges are associated with the El Paso Water Utility's Canutillo Well Field. The Canutillo Well Field is located in the southern Mesilla Valley in Texas, along the Rio Grande. The Canutillo Well Field pumps 20,000 AF to 24,000 AF annually, depleting the flows of the Rio Grande stream system.[26] The associated annual "CWF" charges to EPCWID range from 4,500 AF to 8,000 AF. Based on my familiarity with prior discussions on how to account for Canutillo Well Field pumping effects on the Project, I conclude that the discrepancy between the amount pumped and the amount charged to EPCWID is caused by: 1) an assumption that pumping effects that occur outside of the irrigation season do not have to be charged, and 2) return flow credit awarded for waste water effluent from the North West WWTP; essentially a return flow credit.

2.4 Carryover

An important concern with the 2008 OA allocation process is related to the magnitude and the treatment of Carryover accounts. Allocation that is not used by a District in one year is now carried over into the District's allocation the following year. The limits on these Carryover accounts are high: 232,915 AF for EPCWID, and 305,918 AF for EBID.[27] Recall that prior to 2007, allocated water not used by either District was simply included in pool of water available for allocation the next year.

In practice, EBID has only carried over small amounts of water from one year to the next. In fact, EBID's allocation under the D3 Curve has been insufficient to supply EBID's irrigation water needs, and so EBID generally takes all of the water it is allocated. Typically any unused allocation EBID carries over results from late season allocation increases by Reclamation, or Carryover transfers, that EBID cannot make use of during the current irrigation season. EPCWID, on the other hand, has carried over large amounts of water in some years. For instance, in 2009 EPCWID reached its Carryover limit of 232,915, and transferred 82,044 AF of excess Carryover to EBID.[28]

Early in the allocation process Carryover accounts, plus additional water needed to deliver the amount Carryover,[29] are subtracted from the Usable Water in storage, and effectively sequestered from the allocation process. Current-year allocation is then calculated from the remainder of Usable Water. Some part of the Carryover accounts, however, may not actually be associated with water in storage. Carryover accounts are not reduced for evaporation. Since evaporation does in fact occur, inflows to

[26] Rio Grande stream system includes both the mainstem of the Rio Grande and associated Project conveyances, particularly drains, which are depleted by groundwater pumping.

[27] 2008 OA, p 3.

[28] While in 2010 a transfer of 10,271 AF was made from EPCWID to EBID, this transfer appears to be associated with an attempt to address depletions to Project Supply caused by the EPWU Canutillo Well Field, which is located in the southern Mesilla Basin above Courchesne. The transfer associated with Canutillo Well Field impacts was not repeated; however, starting in 2016 an accounting charge averaging 6,700 AF/Y associated with Canutillo impacts was applied to EPCWID. This is discussed further in the Report, Section 6.3.6.

[29] The amount of allocation in the Carryover accounts is divided by the Diversion Ratio to determine the reservoir release needed to deliver the Carryover allocation. If the Diversion Ratio is less than 1.0, that inflates the amount of water sequestered for Carryover, before any current-year allocation can be made.

the reservoir that otherwise would have been available for allocation are instead sequestered to make the Carryover accounts whole.

In addition, some of the Carryover allocation may be associated with Project credits, such as the ACE Credit, or the accounting credits, rather than any reduction in District orders. As a result, some part of a Carryover account may consist of "paper water," that is not associated with any water in reservoir storage (as opposed to wet, physically existing water). Despite this fact, the allocation process gives the Carryover accounts first priority in allocation, and therefore new inflows to the reservoir are first assigned to fulfill, and reserved for the delivery of, the Carryover accounts, before any of these inflows are available for current-year allocation.

Any Carryover in excess of wet water results in a reduction to the current year allocation of both Districts. The net effect is a negative impact on EBID's the total allocation, because EBID gets so little of the benefits of Carryover. See, for instance, the concrete example below.

2.4.1 2010/2011 Example of Carryover Impact

A clear example of the negative impact to EBID caused by the current Carryover method that occurred in late 2010 through early 2011. Table D.4 summarizes reservoir storage and Carryover conditions at the end of the 2010 irrigation season in October 2010 (releases from Caballo ended on October 7, 2010). As of October 15, 2010, there was a total of 386,735 AF combined storage in Elephant Butte and Caballo storage. When I subtract from that Compact Credit and San Juan-Chama water from that amount, I calculate a total of 224,739 AF of Usable Water in storage. The total unused allocation from 2010, which was carried over into the Districts' 2011 allocations, was 244,362 AF. That is, the amount of Usable Water in storage was less than the amount allocated to the Districts through their Carryover accounts. As a result, all of the inflows to the reservoir for the next several weeks, up to 19,723 AF, went straight into these Carryover accounts, and was not available for "current year" allocation to the Districts.[30] Since EPCWID's Carryover account was by far the largest, most of these inflows accrued to EPCWID.

Once the allocation process for 2011 began, the Project's Carryover Obligation was calculated. The Carryover Obligation is the amount of Caballo release needed to actually deliver the amount of water in the Carryover Accounts, taking into account the hydrologic conditions (gains/losses) obtaining in 2011. The Carryover Obligation is calculated by dividing the total amount in Carryover Accounts by the Diversion Ratio, which was 0.85 in 2011 (final value for the year). The resulting Carryover obligation was 287,485 AF, and this corresponds to the amount of water sequestered from reservoir storage before any Current-Year Allocation is made from the remaining Usable Water.

The net result is that 62,846 AF of the inflow to Elephant Butte occurring after the end of the 2010 irrigation season were required to fulfill Carryover obligations (mostly to EPCWID) under the 2008 OA. As a result there was 62,846 AF less water available for Current-Year Allocation. Both Districts received lower Current-Year Allocations, but EPCWID received the benefit of a large Carryover account from which no evaporative losses had been subtracted, nor any deduction for paper water had been made.

[30] Allocation is measured at canal headings. To compare an allocation amount with the amount of reservoir water release needed to deliver that allocation, it is necessary to divide the allocation amount by the Diversion Ratio. In the comparison I have made in this paragraph, there is an implicit assumption that the diversion ratio is 1.0.

As it turned out, the inflows to Elephant Butte during 2011 were very low, and EBID's Current-Year Allocation was only 67,000 AF. Presumably, if 62,846 AF of the reservoir inflows had not been sequestered to make up EPCWID's large Carryover Account and the resulting Carryover obligation, EBID's Current-Year allocation would have been considerably larger.

Table D.4. 2010 – 2011 Example of New Inflow to Reservoir Needed to Fulfill Existing Carryover Accounts and Obligation

2010 - 2011 Example of when Carryover Accounts Required Additional Inflows			
		Storage, Carryover and Credit Conditions as of October 15 2010	Storage, Carryover and Credit Conditions as of January 1, 2011
Total Water in Reservoir Storage	(AF)	386,735	497,789
CO Compact Credit	(AF)	800	2,700
NM Compact Credit	(AF)	100,500	164,700

Usable Water In Storage	(AF)	224,639	266,139
		Project Accounting 2010	Project Accounting 2011
EBID 2010 Unused Allocation (Carryover from 2010 to 2011)	(AF)	20,014	
EBID 2010 Unused Allocation (Carryover from 2010 to 2011)	(AF)	224,348	
Total Carryover (Carryover from 2010 to 2011)	(AF)	244,362	
2011 Diversion Ratio	(unitless)	0.98	0.85
2011 Carryover Obligation (divide total Carryover by 2011 Diversion Ratio	(AF)		287,485
Inflows to Elephant Butte after October 15, 2010 required to fulfill Carryover Obligation			62,846

3 POST-1978 PROJECT ACCOUNTING CREDITS

Project Credits are an adjustment to either allocation or accounting that increases the amount of water a District can divert. Some accounting credits are associated with the approved diversion and waste of water that is then re-diverted at another location, becoming part of the accounting charge at the second location. Such is the case with the EBID credits described here, and EPCWID's Ascarate Credit. Other credits are associated with the diversion of water that is not considered "Project Supply," diversion and waste of water in excess of orders, and changes in Project infrastructure.

3.1 EBID CREDITS

El Paso Bypass or El Paso Carriage: During dry periods, the canal system may be more efficient than the bed of the Rio Grande at conveying water. Therefore, in some years water destined for delivery to Texas was diverted into the EBID canal system so it could be transported through the canals instead via the Rio Grande, and then wasted back (or returned) to the Rio Grande at the bottom of the Mesilla Basin where it was then delivered to EPCWID canal headings in the El Paso Valley. Project WDRs indicate that such bypass water has been diverted at Percha, Leasburg and Mesilla dams.

Water Delivered to EPCWID in Mesilla Basin: EBID supplies water to Texas lands in the lower Mesilla Basin from the Eastside and Westside Canals. EBID is charged with the total diversions at Mesilla Dam, and then credited with the water delivered to those Texas lands, plus bypass water returned to the river (at Wasteway 32), plus some additional water for carriage. The total credit given to EBID is larger than the charge to EPCWID for water delivered to Texas lands in the lower Mesilla. The water wasted to the Rio Grande at Wasteway 32 is available for diversion and use by EPCWID in the El Paso Valley.

3.2 EPCWID CREDITS

3.2.1 Credit for Diversions Greater than Orders

At times there is more water available at EPCWID's canal headings than was ordered ("excess water"). This occurs despite the fact that Caballo releases are adjusted so as to minimize any excess water at these locations.

EPCWID charges in the El Paso Valley are based on the District's actual diversions at its canal headings in the El Paso Valley. EPCWID is allowed to divert water in excess of its orders. If EPCWID diverts excess water, but then does not use all of that excess water, and returns it through certain wasteways, it will be given credit for the amount of that return. According to Bert Cortez and Phil King[31] this credit is awarded so to encourage EPCWID to use all the surface water that is available to it, in the interests of increasing Project efficiency. Allowing EPCWID to divert water in excess of its order, and crediting it for the unused part of that excess diversion, is believed to increase the total amount both used and charged.

Calculation of the water returned is made on a daily basis using flow measurements from various canals, laterals, drains, and wasteways. Credit for this return is only awarded for days on which the daily

[31] Filberto Cortez of Reclamation and Phil King, Consulting Engineer for EBID.

“adjusted flow” (a measure of the net diversion, adjusted downward for credits already given) is greater than the total order at Franklin and Riverside. The size of the credit is limited by the difference between the adjusted flow and the total order.

3.2.2 Ascarate Wasteway

The Ascarate Wasteway historically discharged water from the Franklin Canal to the Rio Grande. Ascarate was an integral part of Project operations until the completion of the American Canal Extension in 1988.

American Dam gives the Project the ability to divert water from the Rio Grande upstream of the Mexican Diversion. Since 1938, Project practice has been to divert all the water in the Rio Grande at American Dam, except for part that needed to supply the Mexican Diversion required by the Treaty.[32] A large part of the water diverted at American Dam was then wasted back to the Rio Grande delivery to the Riverside Dam. Some of this water was wasted from American Canal, before any EPCWID charge was made on it. The rest of this water was diverted into the Franklin Canal, and charged as part of the Franklin Diversion, and then wasted back to the Rio Grande through the Ascarate Wasteway. To avoid charging that Ascarate water twice, both at Franklin and again at Riverside, the amount of the Ascarate waste was credited to EPCWID. This credit was similar to EBID’s credits, in that it was a credit assigned for a planned waste of water that would then be re-diverted at Project canal heading downstream, and charged in the Project accounting for that location.

Riverside Dam failed in 1987 and was replaced by a temporary rock cofferdam that was in use until completion of the American Canal Extension in 1998.[33] Since that time, the Riverside Canal has diverted water from the American Canal Extension instead of from the Rio Grande. It would appear that accounting changed to reflect this in 1999. Prior to 1999, EPCWID received credit for the full amount wasted at Ascarate: typically 20,000 to 30,000 AF. In 1999 and 2000 no credit associated with Ascarate was given. Starting in 2001, some small credits associated with Ascarate were granted, but these credits were not equal to the total water wasted, indicating a change in Project Accounting has been made to reflect the change in operations.

3.2.3 Haskell R. Street Waste Water Treatment Plant Effluent

EPCWID also receives credit associated with effluent from the Haskell R Street Waste Water Treatment Plant (location shown in Figure D.11; hereinafter ”Haskell WWTP”). Haskell WWTP discharges effluent into the American Canal upstream from the Riverside heading, where that water is diverted together with the other water available at that location. The entire amount diverted at the Riverside canal heading is gaged and included in EPCWID’s Project accounting charges.[34] EPCWID is then awarded a credit in Project Accounting equal to the amount of the Haskell WWTP effluent discharge.

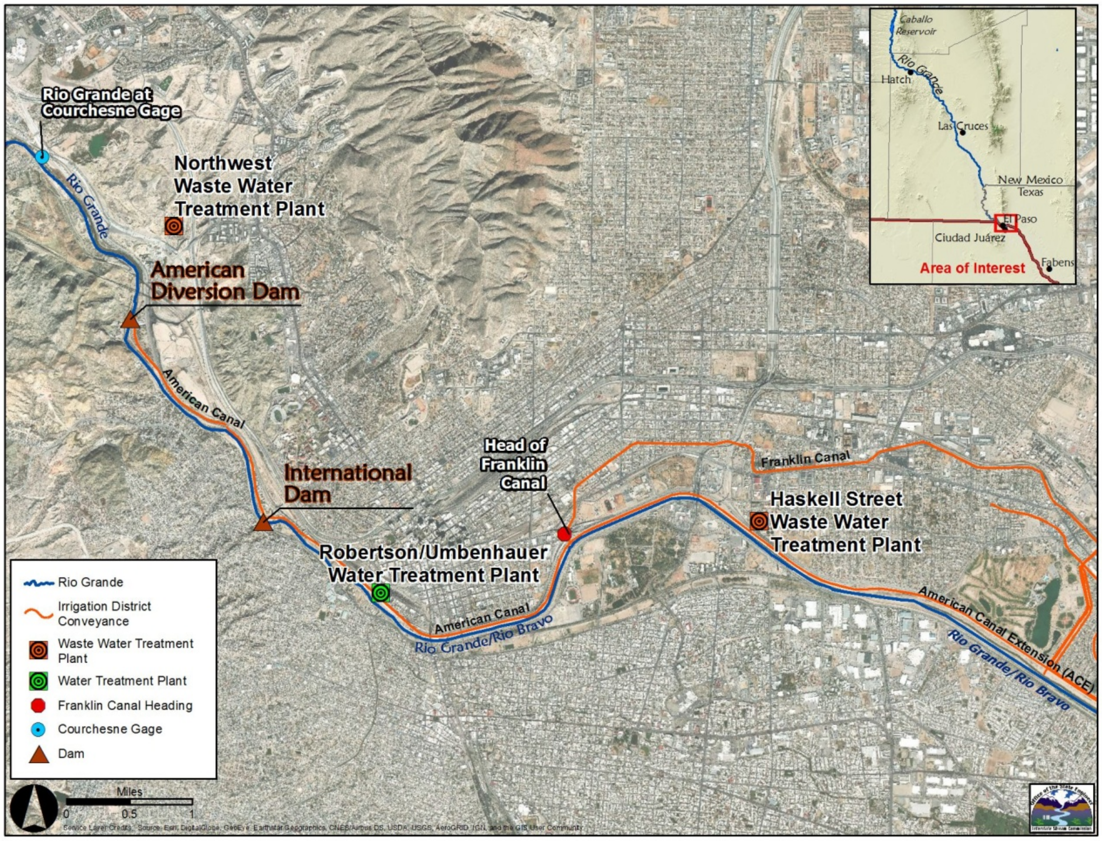
[33] 2001 Final Environmental Assessment for “Replacement of the Old American Canal” Located in El Paso, Texas. prepared for U.S. IBWC by ENCON International, Inc., December 6, 2001 (2001 FEIS).

[34] Part of the water diverted at the Riverside canal heading is gaged as it is diverted to EPWU’s Jonathan Rogers municipal water treatment plant, and the remainder is gaged below the EPWU diversion.

Figure D.11. Location Map of Project Structures in the El Paso Area and Haskell WWTP



The basis for this credit is described in a 1999 letter from Filberto Cortez (Manager of Reclamation's El Paso Office) to El Fifer (General Manager of EPCWID).[35] According to this letter, EPCWID requested that it be given accounting credit for Haskell WWTP effluent, because that water is "non-Project due to the fact that it does not reach the bed of the Rio Grande." The justification provided for this position is EPCWID's Transfer Contract,[36] which states that "Project Water Supply shall mean stored water legally available for release in the Elephant Butte and Caballo Reservoirs and including the legally appropriated waters reaching the bed of the Rio Grande between Caballo Dam and Riverside Diversion Dam."

Prior to 1999, effluent from the Haskell WWTP discharged directly into the Rio Grande below International Dam, and diversion of this water at Riverside was charged to EPCWID.[37] After the

[35] Letter 1999 0708, from Filiberto Cortez, USBR, to Edd Fifer, EPCWID, RE Summary of June 25, 1999 meeting on water accounting.

[36] Contract 1980 0314, No. 0-07-54-X090, for Transfer of the Operation and Maintenance of Project Works, between Bureau of Reclamation and El Paso County Water Improvement District No. 1.

[37] Op. cit. "water charges were based on actual flows at Riverside Canal heading, which included the Haskell Street effluent discharge."

completion of the American Canal Extension in 1998, Haskell WWTP effluent was intercepted by the ACE. I have illustrated the configuration of Project conveyances and the Haskell WWTP effluent discharge in a schematic diagram in Figure D.12.

In 1999, EPCWID argued that the interception of the Haskell WWTP effluent before it reached the bed of the Rio Grande rendered it "non-Project water," and therefore EPCWID should not be charged for diverting and using that water. Reclamation agreed to EPCWID's request, and EPCWID and Reclamation agreed on a modification to Project accounting which gave EPCWID credit for the amount Haskell WWTP effluent discharged into the ACE (no adjustment is made for losses between the point of discharge and the Riverside heading). The annual amount of the Haskell WWTP credit awarded to EPCWID has ranged from 1,700 AF to 12,700 AF.

It is my opinion that the effluent water discharged at Haskell WWTP originated as Project water diverted at EPWU's Robertson/Umbenhauer drinking water treatment plan, combined with groundwater pumped from wells in the Mesilla or Hueco basins which have impacted the water supply available to the Project. This effluent is basically Project return flow, and should be considered Project Supply. The fact that this effluent is now intercepted by the ACE does not change its character, and there is no reason why EPCWID should not be charged for diverting and making use of this water.

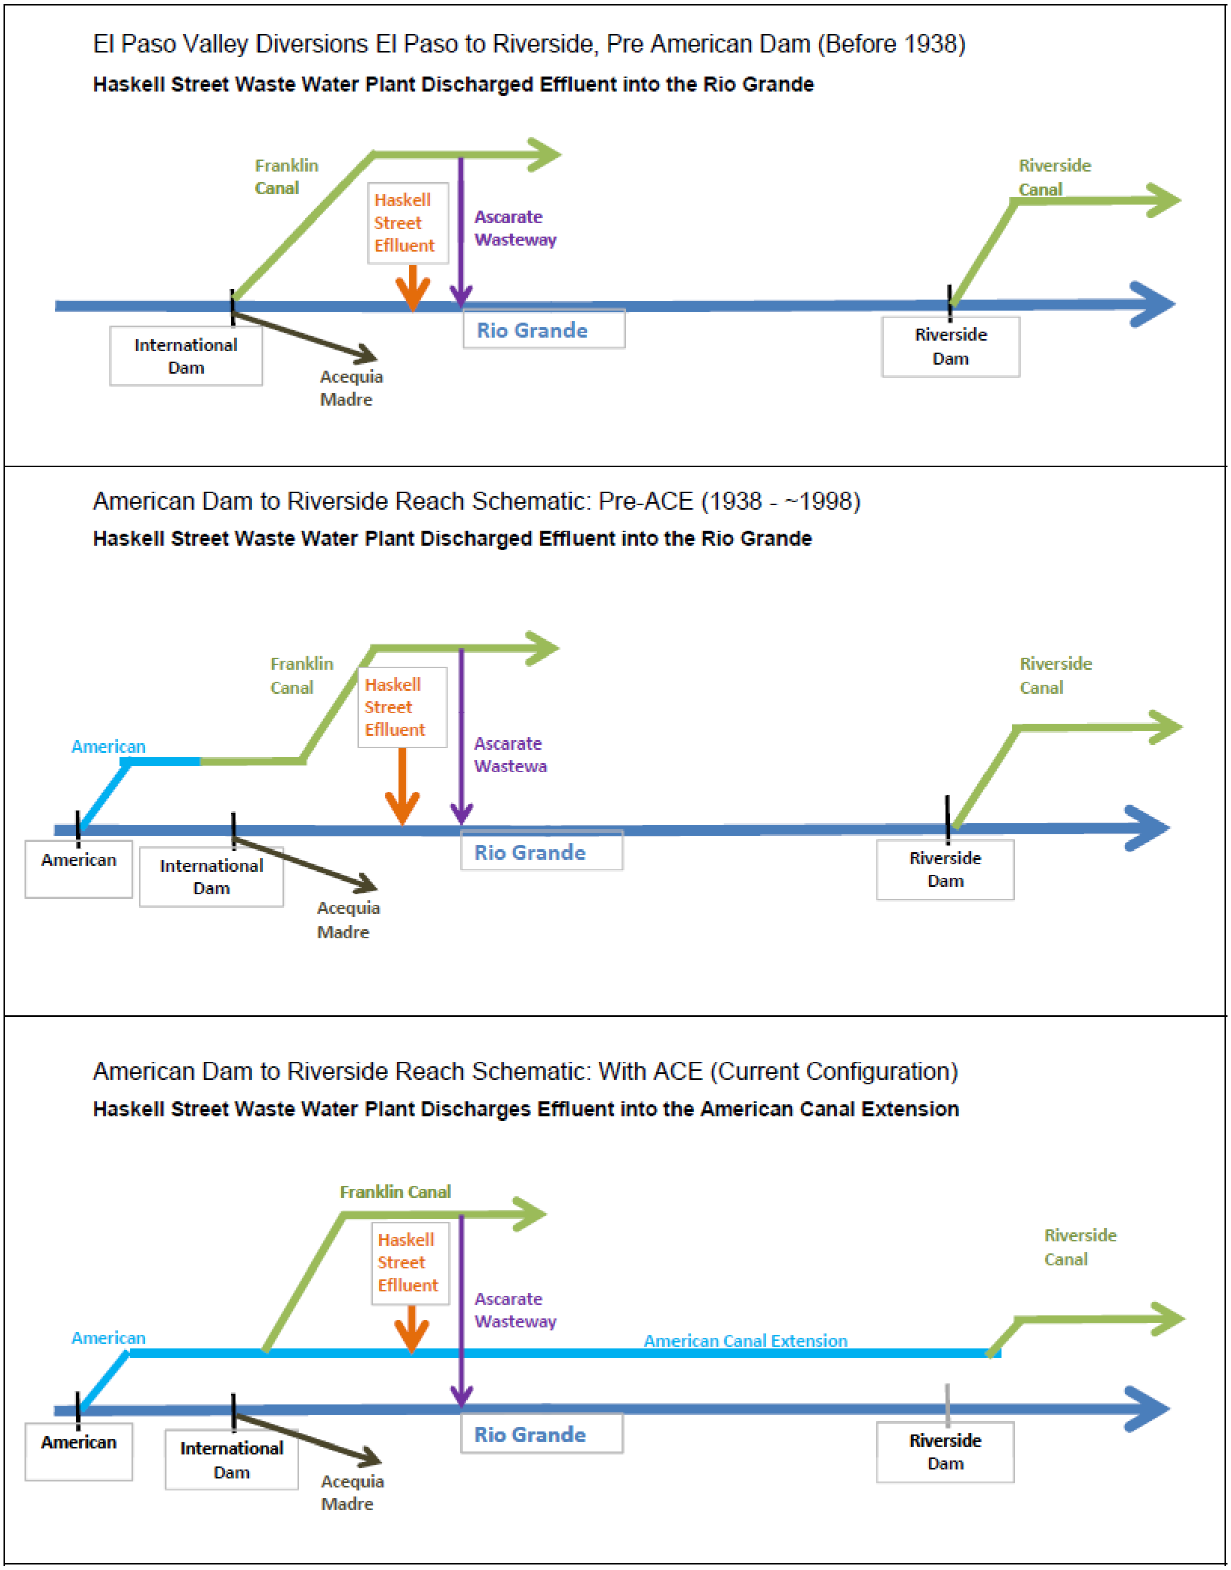
Furthermore, the bed of the Rio Grande is no longer used to convey water to Project headings in the El Paso Valley. The function of the Rio Grande has now been usurped by the ACE. It is therefore reasonable to consider any discharge into the ACE to be Project Water.

Prior to the adoption of D3 Allocation, EPCWID's Haskell WWTP credit had little or no effect on Project allocation. Once D3 Allocation was adopted, the Haskell WWTP credit had a detrimental effect on EBID's D3 allocation:

- Haskell WWTP effluent was part of the water diverted and tabulated during the D2 Period, and therefore is part of the D2 Curve. Since 1999, EPCWID's diversion of Haskell WWTP effluent is now longer included in its charged diversions, and therefore contributes to the negative departure (or gap) from the D2 Curve.
- The net effect of the Haskell WWTP credit is to reduce EPCWID's charged diversions and thereby to reduce the Diversion Ratio (which is based on total charged diversions). EBID's allocation is reduced by any reduction in the Diversion Ratio.

As a result, the Haskell WWTP effluent credit awarded to EPWID has the net effect of reducing the EBID allocation, to the detriment of New Mexico.

Figure D.12. Schematic Diagram of Rio Grande and Project Conveyances in the El Paso to Riverside area, showing the relative location of the discharge of Haskell WWTP effluent



3.2.4 American Canal Extension / Conservation Credit

In 1998 the American Canal Extension ("ACE") project was completed, which lined parts of the existing American Canal, and extended the American Canal to the Riverside Canal heading (as illustrated in Figure D.12). Since 2003, EPCWID's allocation has been increased by a "conservation credit" ("ACE Credit") associated with the ACE.

The ACE Credit is a result of the following conveyance history. Since the completion of the American Dam in 1938, EPCWID diverted into the American Canal all water not needed to supply the Mexican diversion. Prior to the ACE, EPCWID had to waste a large amount of water from American Canal and Franklin Canal back to the Rio Grande, for diversion at its Riverside several miles downstream. The extension of the American Canal has allowed EPCWID to keep this water out of the Rio Grande and deliver it to the Riverside heading through the ACE, presumably reducing conveyance losses.

EPCWID has estimated the amount of water conserved by delivering water to Riverside through the ACE instead of the Rio Grande main stem and this calculation is the basis for a credit awarded to EPCWID, which varies depending on the amount of water EPCWID diverts. The ACE Credit was first granted in 2003. It is my understanding that a dispute the Districts and Reclamation followed. The ACE Credit was not granted in 2005, but was reinstituted in 2006. This Credit is applied as an increase in EPCWID's allocation instead of a reduction in EPCWID's total charges. EPWU was involved in the financing of the ACE, and has gained an increase in the amount of water it can buy from EPCWID as a result.

The effect of the ACE Credit is to reduce EBID's allocation. This can occur in two ways; the first way is by applying it within the allocation spreadsheet; the second way it by adding it onto EPCWID's allocation at the end of the year during the Project accounting process.

- First method: As the 2008 OA is written, the ACE credit is applied within the allocation spreadsheet. The ACE Credit is added to EPCWID's allocation before EBID's allocation is calculated. The allocation spreadsheet calculates the amount of water available for current-year allocation, and then subtracts Mexico's ad EPCWID's allocations to calculate EBID's D3 allocation. As a result, the amount of the ACE credit is subtracted directly (1:1) from EBID's allocation.

  The effect of the ACE in the allocation spreadsheet is illustrated in Figure D.13, which is an image of a modified version of the 2009 allocation spreadsheet. In order to test the effect of the ACE credit on EBID's allocation, I modified the 2010 allocation spreadsheet by copying the 2009 allocation calculations into a second allocation column labeled: Modified No ACE Credit. When I copied the 2009 allocation calculations, I kept all formulas and data entered for 2009, except that I set the ACE Credit (Row 21) to zero. The Total Allocations calculated as a result of this change are shown in Rows 36 and 37, and the difference between the allocations with and without the ACE is shown, highlighted, next to those columns. The net effect of removing the ACE Credit of 17,998 AF is to increase EBID's allocation by 17,998 AF and decrease EPCWID's allocation by that same amount. Therefore, I conclude, that the ACE Credit, as awarded to EPCWID in the allocation spreadsheet, is taken directly out of EBID's allocation, one-for-one. In effect, the allocation of water has become a zero sum game: any increase to EPCWID's allocation comes at the expense of EBID.

Figure D.13. Image of Reclamation Allocation Spreadsheet from 2009, Modified to Test Effect of ACE Credit on Allocation

34	Total EPCWID Allocation (includes Row 21 and 67/155th of Value in Row 30)	635,041		617,043	
35	District to District Allocation Transfer (OA 1.11 Excess Carryover Balance)	82,044		82,044	
36	Total EBID Diversion Allocation (After Transfer)	345,817		363,815	17,998
37	Total EPCWID Allocation (After Transfer)	552,997		534,999	-17,998
38	Total EBID, EPCWID, and Mexico Allocation	952,200		952,200	
39	EPCWID 2009 Allocation Charges (calculated)	320,082		302,084	
40	EBID 2009 Allocation Charges (calculated)	305,474		323,472	
41	EPCWID 2009 Allocation Charges (actual)	320,083		320,083	
42	EBID 2009 Allocation Charges (actual)	305,475		305,475	
43	Mexico 2009 Allocation Charges (actual)	58,688		58,688	
44	Difference in Mexico's Charges and Allocation	-5,302		-5,302	
45	EPCWID Share	-2,292		-2,292	
46	EBID Share	-3,010		-3,010	

- Second method: The ACE Credit has been applied differently in some recent years. Instead of being applied through the allocation spreadsheet, as provided for by the 2008 OA, the ACE Credit has been added onto EPCWID's allocation at the end of the year during the Project accounting process. This application has a negative impact on EBID, but not as great an impact as when it is applied within the Allocation Spreadsheet. When added onto EPCWID's allocation at the end of the year, outside of the Allocation Spreadsheet, the effect of the ACE is to increase EPCWID's Carryover for the next year. This increase in EPCWID's Carryover reduces the amount of Usable Water available for Current-Year Allocation, which will reduce the Current-Year Allocation of both Districts. The associated reduction in EBID's will be on the order of one-half of the ACE Credit, instead of the entire amount of the ACE Credit.

3.2.5 Compilation of EPCWID Credit Data

The tables below summarize the data presently available as to the credits awarded to EPCWID since 1997. Table D.5 is a summary of the total annual accounting credits awarded to EPCWID.

Table D.5. Summary of Project Accounting Credits assigned to EPCWID, extracted from Project Accounting Records

Table D.5. Credits to EPCWID Extracted from Project Accounting (Acre-feet)				
Year	Ascarate Credit	Credit to District for Diversions Greater than Orders	Haskell Effluent Credit	Sum
1997	27701	29956	0	57657
1998	9289	23219	0	32508
1999	0	13758	12732	26490
2000	0	16721	10700	27421
2001	1587	25197	11360	38144
2002	1179	1235	10844	13258
2003	0	1016	9595	10611
2004	0	1925	10759	12684
2005	0	0	9923	9923
2006	0	6412	10347	16759
2007	0	7173	11038	18211
2008	0	7070	11625	18695
2009	0	3307	11597	14904
2010	0	1951	10240	12191
2011	0	0	4337	4337
2012	0	0	5401	5401
2013	0	0	1703	1703
2014	0	0	2489	2489
2015	0	1438	4032	5470
2016	0	0	7712	7712
2017	0	111	7839	7950
2018	0	0	4838	4838

Table D.6 summarizes the ACE Credit quantities that EPCWID has been awarded. In the years 2008-2010 the accounting and allocation records are not clear as to exactly how this credit has been applied. In any case, the ACE Credit is applied to increase EPCWID's allocation. In some years this appears to have been done during the allocation process as part of the allocation spreadsheet. In other years, the ACE Credit is added onto EPCWID's allocation at the end of the year, and shows up only in EPCWID's accounting summary. In some years, the ACE Credit appears in both allocation and accounting, and while it may not have been "double counted," the records we have are not completely clear on this matter.

APPENDIX E

ANALYSIS OF THE D2 DATA SET

TABLE OF CONTENTS

TABLE OF TABLES

Appendix E: Analysis of the D2 Data Set

The purpose of this Appendix is to describe the origin of the Rio Grande Project diversion and delivery data used to derive the D1 and D2 Curves described in Reclamation's Rio Grande Project Water Allocation Procedures ("WSAP") document[1] and that are now incorporated in the D3 Allocation procedure of the 2008 Operating Agreement ("2008 OA"), and to discuss the impact of certain data included in the D2 data set. Project allocation methods are described in more detail in Appendix D.

It is my understanding that the D2 Curve was derived from year-round monthly diversion data and is therefore inflated, compared to the irrigation-season, Post-1979 Accounting data to which the D2 Curve is compared under D3 Allocation. As a result, EBID's annual allocation is reduced to its detriment because of a fundamental accounting discrepancy.

1 D1/D2 Allocation

Both D1/D2 Allocation and D3 Allocation methods are based upon the D1 and D2 Curves. These Curves are linear regression relationships calculated from Project delivery data from 1951 through 1978.

D1 Curve: Defines the correlation between annual reservoir releases and "Total Deliveries." Total Deliveries consist of:

- Total farm deliveries within the U.S.,
- "Non-Farm Deliveries" to the City of El Paso, and
- Total delivery to Mexico at Acequia Madre.

Under D1/D2 Allocation, the D1 Curve is used to determine the allocation to Mexico (the Mexican Delivery). The Mexican Delivery is reduced from the full Treaty amount of 60,000 AF in proportion to any water supply shortage affecting U.S. lands, and this is quantified using the D1 Curve.

D2 Curve: Defines the correlation between annual reservoir releases and "Total Heading Diversions." Total Heading Diversions consist of:

- "Project Net Supply", and
- Total delivery to Mexico at Acequia Madre.

Under D1/D2 Allocation, the D2 Curve was used to determine the total amount of Project Supply to be allocated (for delivery to Project diversion headings) as a function of the amount of Usable Water available in reservoir storage. Once the total amount of Project Supply was calculated, Mexico's share (calculated using the D1 Curve) was deducted, and the remainder of the Project Supply was split: 88/155 (or ~57%) to EBID, and 67/155 (or ~43%) to EPCWID (the 57:43 split).

[1] Water Supply Allocation Procedures, undated, circa 1990, provided to New Mexico by F. Cortez of Reclamation in 2005.

Reclamation's WSAP and 1985 and 1989 Draft Operating Agreements describe the D1/D2 Allocation method, and how these Curves were to be used allocate Project Supply. The D2 Curve was clearly evolving over this period, as different versions of these operating documents have different versions of the D2 data set. My analysis focuses on the D2 data set contained in Reclamation's WSAP document, which appears to have been adopted for Project allocation in 1991.[2] This D2 data set and the resulting D2 Curve have been used for Project Allocation from 1991-2005 as part of D1/D2 Allocation, and from 2006 to present as part of D3 Allocation.

2 D2 Data Source and Analysis

The focus of this analysis is on the nature of the D2 dataset itself. The data used in this analysis include:

1) Reclamation[3] D1 and D2 dataset obtained from Rio Grande Project WSAP drafted by Reclamation circa 1990;
2) 1951-1978 Reclamation Monthly Water Distribution Reports (WDRs) extracted from Rio Grande Project Histories;[4]
3) Supplementary WDRs obtained from Reclamation El Paso Field Office by New Mexico;[5] and
4) Gaged flow data for Rio Grande below Caballo Dam location obtained from the International Boundary Water Commission ("IBWC") website.[6]

2.1 Reclamation D1 and D2 Data Sets

The data tabulated in the WSAP document for the D1 and D2 Curves are provided below in Tables E.1 and E.2. The data set spans the years from 1951 through 1978, and this period of time will be referred to as the D2 Period.

[2] Full-supply District allocation amounts from 1991 through 2002 are equal to the full-supply District allocations defined in the WSAP document.

[3] 1985 Draft Operating Agreement (cover letter dated 1985), 1989 Draft Operating Agreement (undated, latest data contained in it are dated 1989).

[4] Reclamation Form 7-322 in Reclamation's "Project Histories of the Rio Grande Project."

[5] Supplementary Monthly Water Distribution Reports.

[6] The gages are: DIVERSIONS FROM THE RIO GRANDE, ACEQUIA MADRE AT CD. JUAREZ, CHIH. 08-3625.00 and RIO GRANDE BELOW CABALLO DAM, NEW MEXICO 08-3655.00 as downloaded from http://www.ibwc.gov/Water_Data/histflo1.htm.

1971	34,847	556,910	591,757	498,375
1972	16,077	279,618	295,695	260,911
1973	60,000	646,177	706,177	617,461
1974	60,050	704,544	764,594	640,843
1975	60,052	693,609	753,661	580,617
1976	60,172	808,169	868,341	679,676
1977	24,824	468,239	493,063	416,496
1978	14,903	321,478	336,381	356,167

The data in the columns "Acequia Madre" and "Release from Storage" are consistent with IBWC gage data from pertinent gages within 0.2%.

The "Project Net Supply", "Delivered to Farms", and "Non-Farm Deliveries" data is consistent with Reclamation's WDRs, as described in the following section.

2.2 WATER DISTRIBUTION REPORTS (WDRS)

Project water distribution data was summarized and reported annually by Reclamation during the D2 Period (1951-1978) using Form 7-322, which is titled "Monthly Water Distribution." One set of the historical forms upon which I rely was obtained from Reclamation's Project Histories of the Rio Grande Project. Additional historical forms (some duplicative) were obtained directly from the Reclamation El Paso Field Office by New Mexico OSE/ISC staff and contractors.

The WDR forms for the D2 Period summarize monthly and annual distribution data for the Project as a whole, and typically for each of four Project Service Units that comprise the Project: Rincon Valley Unit, Leasburg Unit, Mesilla Unit, and El Paso Valley Unit. Summary forms are also available for the Mesilla Valley which comprises the Leasburg Unit and Mesilla Unit. Distribution data from the Project-wide WDRs can be obtained by summing the applicable values from the Rincon, Leasburg, Mesilla and El Paso Valley Units, adjusting for water by-passed from one unit to another.

The WDR forms typically include the following types of data:

1) Diverted from Stream[7]
2) Net Supply
3) Total Waste
4) Total Losses
5) Non-Irrigation Deliveries
6) Total Deliveries to Farm
7) Additional fields related to El Paso Carriage, Leasburg by-pass, EBID Wells and other local distribution terms

After thorough review of the Project-wide WDR data, I conclude that these Reclamation forms are the source of the D1 and D2 data sets provided in the Reclamation WSAP, and the basis of the D1 and D1 Curves that are used in the 2008 OA and associated operating manuals. Comparison of the Project-wide WDR data to the D1 and D2 data sets is shown in the following two sections, and observations and conclusions follow thereafter.

[7] "Diverted from Stream" is a measure of the amount of water diverted into Project canals that is available to unit (or units). In the Project-wide WDRs, "Net Supply" is identical to "Diverted from Stream." In Unit or Valley WDRs, some "Net Supply" values differ "Diverted from Stream" values, having been adjusted downward to prevent double counting of El Paso Carriage (intended for delivery to Texas), or upward to include the waste of water from the Leasburg Unit into the Mesilla Unit.

2.3 Tabulation of WDR Data and Comparison with D1 Data Set

Table E.3 shows a comparison of values extracted from the Project-wide WDRs for the D1/D2 Period to the D1 data set from the WSAP. All values are identical, except for farm deliveries in 1957 (off by 133 AF) and Non-irrigation Deliveries in 1967 (off by 11,299 AF), which I have highlighted. At this time there is no information as to which of the differing values are correct.

Table E.3. Comparison of WSAP D1 Data Set with Delivery Data from Reclamation WDR sheets

Table E.3. Comparison of WSAP D1 Dataset with Data Extracted from Reclamation Water Distribution Reports (Discrepancies between data sets highlighted)

Calendar Year	WSAP D1 Data Set	Reclamation WDR for Project		WSAP D1 Data Set	Reclamation WDR for Project

1977	193,221	193,221	0	5,234	5,234	0
1978	112,349	112,349	0	3,587	3,587	0

2.4 Tabulation of WDR Data for Comparison with D2 Data Set

Table E.4 shows a comparison of data from the "Diverted from Stream" or "Net Supply" field of the Project-wide WDR to the WSAP D2 data set's "Project Net Supply." These two sets are identical except for the year 1961, when the values in the D2 data set is 115,084 AF lower than that reported in the WDR. Review of the 1961 Project History, and of the other WDR's for that year does not provide any insight into this discrepancy. One possible explanation is that El Paso Conveyance was not properly accounted for in the copies of the WDR forms available to me, but that adjustment was made in other copies, or by Reclamation staff when they compiled the D2 data set.

Table E.4. Comparison of WSAP D2 Data Set with Diversion Data from Reclamation WDR sheets

2.5 COMPARISON OF WDR PROJECT-WIDE DATA WITH WDR UNIT DATA

This section presents tabulation of monthly and annual WDR Diversions (from the "Diverted from Stream" and "Net Supply" fields of Tables E3 and E4).[8] In Table E.5, monthly WDR Diversions from Rincon Valley, Leasburg Unit, Mesilla Unit and El Paso Valley WDRs are tabulated and compared with Project-wide monthly WDR Diversions. In Table E6, the monthly WDR Diversions for each of these Units and Valleys are summed into annual values, and then these unit/valley values are summed for comparison with the Project-wide reported annual WDR Diversions. These Project-wide reported WDR Diversions are again compared with the "Project Net Supply" values from Reclamation's WSAP document.

Tables E.5 and E.6 show (with a few discrepancies) that:

1) Monthly WDR data from the Project-wide can be derived as the sum of the monthly WDR data from the Rincon, Leasburg and El Paso Valley Units;
2) Annual WDR Diversions are the sum of monthly WDR Diversions from January through December; and
3) Annual WDR Diversions form the basis of the D2 Curve.

The annual total Net Supply or Diverted from Stream values are derived as the sum of monthly Net Supply or Diverted from Stream values from the ***entire calendar year***, January through December.

2.6 DISCUSSION OF EL PASO VALLEY DIVERSION ISSUES

In general, the WDR diversions for the Rincon Valley Unit, Leasburg Unit, Mesilla Unit and Mesilla Valley can be obtained from available data on the total gaged diversions in those parts of the Project, with adjustment for El Paso Valley Carriage and waste from the Leasburg Unit into the Mesilla Unit.
The diversion data from the El Paso Valley unit is more complex. In WDR's from the 1940's and 1950's, some copies of the El Paso Valley Unit WDR (*see* Figure C.16 in Appendix C) include notes on what terms are included in the diversion, as follows (from 1951):

(1) Franklin Canal
(2) Riverside Canal
(3) Drain to Canal
(4) Less Ascarate W.W.
(5) Less Riverside W.W. 1 & 2
(6) Less Playa Lateral Waste to Riverside Canal

The first two terms, Franklin and Riverside, are the main diversions in the El Paso Valley that we would expect to form the basis of the reported diversions. The third term, Drain to Canal, is discussed in more detail in Section 7 of the report as well as Appendix C, and represents a discrepancy from current Project accounting, and perhaps a change in what water is actually available for diversion in the El Paso Valley. The fourth term, "Less Ascarate W.W.," represents an adjustment for planned, approved Project Waste. The Ascarate adjustment is made to avoid double counting of water that is diverted at Franklin

[8] Selection of diversion data from the WDR forms was made so as to avoid double counting of El Paso Carriage and water wasted from the Leasburg Unit to the Mesilla Unit.

then wasted back to the Rio Grande for rediversion, and is applied to avoid double counting. The Ascarate adjustment is similar to the adjustments for El Paso Valley Carriage that is made for the WDRs in the Rincon, Leasburg and Mesilla Unit WDRs to avoid double counting of water that is diverted above Courchesne for the sole purpose of delivering that water to American Dam more efficiently so that it can be rediverted for the El Paso Valley. The Ascarate wasteway adjustment (or credit) was applied in Project accounting until 1999, at which time this waste/rediversion operation was discontinued due to the completion of the ACE (*see* Appendices C and D).

The other two terms, "Less Riverside W.W. 1 & 2" and "Less Play Lateral Waste to Riverside Canal" are less well understood or documented. There is no available documentation of how those terms were calculated, nor any records of the resulting quantities. It is therefore unclear as to what effect these terms have on the D2 Curve and on the current negative departures from D2. It is possible that the "Less Riverside W.W. 1 & 2" term represents an early version of the current Project accounting term: "Credit to District for Diversions Greater than Orders" (*see* Appendix D).

3 INCONSISTENCY BETWEEN THE D2 DATA SET AND POST-1978 ACCOUNTING TO THE DETRIMENT OF EBID

As shown above, the D2 Curve was derived from data from the twelve-month calendar year. However, Post-1978 Accounting[9] does not charge either District for water diverted at times when there are no releases made from Caballo. The 1985 Draft Operating Agreement, which appears to summarize Post-1978 Accounting, states on page 3: "*All diversions made by the Districts during the nonirrigation season utilizing return flow waters shall not be charged against the Districts' respective allocations.*" The 2008 Operations Manual states on page 3: "*All diversions made by the Districts during the non-irrigation season utilizing return flow waters shall not be charged against the District's respective allocations*."

This is an important discrepancy between the premises upon which the D2 Curve is based and Post-1978 Project accounting practices. I estimate the amount of this discrepancy by determining how much water was diverted during the "off-season," when no releases were being made from Caballo, during the D2 Period.

Table E.7 contains the monthly (WDR) diversion data from D2 Period for the Rincon, Leasburg, Mesilla and El Paso Valley Units. Also included in Table E.7 is the monthly gaged flow below Caballo Dam, and a column of indicator values which are set to "1" during months in which Caballo Releases are occurring, and set to zero if no releases are being made (or if no diversion of released water occurring, as in February 1967 and February of 1968, when releases began on the last days of the month).[10] Review of the data in Table E.7 indicates that in some years substantial amounts of diversion occurred in late-fall and winter months, when no releases were being made from Caballo. Most of the water diverted

[9] *See* Appendix D of this Report for a detailed discussion of Post-1978 Accounting.

[10] Review of the daily release data indicates that Caballo releases during this period ended several days before the end of the last month of release, except for 1973, 1975 and 1976, so that in most years my analysis will not be influenced by the residual diversion of the last releases of the season.

during these times was diverted by the El Paso Valley Unit, with smaller amounts diverted by the Leasburg and Mesilla Units.

Table E.8 contains annual totals of the monthly Sum of All Unit Diversion from Table E.7, as well as the dates of the first and last releases from Caballo for each year as determined from the daily gaged flow below Caballo Dam. Annual diversion totals are provided for the entire calendar year (January-December) and for the release period of each year, defined using the Caballo gage data, with adjustment when Caballo releases ended close to the end of a month.[11] The final column is the amount of the total annual diversion that occurred outside of the release season: the amount varies from approximately 40,000 AF/Y during periods of high supply, to 5,000 AF/Y during the drought of the 1950s.

What this means as far as the D2 Curve being relied upon to allocate water to EPCWID is that ***the D2 Curve is inflated*** by the inclusion of diversions that are no longer counted as Project Supply. In effect, the 5,000 AF to 40,000 AF of off-season diversions that were historically supplied by drain flow and effluent, are now included as part of the demand for Caballo release. This inconsistency between the D2 Curve, based upon the D2 data set, and current accounting artificially inflates the negative departure (or gap) between recent accounting data and the D2 Curve. Since EBID's allocation is reduced by the amount of this negative departure, EBID's allocation is reduced by the amount of this accounting discrepancy.

In recent years, EBID's allocations have been extremely low, partly due to drought but partly due to D3 Allocation under the 2008 OA. These low-supply conditions have contributed to the reduction in drain flows in the Rincon and Mesilla Valley. El Paso Valley drain flows have also been greatly depleted by extensive groundwater pumping by Texans in the Hueco Bolson; *see* Appendix C. As a result, in recent years the amount of water available for off-season diversion, and the amounts of off-season diversions actually made, are probably relatively small. Regardless of the amount of winter diversions, these diversions would not be charged under Post-1978 Accounting procedures documented in both the 1985 Draft Operating Agreement and the 2008 Operations Manual. If aquifer recovery increases drain flows and off-season diversions, these diversions would still not be charged, resulting in an artificial departure from the D2 Curve. As discussed more completely in Appendix D, it is New Mexico and New Mexico alone being penalized for these negative departures from the D2 Curve through the application of the 2008 OA D3 Allocation.

---

[11] In 1973, 1975 and 1976 Caballo releases ended so late in September that a portion of the October diversion included reservoir release water. I performed an adjustment in those years to account for this. This adjustment consisted of calculating the amount of the October diversions that was in excess of the 1972 or 1974 October diversions (which I assume to be free from reservoir release water), and adding that amount to the "Total Diversion During Release Season" and omitting that amount from the "Non-Release Season Diversions."

1962	5-Mar	14-Sep	770,701	731,653	39,048	
1963	5-Mar	10-Sep	647,655	623,418	24,237	
1964	15-Mar	10-Sep	229,936	218,946	10,990	
1965	20-Mar	17-Sep	443,130	431,784	11,346	
1966	5-Mar	18-Sep	625,853	601,451	24,402	
1967	27-Feb	18-Sep	503,037	479,126	23,911	
1968	27-Feb	20-Sep	539,878	514,837	25,041	
1969	27-Feb	22-Sep	742,543	704,208	38,335	
1970	23-Feb	19-Sep	743,097	712,251	30,846	
1971	26-Feb	8-Sep	556,913	530,420	26,493	
1972	1-Mar	13-Sep	279,618	261,714	17,904	
1973	9-Mar	30-Sep	646,177	627,942	18,235	*
1974	2-Mar	16-Sep	704,544	673,381	31,163	
1975	24-Jan	30-Sep	693,559	673,373	20,186	*
1976	16-Jan	28-Sep	808,169	796,141	12,028	*
1977	3-Mar	11-Sep	468,239	448,712	19,527	
1978	10-Mar	14-Sep	321,478	307,272	14,206	

* In 1973, 1975 and 1976, Caballo releases ended late enough in September so that a portion of October diversion included reservoir water. I corrected for this by including the amount of the October diversions in those years in excess of the 1972 October diversion as part of the "Total Diversion During Release Season" and omitting that amount from the "Non-Release Season Diversions."

APPENDIX F

TIMELINES

IMPORTANT RIO GRANDE COMPACT AND RIO GRANDE PROJECT DATES

1890

- 1890s — Contention among Colorado, New Mexico, Texas and Mexico users over supply of Rio Grande water
- 1905 — Congress authorized the USBR to construct the Rio Grande Project
- JUNE 1906 — Contract among USBR, Elephant Butte Water Users Association, and El Paso Valley Water Users Association
- 1906 — 1906 Convention between the U.S. and Mexico
- 1907 — New Mexico Water Code enacted
- 1912 — Construction of some Project infrastructure began
- 1915 — USBR made 1st deliveries of Project water: equal water to each Project acre
- 1918 — Necessity for drainage on the Project became apparent

1920

- 1920s — EBID and EPCWID organized
- 1925 — Tornillo Canal completed; system of open drains completed
- 1929 — Rio Grande Compact (temporary) entered
- 1929 — New Mexico Groundwater Code enacted
- 1937 — Rio Grande Joint Investigation concluded; contracts executed between US/EBID and US/EPCWID

US_MSJ_00000842

IMPORTANT RIO GRANDE COMPACT AND RIO GRANDE PROJECT DATES

1938 — Rio Grande Compact entered; EBID/EPCWID Interdistrict Contract executed; IBWC Rectification river realignment completed; American Dam, Caballo Dam and reservoir constructed

DECEMBER 1939 — Rules and Regulations for the Administration of the Rio Grande Compact adopted by RGCC

1940

1940 — First year under the Rio Grande Compact

1941 — First Project municipal and industrial contract: USBR/EPWU/EPCWID

1943 — IBWC Canalization Project completed

1948 — RGCC Resolution amending Compact Article IV

LATE 1940s — Project farmers began to drill irrigation wells

1950

1950s — Pumping within the Project escalated to deal with drought

1951 — USBR limited allotment of Project water to individual US farms each year; farmers supplemented through pumping

1979 — Districts repaid USBR; USBR changed Project allocation, accounting and operations

1979-1980 — Transfer contracts signed between USBR, EBID, and EPCWID

SEPT 1980 — New Mexico State Engineer declared Lower Rio Grande Groundwater Basin

EARLY 1980s — USBR developed and implemented D1/D2 Curves based upon 1951-1978 historical water distribution data

IMPORTANT RIO GRANDE COMPACT AND RIO GRANDE PROJECT DATES

1983 — *City of El Paso v. Reynolds*, 563 F.Supp. 379 (D.N.M.1983) -federal court holds New Mexico Compact delivery obligation is to Elephant Butte Reservoir

1985 — USBR released 1985 Draft Operating Agreement with D1/D2 Allocation method

2000

EARLY 2000s — Litigation initiated between the Districts and USBR in a number of judicial forums relating to Project operations

2003-2004 — USBR employed an ad hoc allocation method without reference to the D-2 Curve

2004 — New Mexico State Engineer AWRM regulations promulgated, including Metering Order; litigation ensued

2006 — USBR unilaterally allocated in accordance with D3 Curve and carried over 1/2 of Districts' unused allocation at end of year; RGCC issued Directive regarding Credit Water

2007 — USBR unilaterally implemented new Project operating procedures incorporating D3 Allocation and Carryover

MAR 2008 — Districts and USBR entered Settlement Agreement as to 2 litigations; includes the 2008 OA

2009 — Metering Order by New Mexico OSE in effect

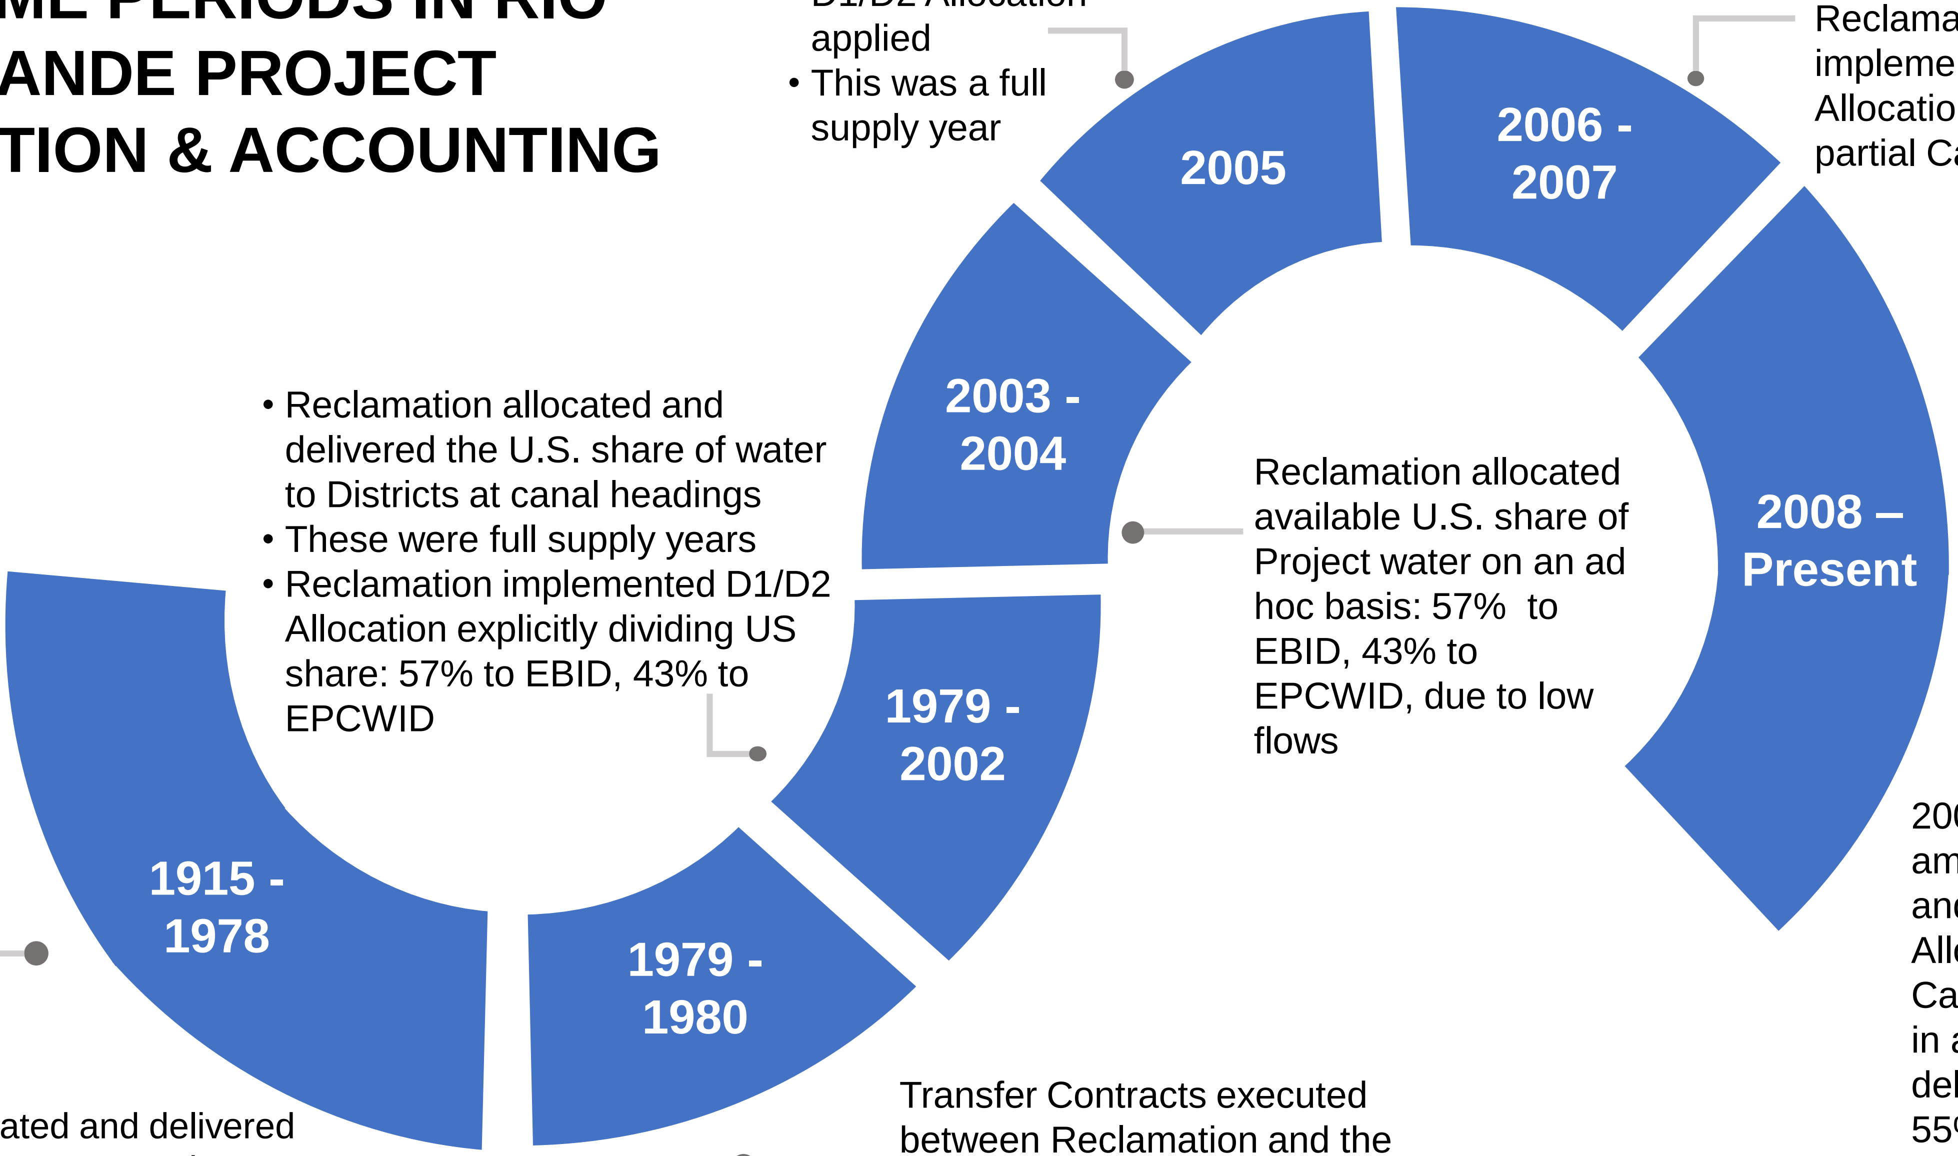
2010

2011 — USBR made an unauthorized New Mexico Credit Water release to Texas; New Mexico filed litigation in Federal district court against USBR

2013 — Texas filed Complaint against New Mexico and Colorado in United States Supreme Court (Original Action No. 141)

2018 — US Supreme Court decision that the Rio Grande Compact is inextricably intertwined with the Rio Grande Project and Downstream Contracts

KEY TIME PERIODS IN RIO GRANDE PROJECT ALLOCATION & ACCOUNTING



Reclamation allocated and delivered the U.S. share of water to Project farms: each Project acre is entitled to equal delivery equating roughly to 57% to EBID, 43% to EPCWID

Transfer Contracts executed between Reclamation and the Districts resulting in transfer of Project conveyances and responsibilities to Districts

- Reclamation allocated and delivered the U.S. share of water to Districts at canal headings
- These were full supply years
- Reclamation implemented D1/D2 Allocation explicitly dividing US share: 57% to EBID, 43% to EPCWID

Reclamation allocated available U.S. share of Project water on an ad hoc basis: 57% to EBID, 43% to EPCWID, due to low flows

- D1/D2 Allocation applied
- This was a full supply year

Reclamation implemented D3 Allocation with a partial Carryover

2008 OA executed among Reclamation and Districts: D3 Allocation with Carryover, resulting in an average of 45% delivered to EBID, 55% delivered to EPCWID

TestACE_AllocationSS.xlsx 2009 Allocation-ACE

1	**Rio Grande Project Diversion Allocations (EOM OCT 2009 Project Data)**	**Original Data**		**Modified: No ACE credit**	
2	Elephant Butte Reservoir Storage	454,530		454,530	
3	Caballo Reservoir Storage	26,100		26,100	
4	Total Rio Grande Project Storage	480,630		480,630	
5	Estimated Rio Grande Compact Credit Waters	-126,600		-126,600	
6	Estimated San Juan-Chama Water	-37,298		-37,298	
7	Water Released from Storage	693,289		693,289	
8	Total Usable Water Available for Release	1,010,021		1,010,021	
9	Carryover Obligation using Estimated Diversion Ratio	235,960		235,960	
10	Total Usable Water Available for Current Year Allocation	774,061		774,061	
11	EBID Allocation Balance (Previous Year)	-4,304		-4,304	
12	EPCWID Allocation Balance (Previous Year)	232,882		232,882	
13	EBID Allocation Balance (End-of-Year)	40,343		40,343	
14	EPCWID Allocation Balance (End-of-Year)	232,915		232,915	
15	Storage for EBID and EPCWID Allocation Balance (End-of-Year)	276,869		276,869	
16	Current Usable Water	733,152		733,152	
17	End-of-Year Release for Diversion Ratio	693,289		693,289	
18	D1 Delivery	470,416		470,416	
19	Mexico's Current Diversion Allocation	53,386		53,386	
20	Gross D2 Diversion Allocation	942,117		942,117	
21	EPCWID ACE Conservation Credit	17,998		0	
22	Net D2 Diversion Allocation for EBID and EPCWID	888,731		888,731	
23	D2 Diversion Allocation for EPCWID	384,161		384,161	
24	EPCWID Diversion Allocation (w/o Conservation Credit)	617,043		617,043	
25	EPCWID Diversion (w/o Conservation Credit or 67/155ths of Row 30)	384,128		384,128	
26	Diversion Ratio	0.986956		0.987	
27	Diversion Ratio Adjustment	-9,563		-9,563	
28	Sum of Release and Diversion Ratio Adjustment	723,589		723,589	
29	EBID D2 Diversion Allocation	504,570		504,570	
30	Difference between EBID Diversion Ratio Allocation and D2 Diversion Allocation	0		0	
31	EBID Diversion Ratio Allocation	268,077		286,075	
32	EBID Diversion Allocation	268,077		286,075	
33	Total EBID Diversion Allocation (includes 88/155th of Value in Row 30)	263,773		281,771	
34	Total EPCWID Allocation (includes Row 21 and 67/155th of Value in Row 30)	635,041		617,043	
35	District to District Allocation Transfer (OA 1.11 Excess Carryover Balance)	82,044		82,044	
36	Total EBID Diversion Allocation (After Transfer)	345,817		363,815	17,998
37	Total EPCWID Allocation (After Transfer)	552,997		534,999	-17,998
38	Total EBID, EPCWID, and Mexico Allocation	952,200		952,200	
39	EPCWID 2009 Allocation Charges (calculated)	320,082		302,084	
40	EBID 2009 Allocation Charges (calculated)	305,474		323,472	
41	EPCWID 2009 Allocation Charges (actual)	320,083		320,083	
42	EBID 2009 Allocation Charges (actual)	305,475		305,475	
43	Mexico 2009 Allocation Charges (actual)	58,688		58,688	
44	Difference in Mexico's Charges and Allocation	-5,302		-5,302	
45	EPCWID Share	-2,292		-2,292	
46	EBID Share	-3,010		-3,010	

Figure 7.1. D2 Curve and D2 Data (from WDR forms) Compared with Accounting Data (Charged Diversions) from 1979 – 2018

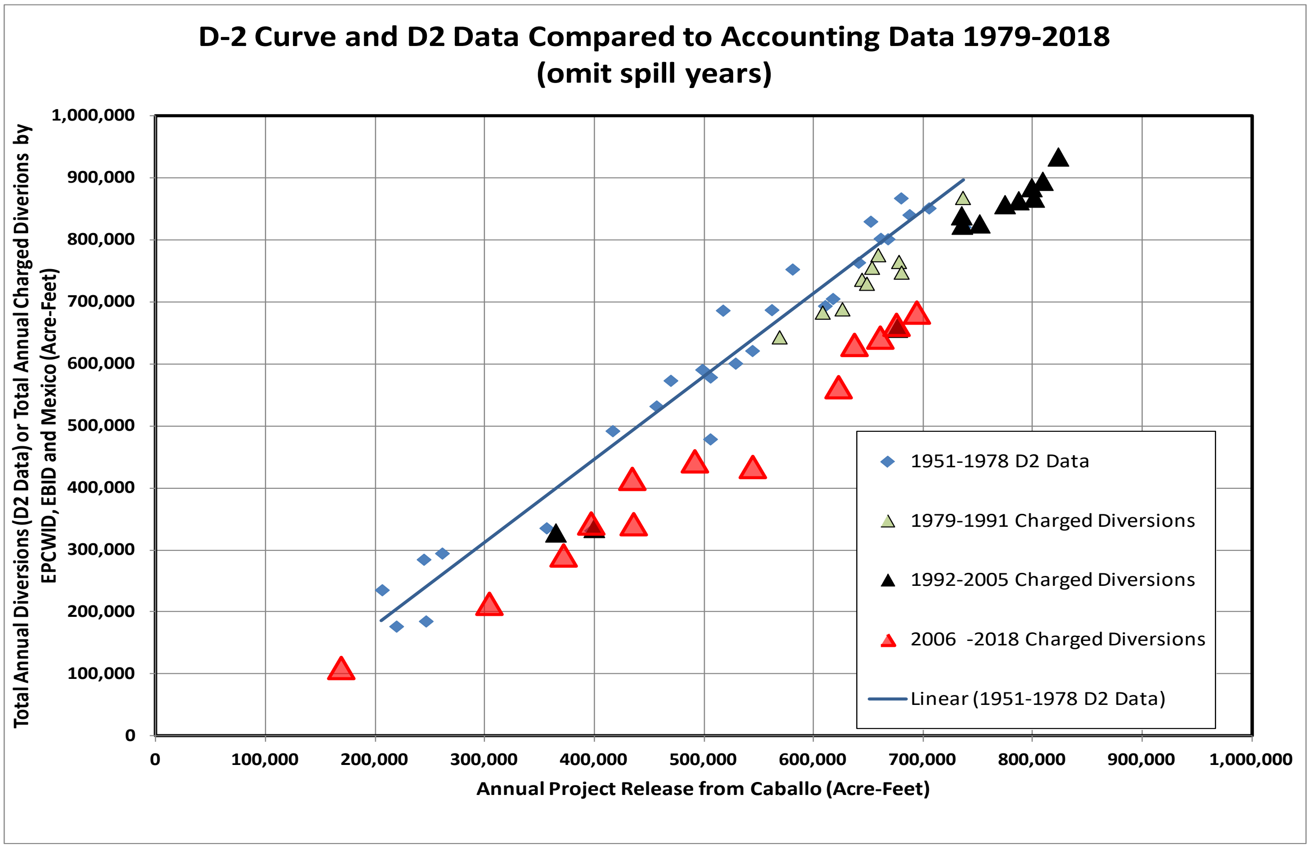

Figure 7.2. D2 Curve and D2 Data, Highlighting the 1969 data point

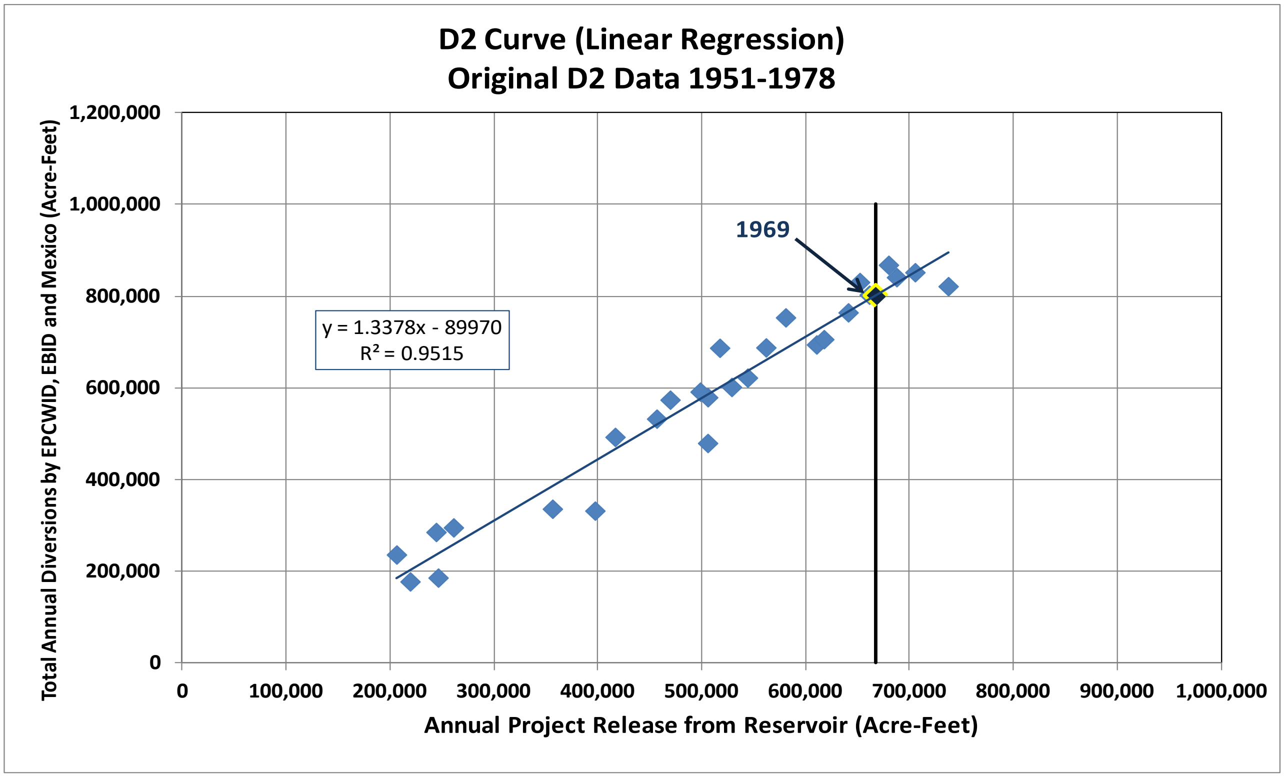

Table 7.1. Analysis of 1968 Diversions as reported in Reclamation WRD forms

Analysis of 1969 WDR Diversions			
	WDR Values*	WDR Values by Component	Estimated Charged Diversion using Post-1978 Accounting
EBID Diversion	421,000	404,000	404,000
EPCWID Diversion	321,000	263,708	263,708
Mexico	60,000	60,000	60,000
Off-Season Diversions		38,000	
EPV Drain to Canal		2,292	
Estimated Post-1978 Credits EBID **		17,000	
Estimated Post-1978 Credits EP#1**		17,000	
Total	802,000	802,000	727,708

* WDR Values adjusted so that Mesilla Dam Diversions are split between the Districts Pro-Rata

** Total Estimated Post-1978 Credits calculated as the difference between total diversions and Charged Diversion in a year of similar water supply to 1969. This total was split 50:50 between EBID and EPCWID

Figure 7.3. 1969 Project Diversion Analysis

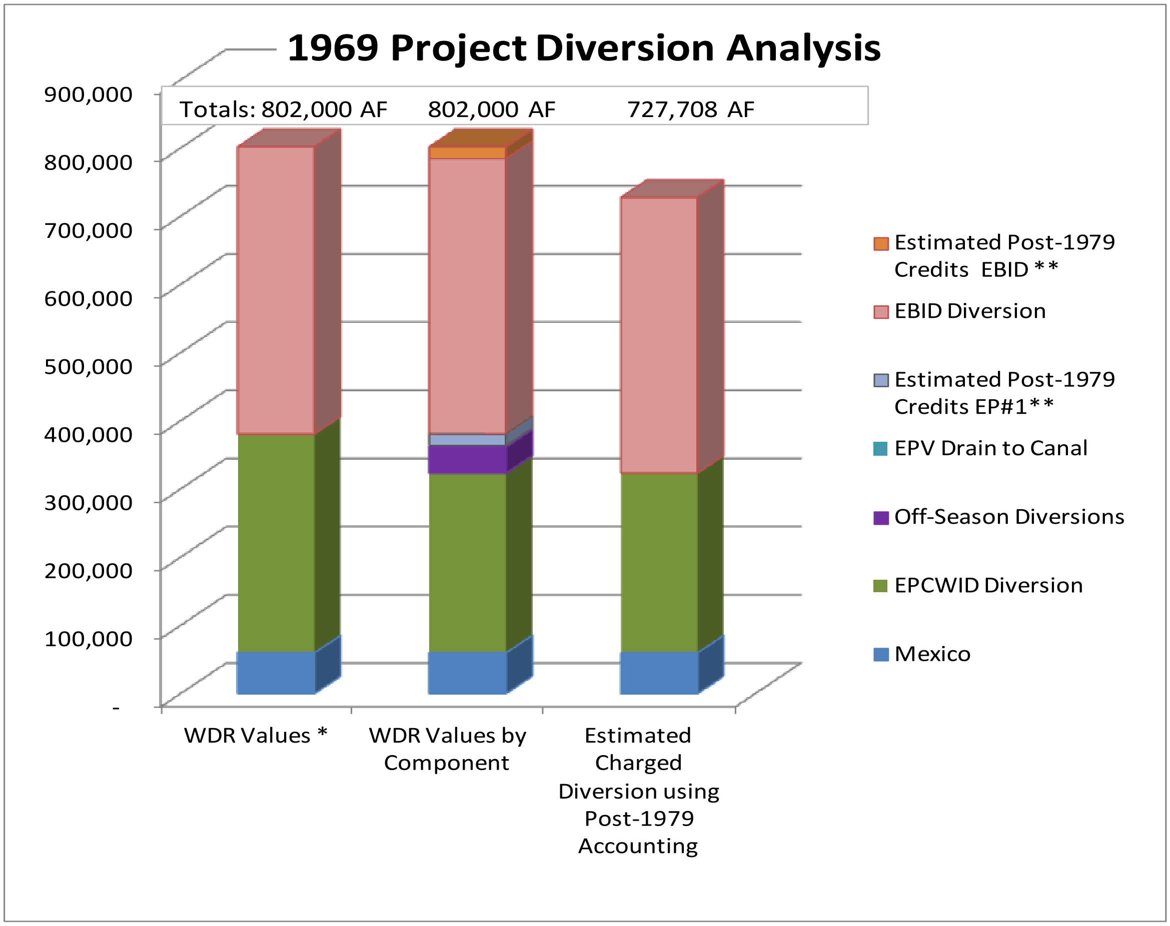

Figure 7.4. D2 Curve and D2 Data, Accounting Data from 2006-2018, Illustrating effect of Post-1978 Accounting on 1969 Diversion Data

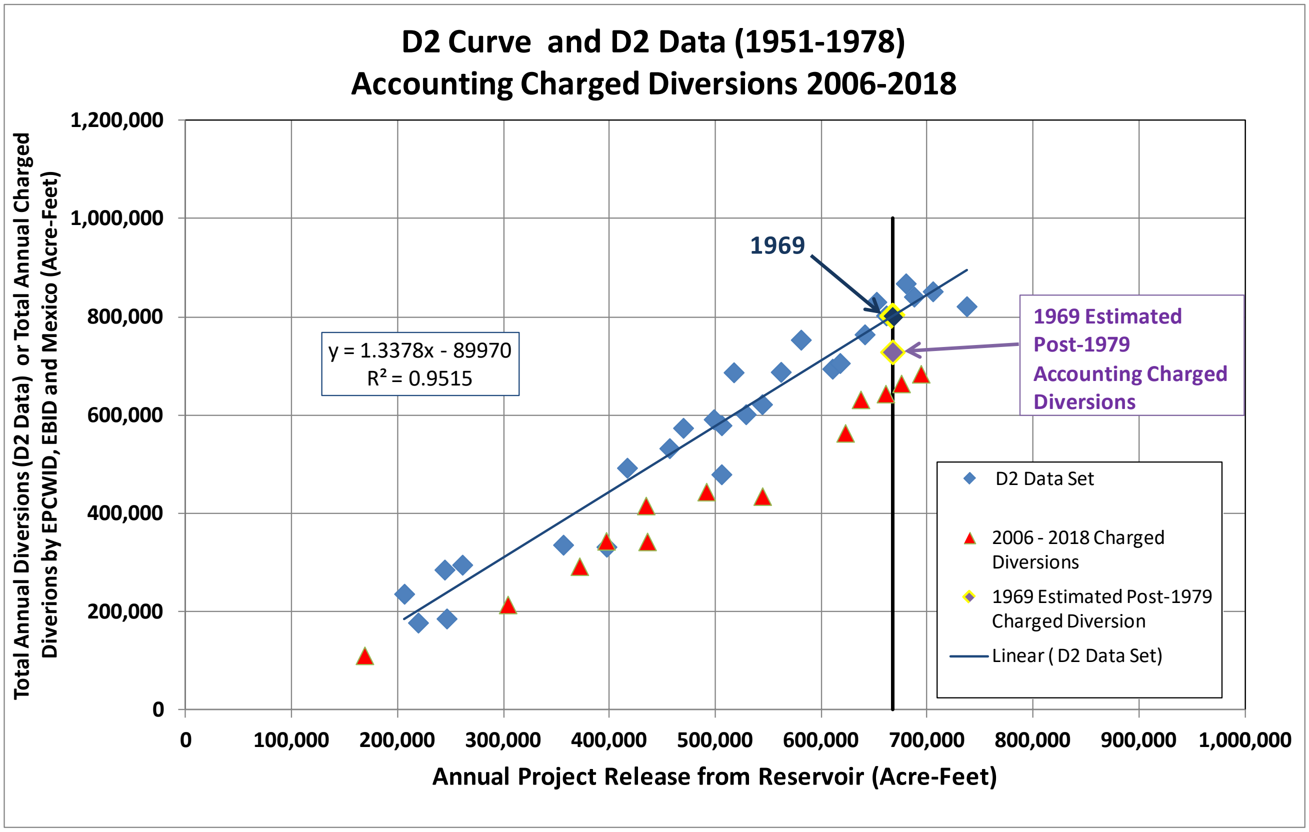

Figure 8.1. Project Accounting Data 2006 – 2018 (Charged deliveries to EBID and EPCWID plus the delivery to Mexico) Plotted together with the D2 Curve

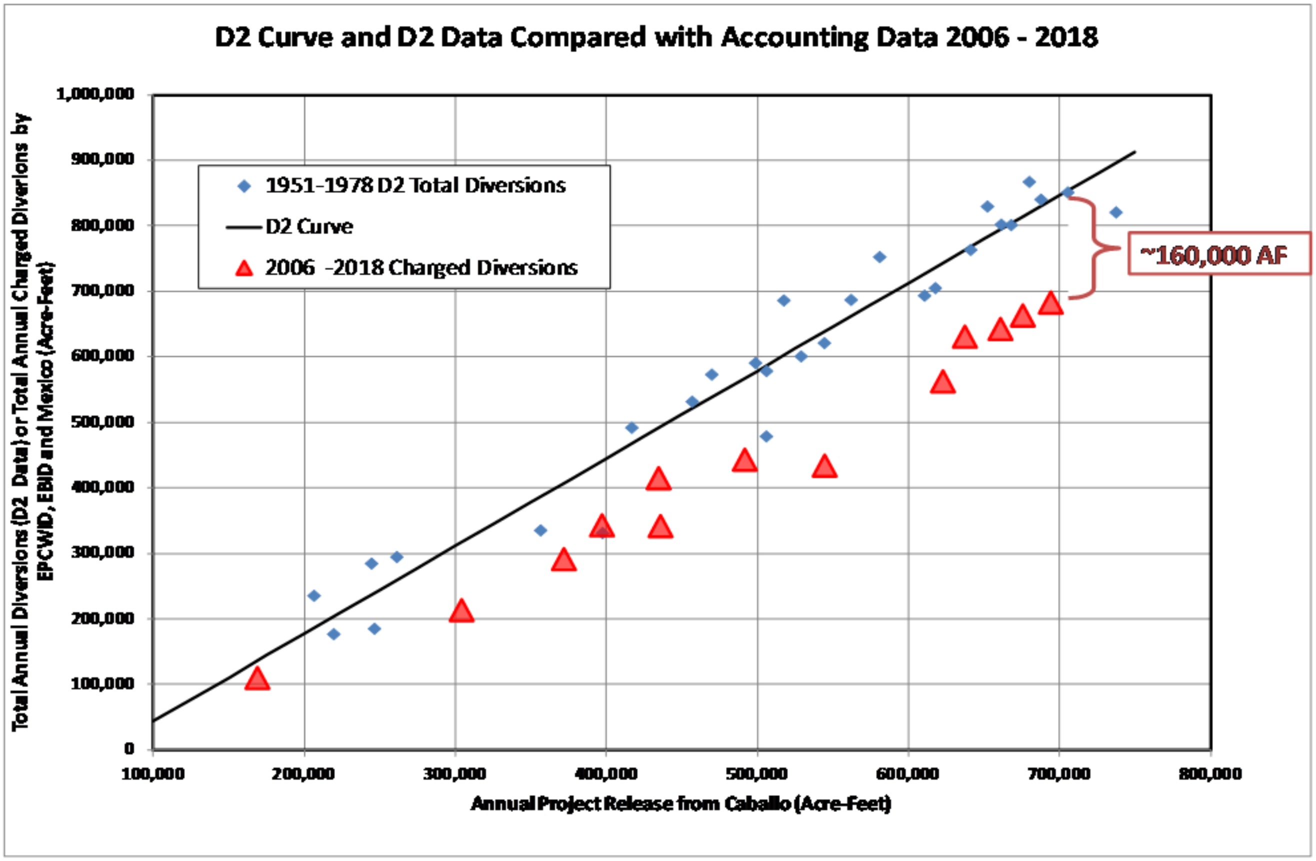

Table 8.1. Reported Usable Water, EPCWID Current-Year Allocation and Mexican Allocation for Years Designated "Full-Supply" Under D3 Allocation

Year	Total Usable Water Available for Release (Allocation Spreadsheet, Row 8)	EPCWID's current-year allocation	Mexican Allocation
2007	Unknown	367,291 AF	58,769 AF
2008	1,118,436 AF	405,073 AF	60,000 AF
2009	1,010,021 AF	402,159 AF	53,386 AF
2017	876,901 AF	401,842 AF	60,000 AF

[1] Diversion amount exclusive of waste at head gates for sand sluicing, etc.
[2] Reservoirs connected with distributing system only.
[3] Diversions plus inflow from reservoirs and other sources less delivery to reservoirs.
[4] Measured at
[5] Measured at

GOVERNMENT PRINTING OFFICE 6—7283

NOTE: Tabulation does not include water delivered to City of El Paso Water Treatment Plant.

(OVER)

(A) Diversions

(1) Franklin Canal
(2) Riverside Canal
(3) Drain to Canal
(4) Less Ascarate W.W.
(5) Less Riverside W.W. 1 & 2
(6) Less Playa Lateral Waste to Riverside Canal

(B) Waste

(1) Total from Island
(2) Tornillo No. 1
(3) Tornillo No. 2
(4) T - 131
(5) T - 216
(6) T-520
(7) Residual Waste at Fabens

Figure D.3. D2 Curve plotted with Original D2 Data from 1951-1978

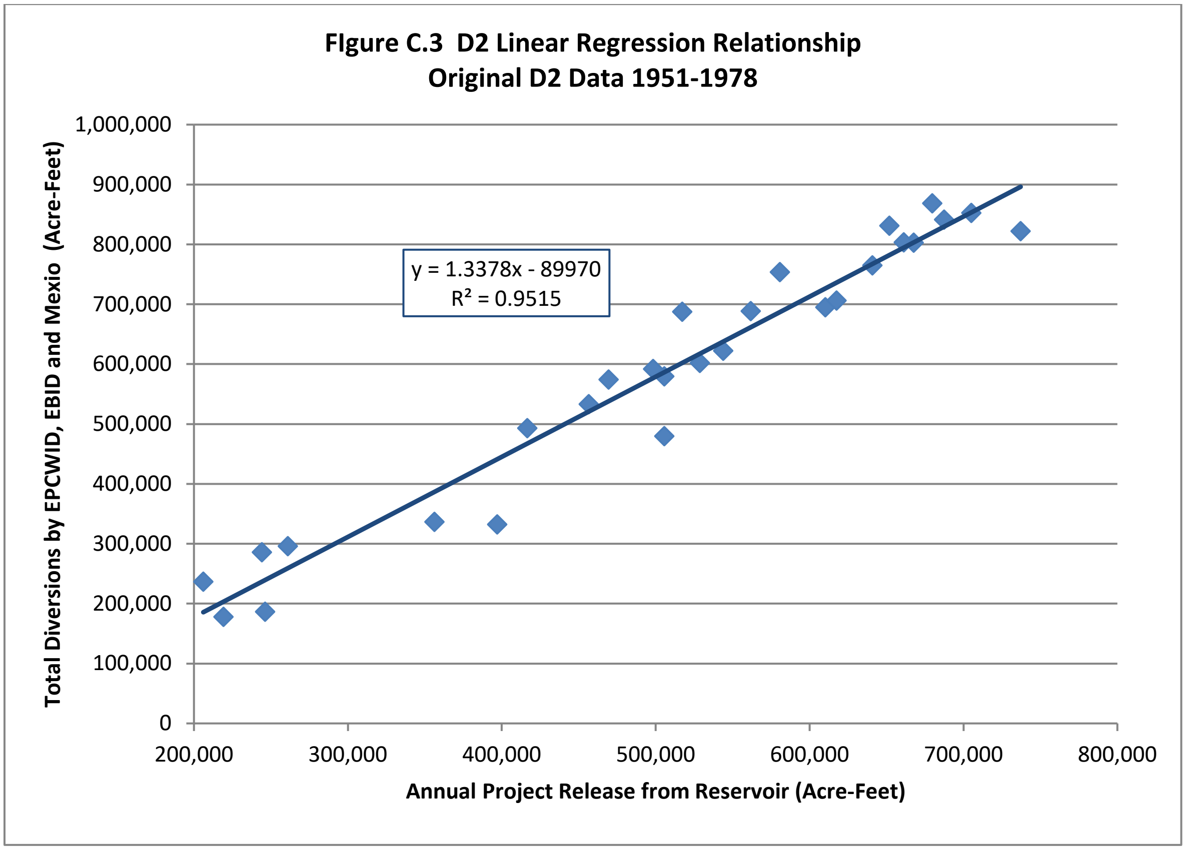

Table D.1. D1/D2 Rio Grande Project Allocations for Full Water Supply from WSAP

Allocations for a Full Water Supply[1] (acre-feet)						
Release Requirement[2]	Net Diversions at Headings[3]	Mexico Allocation	EBID Allocation	EBID Percentage[4]	EPCWID Allocation	EPCWID Percentage[4]
763,842	931,841	60,000	494,979	56.77%	376,860	43.23%

1. Full water supply is 468,700 acre-feet to farm head gates of US lands (3.024 AF/A for 155,000 authorized acres) and 60,000 acre-feet to Mexico at the International Dam
2. Release from Caballo Reservoir necessary to meet full water supply at diversion headings
3. Net Diversion at Headings determined from Curve D2 (includes US and Mexico)
4. Percentage is based upon the net amount remaining to U.S., after deducting Mexico's allocation

Figure D.6. D2 Curve and D2 Data (WDR), with additional 1979 – 1991 data from Project WDR sheets

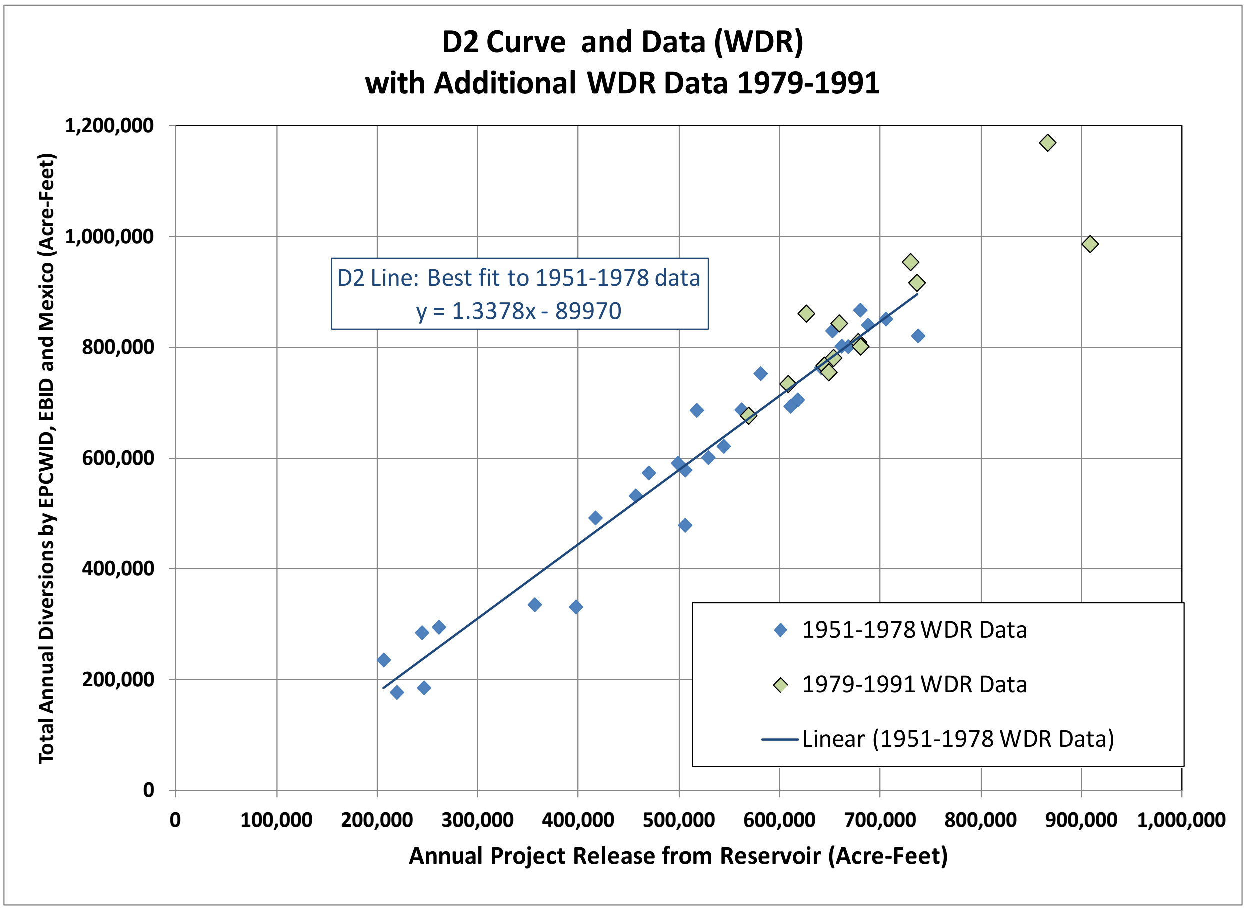

Figure D.7. D2 Curve and D2 Data (1951-1978), with Additional WDR Data (1979 – 1991), and Accounting Data (1979 – 1991)

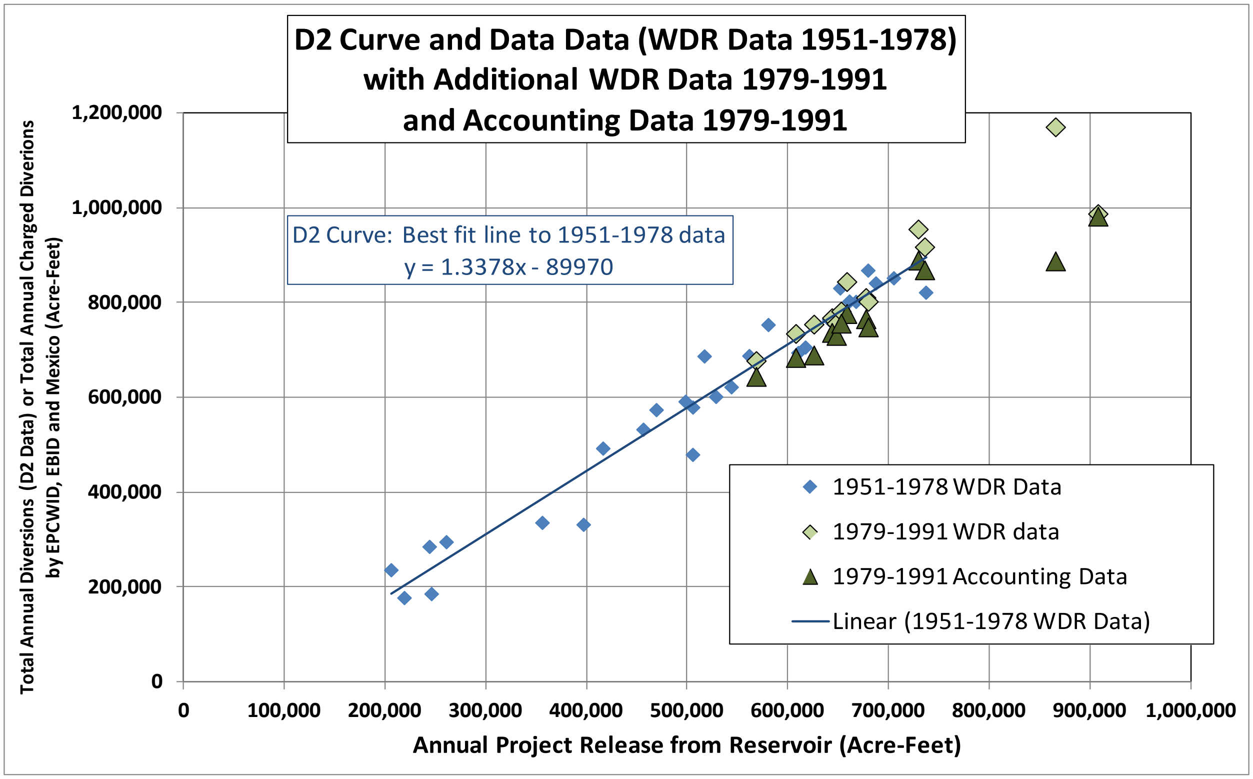

Figure D.8. D2 Curve and D2 data plotted together with 1979 – 2005 Charged Diversions as reported by Reclamation, calculated using Post -1979 Accounting

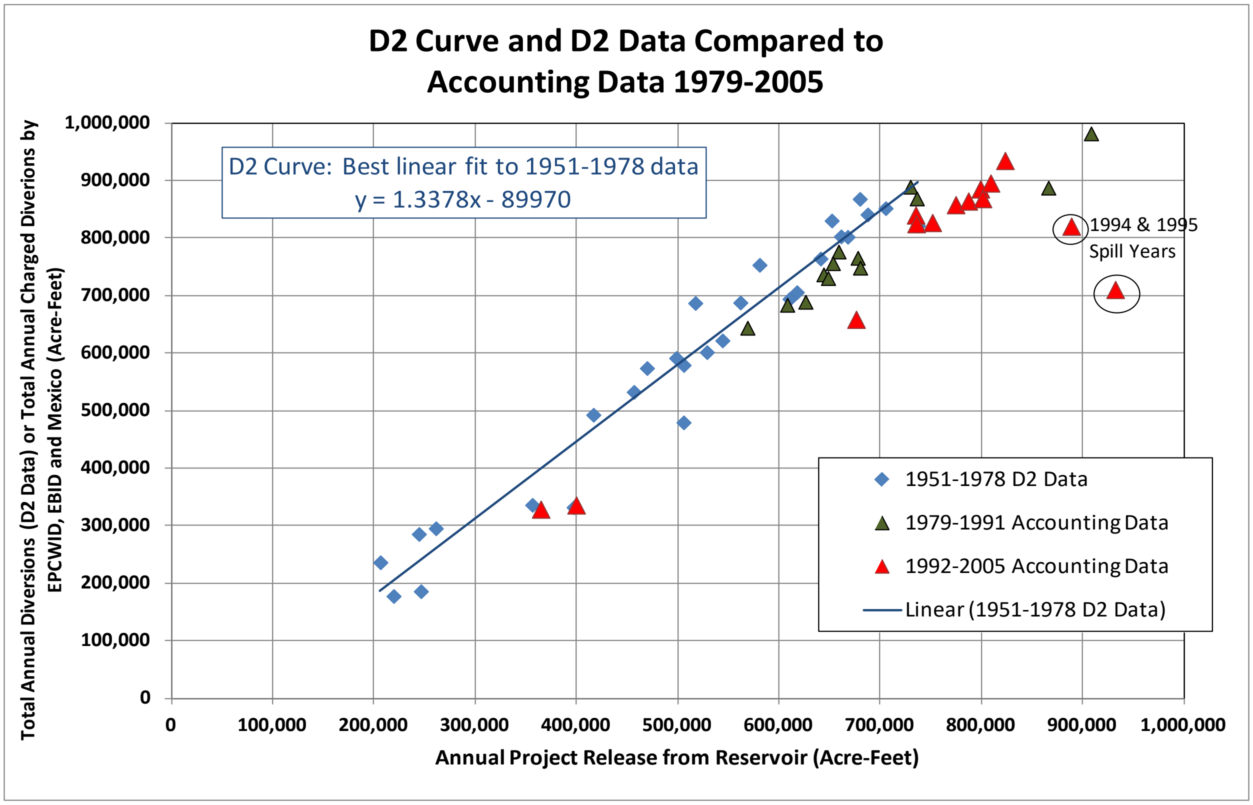

Table D.2. Illustration of the Effect of Variation in the Diversion Ratio
(D3 Allocation, Full-Supply)

Illustration of the Effect of Variation in the Diversion Ratio under D3 Allocation. (Values rounded to nearest 1000 AF)		
Diversion Ratio (unitless)	1.1	1.0
Usable Water (AF)	764,000	764,000
Mexican Allocation (AF)	60,000	60,000
EPCWID's Allocation (AF)	377,000	377,000
EBID's Allocation (AF) [(Usable Water x Diversion Ratio) – Mexican Allocation – EPCWID Allocation]	403,000	327,000

Figure D.9. D2 Curve and D2 data plotted together with 1979 – 2018 Charged Diversions as reported by Reclamation, calculated using Post -1979 Accounting

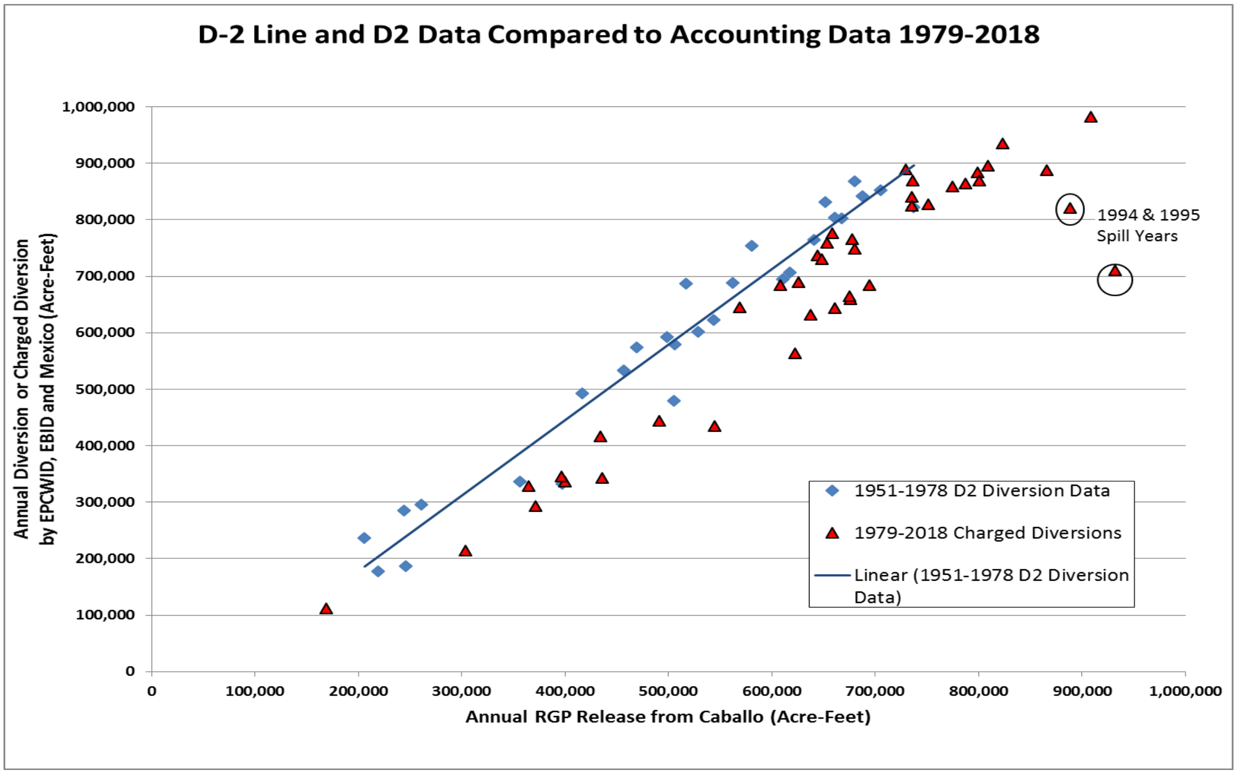

Table D.3. Simplified Allocation Example, D3 Allocation plus Carryover, Full-Supply Year, Amounts rounded to nearest 1000 AF

	Allocation Term	Quantity (AF)	Calculation
A	Total Usable Water Available for Release	1,000,000	
B	EBID Carryover from Previous Year	20,000	
C	EPCWID Carryover from Previous Year	190,000	
D	Total Usable Water Available for Current Year Allocation	790,000	A – B- C
E	Mexican Allocation	60,000	Use D1 Curve
F	EPCWID Current-Year Allocation	390,000	Use Extended D2 Curve
G	EPCWID ACE Credit	20,000	
H	Diversion Ratio	1.0	
I	Deliverable Allocation	790,000	D x H
J	EBID Current-Year Allocation	320,000	I – E – F – G
K	EBID Total Allocation	340,000	J + B
L	EPCWID Total Allocation	590,000	F + C
M	Mexican Allocation	60,000	E

Table D.4. 2010 – 2011 Example of New Inflow to Reservoir Needed to Fulfill Existing Carryover Accounts and Obligation

2010 - 2011 Example of when Carryover Accounts Required Additional Inflows			
		Storage, Carryover and Credit Conditions as of October 15 2010	Storage, Carryover and Credit Conditions as of January 1, 2011
Total Water in Reservoir Storage	(AF)	386,735	497,789
CO Compact Credit	(AF)	800	2,700
NM Compact Credit	(AF)	100,500	164,700
San Juan Chama Water	(AF)	60,796	64,250
Usable Water In Storage	(AF)	224,639	266,139
		Project Accounting 2010	Project Accounting 2011
EBID 2010 Unused Allocation (Carryover from 2010 to 2011)	(AF)	20,014	
EBID 2010 Unused Allocation (Carryover from 2010 to 2011)	(AF)	224,348	
Total Carryover (Carryover from 2010 to 2011)	(AF)	244,362	
2011 Diversion Ratio	(unitless)	0.98	0.85
2011 Carryover Obligation (divide total Carryover by 2011 Diversion Ratio	(AF)		287,485
Inflows to Elephant Butte after October 15, 2010 required to fulfill Carryover Obligation			62,846

No. 141, Original Action

In the

Supreme Court of the United States

Texas v. New Mexico and Colorado

Rebuttal Expert Report of

Margaret Barroll, Ph.D.

June 15, 2020

Prepared for:

State of New Mexico

Margaret Barroll, Ph.D.

TABLE OF CONTENTS

TABLE OF FIGURES

TABLE OF TABLES

OVERVIEW

I have reviewed the Summary Rebuttal Opinions of experts Drs. Ferguson, King, and Blair proffered by the United States in December of 2019. None of these experts refutes my quantitative conclusions as to the extent to which implementation of the D3 Method in the 2008 Operating Agreement has reduced EBID's full-supply allocation and delivery of Project Supply (by approximately 1/3, or more than 150,000 AF in full-supply or near-full-supply years).[1] The only apparent disagreement with my numbers was by Dr. Ian Ferguson in his Summary Rebuttal Opinions (page 8) with reference to my Opinion 8, stated that he calculated different percentages of allocation distribution for recent years. Dr. Ferguson did not provide his calculated values in his written opinions, or at deposition, but my analysis of the data he provided in discovery suggests the differences between our percentage averages numbers are minor and result merely from differences in calculation period and averaging method.[2]

Rather than refuting my conclusions and opinions, the United States' experts instead attempt to justify and explain the reasons behind this large change in allocation. Their explanations assign to New Mexico all responsibility for the negative departure in Project performance relative to the levels obtaining during the D2 period (1951 – 1978). The U.S. experts completely ignore the other factors I identified that contribute to this negative departure. None of the U.S. experts address the fact that changes in Project Accounting since the D2 period, the current exemption of all El Paso Valley municipal wastewater from being accounted as Project Supply, and the effects of Texas groundwater pumping have also contributed to the changes in Project performance as measured by the Diversion Ratio.

The Diversion Ratio is a new feature of Project Allocation, introduced in 2006 as part of the D3 Allocation Method. It is a measure of Project Performance, or delivery efficiency. The Diversion Ratio is calculated as the total amount of Project Supply delivered and charged each year divided by that year's Release from Caballo. As explained in Barroll (2019) at pages D14 and D15, the Diversion Ratio is used to calculate EBID's Allocation, and EBID's Allocation is extremely sensitive to small changes in Diversion Ratio. The lower the Diversion Ratio, the less water EBID receives. The Diversion Ratio is ostensibly a

---

[1] References to my conclusions are to those set forth in my initial Expert Report of Margaret Barroll, Ph.D., October 31, 2019, hereinafter "Barroll (2019)."

[2] My review of Dr. Ferguson's spreadsheet calculations suggests that the difference in percentage distribution values is caused, in part, by differences in what years were included in the calculations. In Dr Ferguson's spreadsheet Compare_Allocations_EBIDvEPCWID.xlsx, which he provided during Discovery, in the Compare Alloc tab, his table "Percent of Total Diversion Allocation (With ACE, Excluding Carryover)" tabulates the same type of data as my Table A10. I calculate EPCWID's % of US Allocation to be 56% whereas Dr. Ferguson calculates 53%. There are the following differences in our calculations: 1) Dr. Ferguson tabulates and averages data from 2008 through 2018, whereas I tabulate data from 2006 through 2018, 2) Dr. Ferguson takes an average of the allocation percentages, whereas I calculate the percentage of the average allocations, which takes into account the larger influence of higher supply years. Similarly, Dr. Ferguson's Table "Percent of Total Diversion Allocation (With Carryover and ACE)" generally tabulates the same type of data as my Table A11, although Dr. Ferguson does not include Carryover Transfers in his table. I calculate EPCWID percentage of Total US Allocation to be 62% (2008 – 2018) or 61% (2006 – 2018) whereas Dr. Ferguson calculates 61% (2008 – 2018).

measure of Project Performance, but it is also impacted by Project Accounting: if water diverted and used is not charged in Project Accounting, then the Diversion Ratio will be lower as a result, and EBID will be allocated less water. My report demonstrates the impact of the accounting issues that I raise on the Diversion Ratio and the reduction in EBID's Allocation that is attributable to these factors.

In summary: the analyses, conclusions, and opinions in Barroll (2019) stand uncontested.

R1 THE UNITED STATES ASSERTS THE 2008 OPERATING AGREEMENT IS INTENDED TO OFFSET THE EFFECTS OF NEW MEXICO GROUNDWATER PUMPING ON THE BASIS THAT NEW MEXICO GROUNDWATER PUMPING IS IN EXCESS OF THE LEVELS OBTAINING DURING THE D2 PERIOD (1951 – 1978).

Dr. Ferguson (Opinion under heading B, page 4) states that the D2 Curve (which was used to determine Project Supply from approximately 1980 through approximately 2005, and is currently used to determine EPCWID's allocation) *"incorporates effects of groundwater pumping on Project water supplies during the period 1951 – 1978."* Dr. Ferguson, Dr. King and Dr. Blair indicate that the D3 method is intended to offset impacts of "excessive" New Mexico groundwater pumping that was occurring prior to the initiation of D3 allocation, to protect EPCWID from those impacts, and/or account for Project water captured by New Mexico groundwater pumping.

Dr. King (3rd Opinion, page 7) states that *"the largest factor in deviations from D2 is increased groundwater withdrawals in New Mexico relative to the 1951-1978 D2 period, consisting of EBID constituent pumping and non-Project pumping,"* and Dr. Blair (Opinion #6, page 6) states *"the largest component of which [reduction in Project diversions] is groundwater pumping in New Mexico which is capturing Project Water supply."*

Dr. Barroll Reply: First, it is important to note that the US rebuttal experts concede that the D2 Curve "grandfathered-in" the groundwater pumping occurring from 1951-78.

As to the substance of the US's rebuttal arguments, while the D3 Method does reduce EBID's allocation to account for the effects of any New Mexico groundwater pumping in excess of that occurring during the D2 period, it also reduces EBID's allocation as a result of changes in Project water accounting since the D2 period unrelated to New Mexico groundwater pumping.

Neither Dr. Blair nor Dr. King provide evidence supporting their contention that increases in New Mexico pumping relative to the D2 period cause the largest part of the recent deviation from the D2 Curve. Furthermore, even if this contention is true, it does not justify reducing EBID's allocation for all deviations from the D2 Curve, including those not resulting from New Mexico groundwater pumping. As I demonstrated in Barroll (2019) Section 7 and Appendix D changes in Project accounting since the D2 period have created significant inconsistencies between current accounting data and the data used to calculate the D2 Curve. These accounting discrepancies cause a significant part of the observed departure from the D2 Curve.

Historical irrigation groundwater pumping data and estimates by New Mexico experts (Expert Report of Gregory K. Sullivan and Heidi M. Welsh, Spronk Water Engineers, Inc., October 31, 2019, hereinafter

“Spronk (2019)”)[3] are shown in Figures 1 and 2. I have calculated the pumping averages over various time intervals, and included these results on Figure 1. The data in these figures indicate:

1) Irrigation well pumping in recent years of low Project Supply are comparable to those occurring in low-supply years during the D2 period.
2) Irrigation pumping amounts have historically been highly variable, depending on Project Supply levels (which depend on runoff from the northern New Mexico and Colorado mountains), and therefore it is difficult to make a useful comparison between the irrigation pumping levels during the D2 period to those levels during recent years. As illustrated in Figure 1, calculated averages vary substantially depending on which time intervals the averages are calculated over.
3) Since 2006, New Mexico irrigation well pumping has not dropped below 100,000 AF/yr even in full supply years such at 2007, 2008, 2009 and 2017[4]. This high level of pumping in full-supply years reflects New Mexico’s increased need to pump groundwater because of the low surface water allocations given EBID under D3 Allocation.
4) Irrigation well pumping in New Mexico during the full-supply years 1979 through 2002 (shown in Figures 1 and 2), averaged approximately 65,000 AF/yr according to Spronk (2019) and approximately 85,000 AF/yr according to estimates by Texas experts (Expert Report of Staffan W. Schorr and Collin P. Kikuchi, Montgomery and Associates, May 31, 2019, hereinafter “Montgomery & Associates (2019)”). Neither set of estimates suggests an upward trend in irrigation well pumping in New Mexico during the 1979 through 2002 period.

---

[3] Prior to 2009, in the absence of irrigation well meter data, Spronk estimates irrigation well pumping based on the difference between the farm demand (based on Consumptive Irrigation Requirement and estimated farm efficiency) and the reported delivery of surface water.

[4] I define full-supply” years as those in which over 764,000 AF of Usable Water are available to the Project. Dr. Ferguson differs, suggesting a higher standard (Ferguson rebuttal opinion, page 8). The application of either standard in my analysis produces similar results, and does not change the conclusions of my work. “Low-supply years” are less well defined, and depending on context may suggest that less than 600,000 AF or less than 400,000 AF of Usable water are available to the Project. Note that Dr. Ferguson, on page 8 of his rebuttal opinion, indicates that under the 2008 OA, the definition of full-supply conditions changed from a threshold of 763,800 acre-feet of Usable Water (my definition) to a threshold equal to 790,000 AF **plus** the total amount of District Carryover (which has often exceeded 200,000 AF) **plus** any water needed to deliver that Carryover. As a result, Dr. Ferguson does not consider 2009 a full-supply year even through Reclamation’s Allocation Spreadsheet for that year indicates that the “Total Usable Water Available for Release” was 1,020,021 AF.

Figure 1. Annual Irrigation Well Pumping in New Mexico LRG Spronk (2019)

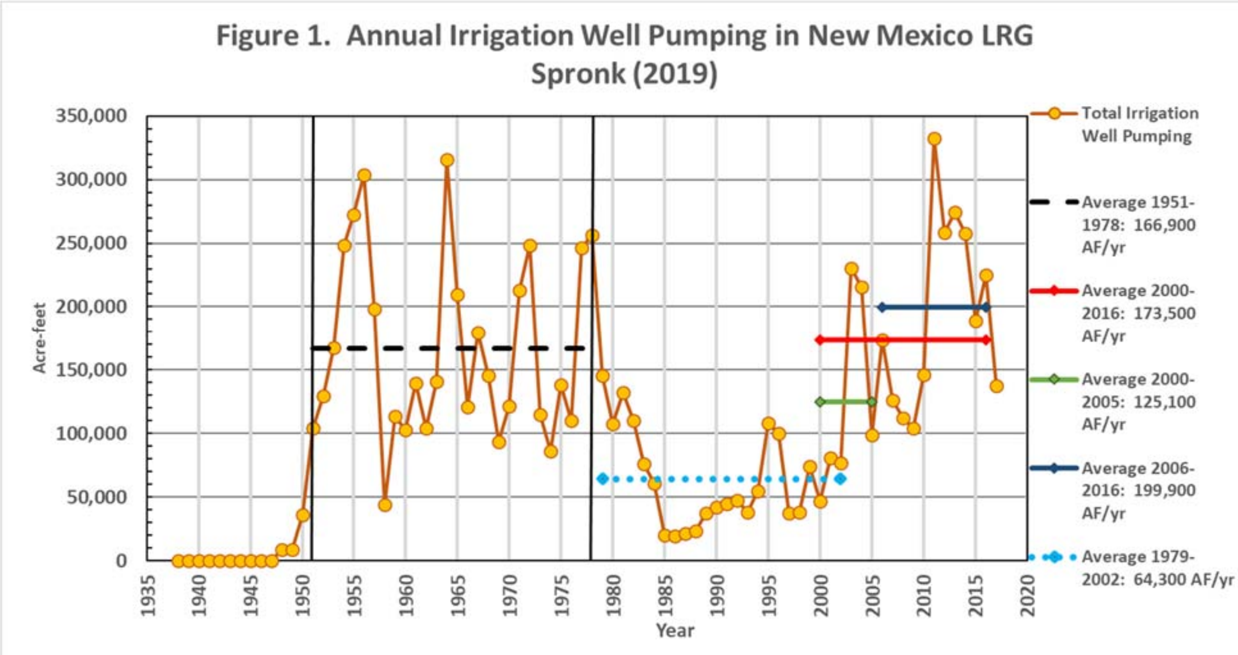

Figure 2. Annual Estimated Irrigation Well Pumping (IWP) in NM LRG 1979-2002 (Full-Supply Years)

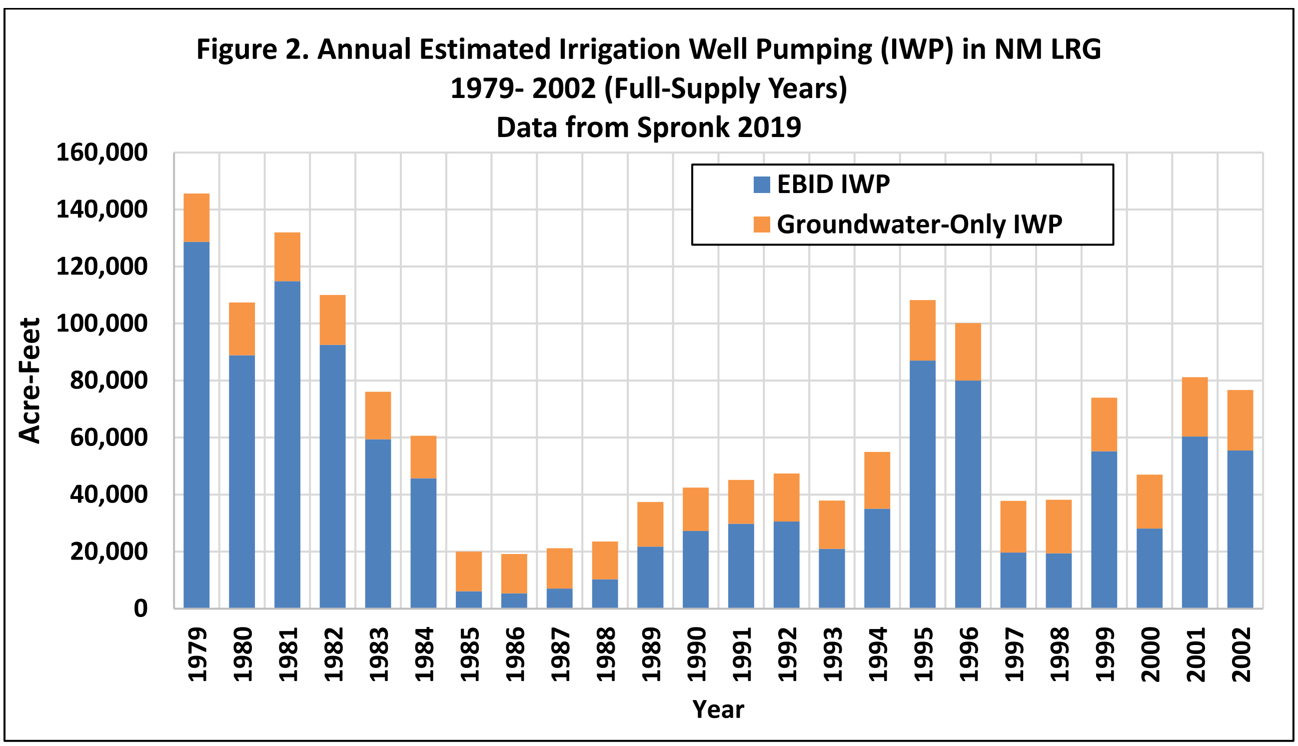
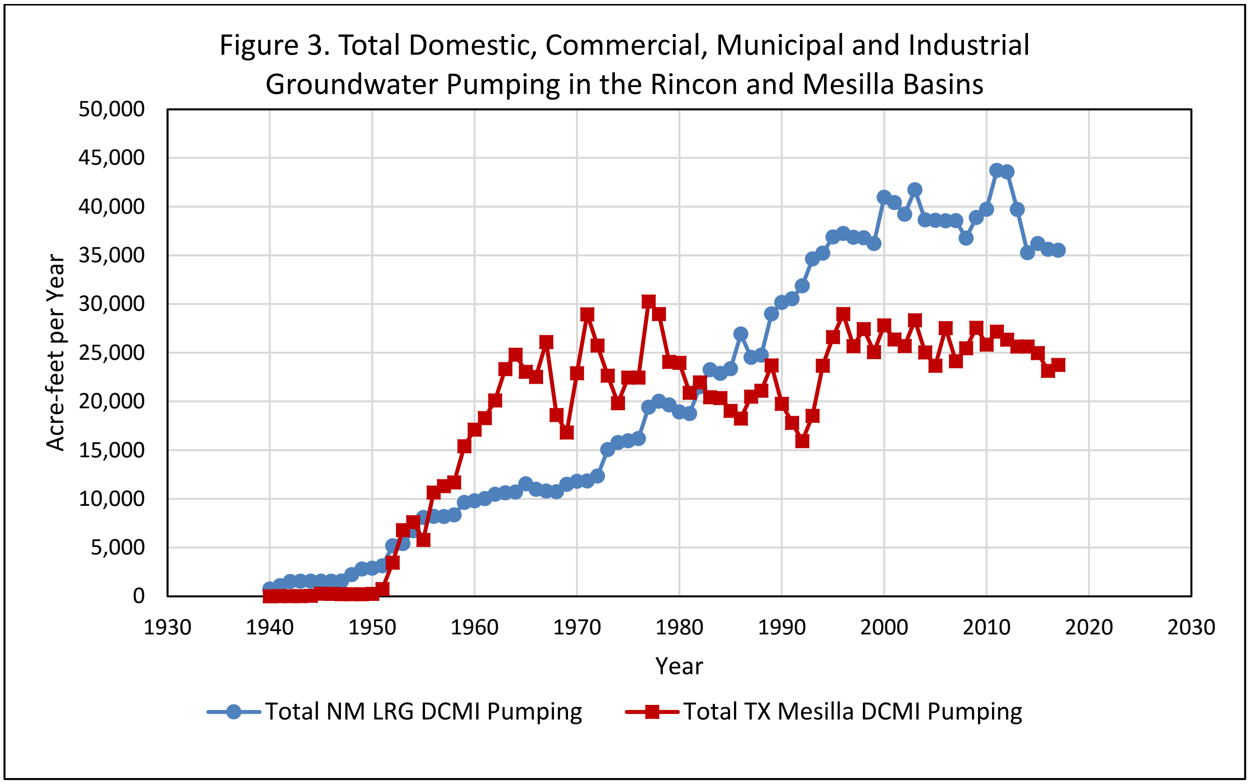


Groundwater diversions for domestic use, drinking water, and commercial (DCMI) use in the Rincon and Mesilla basins in New Mexico increased with time from 1940 through the year 2000, Over the past 20 years there is no trend of increased DCMI pumping in New Mexico, as shown in Figure 3.

Note that DCMI pumping does not have a 1:1 impact on stream flows. The larger municipal users, such as the City of Las Cruces, generate treated effluent that is returned to the Rio Grande, and the diversion and use of this water is treated as Project Supply. The municipal effluent acts to offset part of Las Cruces' pumping impacts on the stream and on the Project. In addition, Las Cruces makes use of water pumped from the Jornada del Muerto basin, which has very little hydrologic connection with the Rio Grande stream system. Effluent returns into the Rio Grande from Las Cruces's Jornada pumping is largely imported water that provides additional mitigation for Las Cruces pumping within the Mesilla basin.

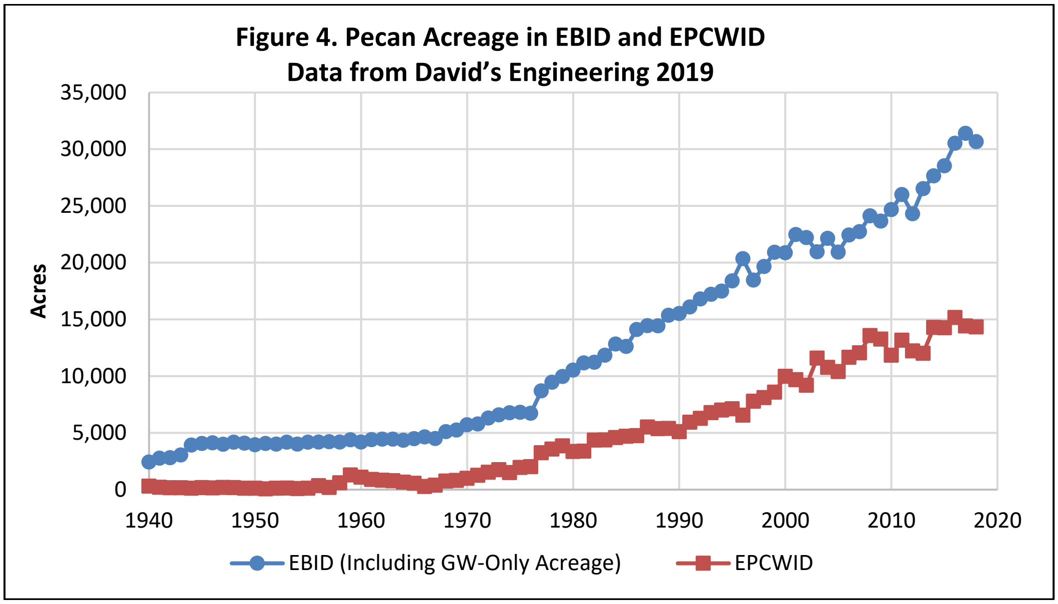
Figure 3. Total Domestic, Commercial, Municipal and Industrial Groundwater Pumping in the Rincon and Mesilla Basins



The irrigation water demand on a per-acre basis has increased over past decades in both New Mexico and Texas as more water-intensive crops have replaced cotton. The transition to more profitable and more water-intensive crops, such as pecans, has occurred in both the New Mexico and Texas parts of the Rio Grande Project as shown in Figures 4 (acreage) and Figure 5 (percentages). In recent years, pecan orchards comprise approximately 40% of the irrigated acreage in both EBID and EPCWID. Both EBID farmers and farmers in large parts of EPCWID have access to groundwater that allows them to successfully maintain these orchards in years when the Project has a short supply.

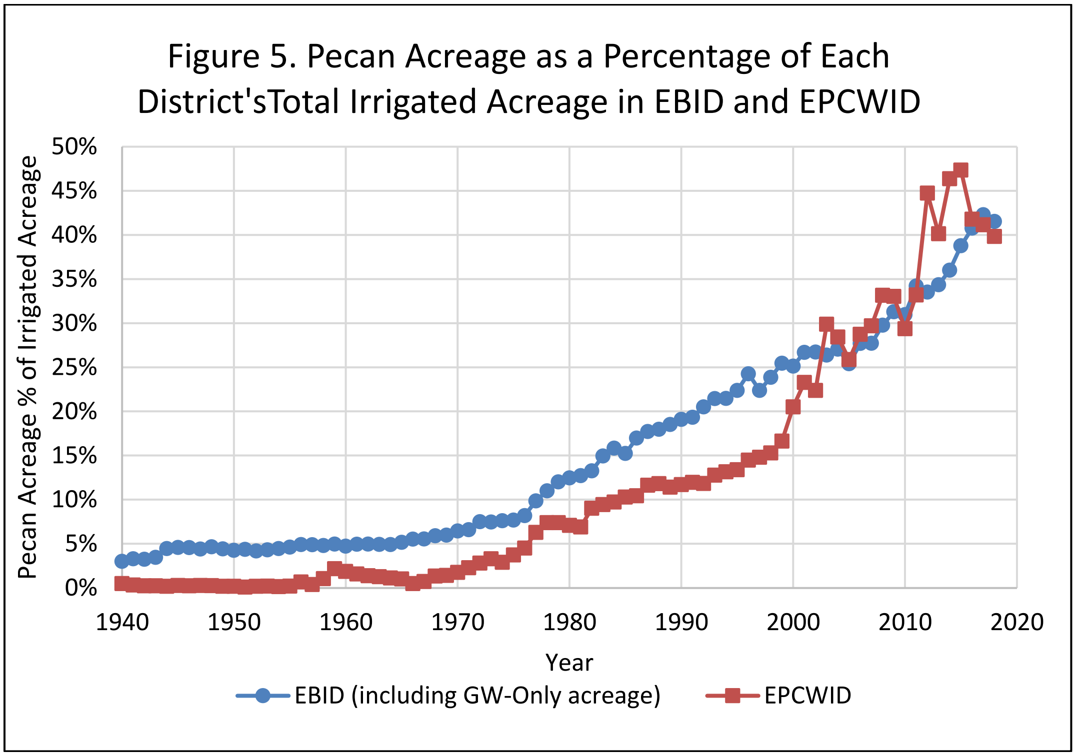
Data compiled in Spronk's Rio Grande Project Canal and Farm Budget spreadsheet[5] indicate an increase in the consumption of irrigation water per irrigated acre in New Mexico through time, from an average of 2.6 acre-feet per acre (AF/A) during the 1951 – 1978 period to an average of 2.9 AF/A in more recent years. (Similarly, within EPCWID, the per acre consumption rose from 2.4 AF/a to 2.6 AF/A).

Figure 4. Pecan Acreage in EBID and EPCWID



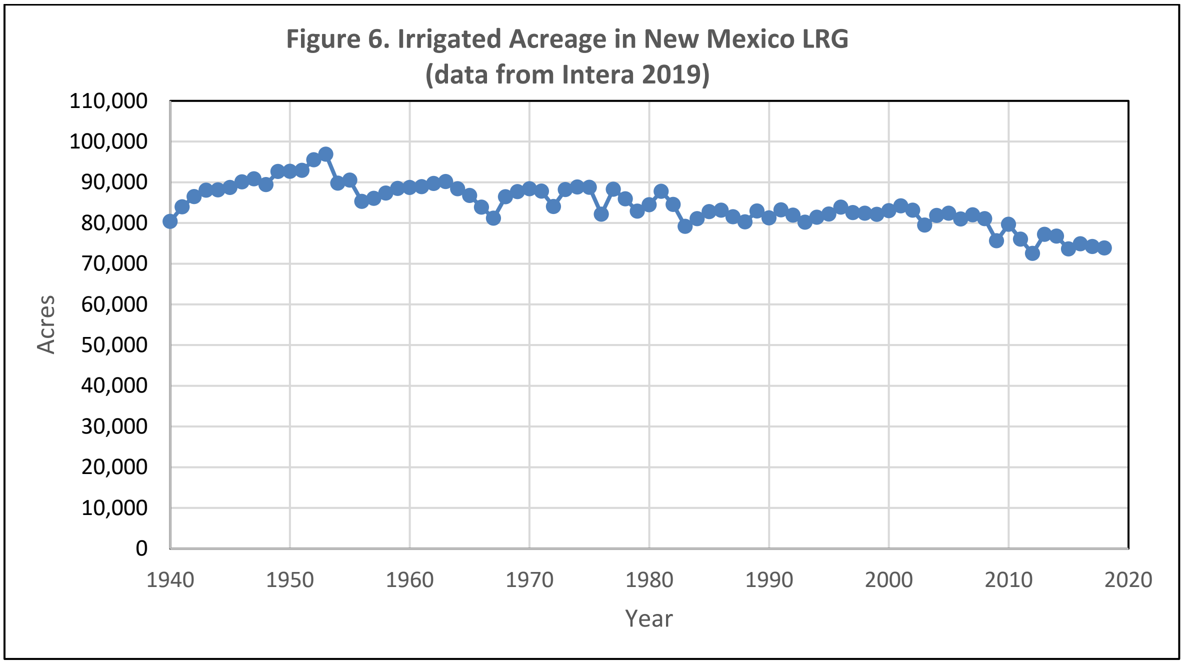
[5] Spronk Spreadsheet named 2019-10-25 Rio Grande Project Canal and Farm Budget.xlsx, analysis of data from the tab named TablsAnn for EBID Total.

Figure 5. Pecan Acreage as a Percentage of Each District's Total Irrigated Acreage in EBID and EPCWID



While per acre irrigation consumption in New Mexico appears to have increased, the total irrigated acreage in the New Mexico part of the LRG has declined, from a reported high exceeding 90,000 acres during the 1950's, to approximately 75,000 acres in recent years, as shown in Figure 6. Total irrigation demand is the product of the per-acre demand and the irrigated acreage. As will be shown in the figures below, data from New Mexico experts indicates that the decrease in irrigated acreage has compensated for the increase in per acre consumptions, and that total consumption of irrigation water in New Mexico has not increased.

Figure 6. Irrigated Acreage in New Mexico LRG



The availability of meter data from irrigation wells in the New Mexico portion of the Project starting in 2009 allows us to explore the actual relationship between irrigation pumping and surface water supply using hard data. All groundwater use in the Rio Grande Project in New Mexico is measured by calibrated flow meters.[6] Table 1 (a revised version of Table 4.2 from Barroll (2019)) shows annual values of key Project Supply parameters related to EBID, and the annual metered irrigation well pumping, for the period 2008 through 2018. The metered irrigation well pumping is strongly dependent on surface water supply: when EBID's supply of Project water is low, metered irrigation well pumping is high, and vice-versa.

When EBID's farm deliveries (of Project surface water) are added to irrigation well pumping, the result represents the total farm delivery of groundwater and surface water. The total farm delivery of groundwater and surface water can be divided by the irrigated acreage to calculate the average farm delivery per acre. Table 1 shows that the average farm delivery per irrigated acre in recent years is 4.0 AF/A, which is the same amount of water that EPCWID allots to its farmers in full-supply years (Blair 2001[7]). If that same total farm delivery of groundwater and surface water is instead divided by the

[6] Except for some exempt small stock and single-family domestic wells

[7] Blair, 2001, Sources and Quantity of Rio Grande Project Water Available for Conversion to Uses Other than Irrigation under the Proposed Third Party Implementing Contract among EPCWID, the City of El Paso, and the United States. Exhibit D of Contract No. 01-Wc-40-6760, page 57 of 74, line 10, "In this report, the determination of a "full supply" year … assumes a District Project Water delivery requirement of 4.0 acre-feet per acre per year to all lands held by taxable owners of "First Class" Water Rights Lands…"

EBID's authorized acreage, 90,640 acres, I calculate an average farm delivery per assessed acre of 3.4 AF/A. This value is somewhat higher than the full-supply farm delivery value calculated by Reclamation for the period 1946 through 1950, 3.024 AF/A, suggesting a net increase in total irrigation water demand since the late 1940's. In 1961 Gunaji reported that "The normal use of water per acre ranges from 3.25 to 3.5 acre-feet per acre delivered to first class water right land [in EBID]"[8] When calculating irrigation demand for the 1950's, Gunaji uses a per-acre farm demand of 3.5 AF/A, consistent with the farm delivery per assessed acre value I calculate in Table 1.

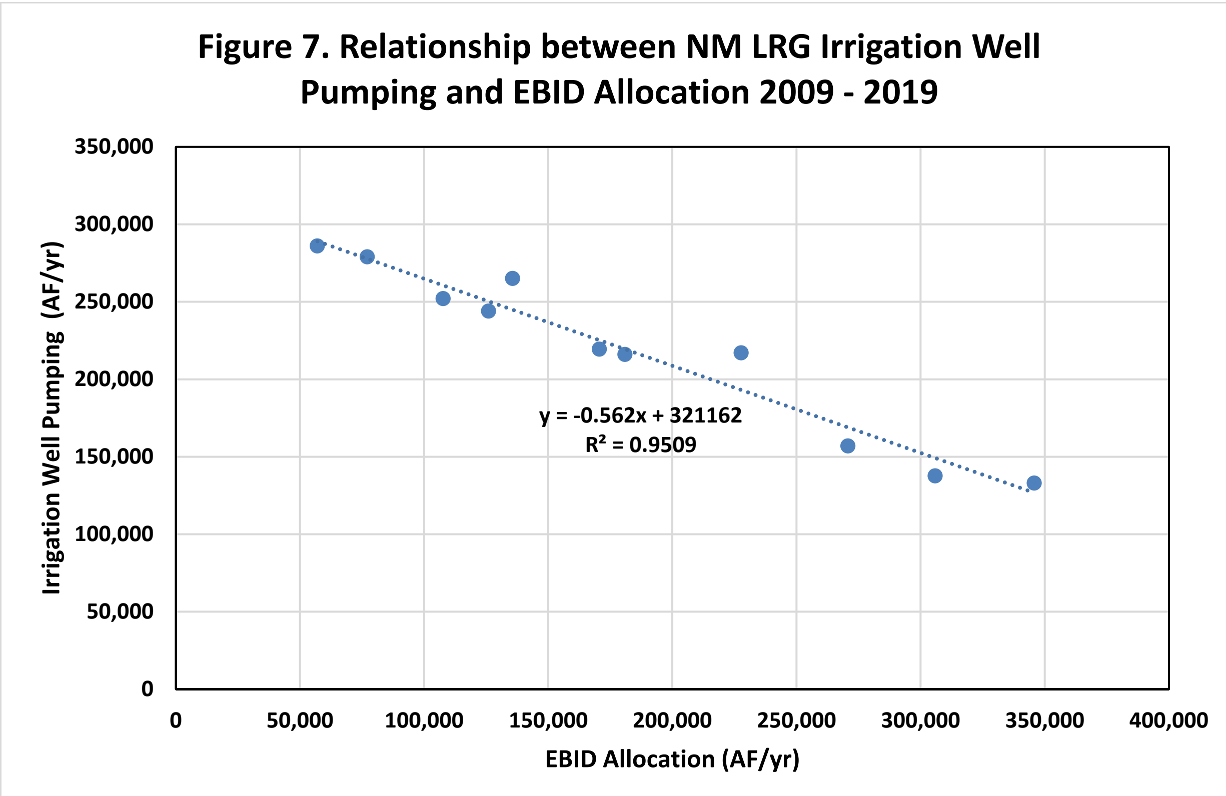
Estimated Values: 2008 Irrigation well pumping set equal to metered 2009 irrigation well pumping. 2019 Irrigated Acreage set to reflect levels in recent years.

[8] Gunaji, Narendra, *Ground Water Conditions in Elephant Butte Irrigation District*, Engineering Experiment Station, NM State University, November 1961.

In Figure 7, I plot metered annual irrigation well pumping from 2009 through 2019 as a function of EBID's allocation of Project Water. As expected, irrigation well pumping is higher when the allocation is low, and vice versa. The data are tightly correlated, with a regression coefficient (R^2) of 0.95, showing that **variation in irrigation well pumping is almost completely driven by variation in surface water supply** and the resulting shortage of water necessary to maintain crops.

Figure 7. Relationship between NM LRG Irrigation Well Pumping and EBID Allocation 2009-2019



In Figure 8 I plot the total reported farm delivery of Project water in EBID with total metered irrigation well pumping in the New Mexico LRG for the years in which this meter data is available: 2009 – 2018. This plot represents actual farm demand in the New Mexico Project area[9] over this period and shows a stable level of demand over this period. Figure 9 is the equivalent plot for the historical record since 1940, using values for irrigation well pumping calculated by Spronk[10] (2019). This plot also shows a relatively stable farm demand for water in the New Mexico Project area over a much longer period of time.

[9] Including irrigation well pumping on EBID lands, and also pumping for a few thousand irrigated acres in New Mexico that are not part of EBID, and that use exclusively groundwater for irrigation.
[10] Prior to 2009, in the absence of irrigation well meter data, Spronk (2019) estimates irrigation well pumping based on the difference between the farm demand (based on Consumptive Irrigation Requirement and estimated farm efficiency) and the reported delivery of surface water.

Figure 8. Total Reported Farm Delivery of Surface Water and Irrigation Well Pumping in NM LRG (2009-2018)

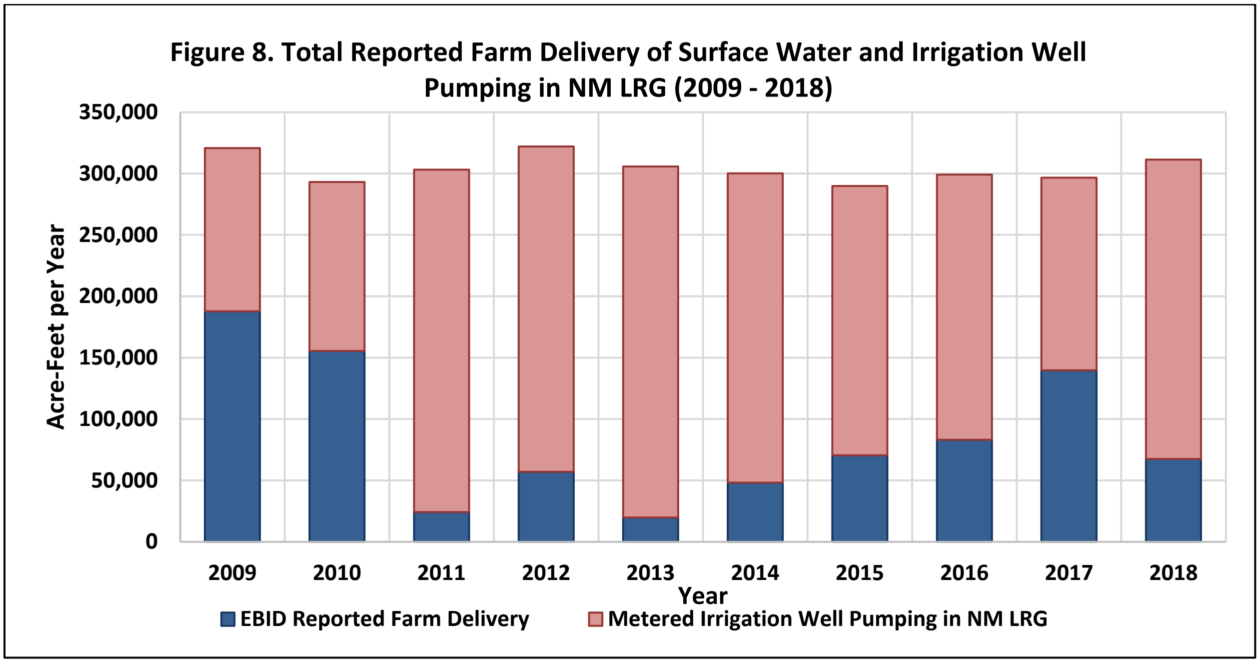


Figure 9. New Mexico LRG: Total Farm Delivery Project Water and Irrigation Well Pumping (IWP) Values from Spronk (2019)

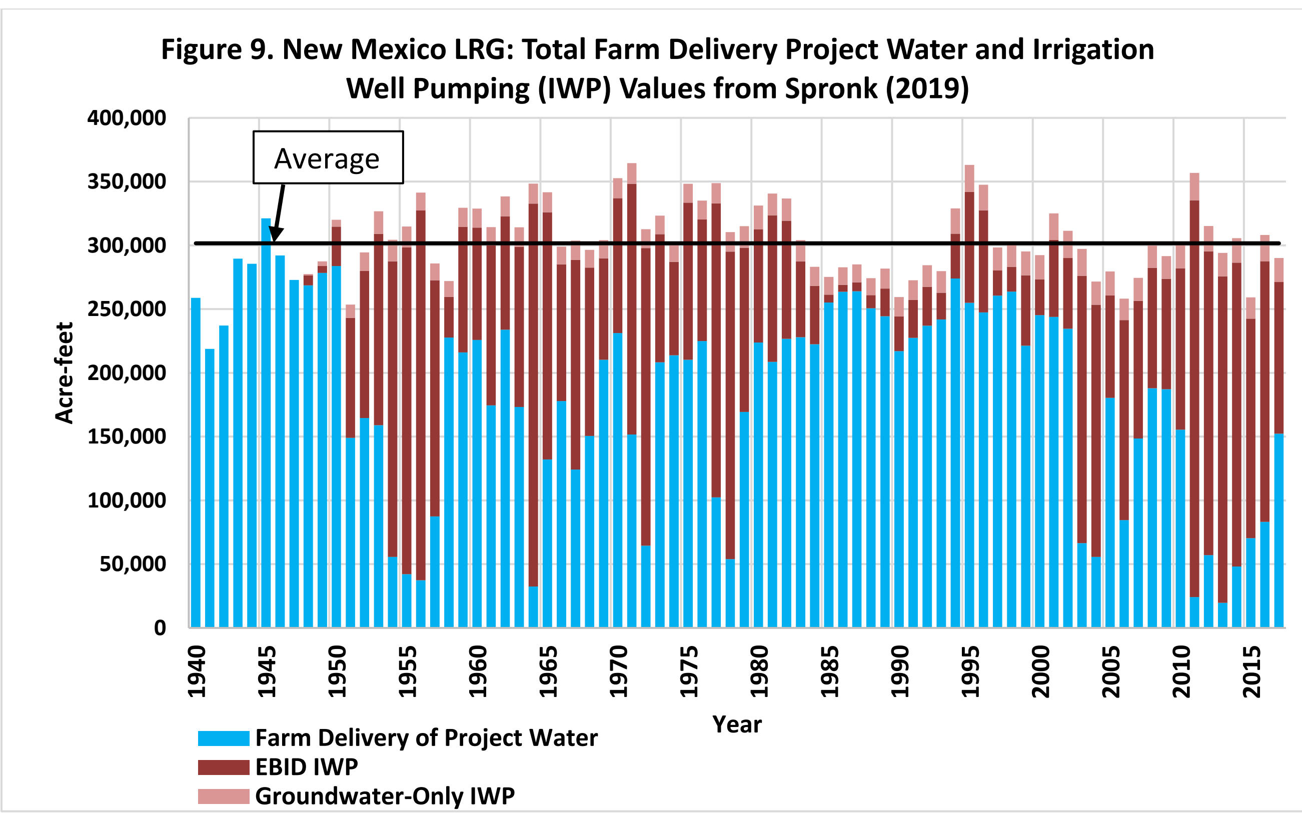
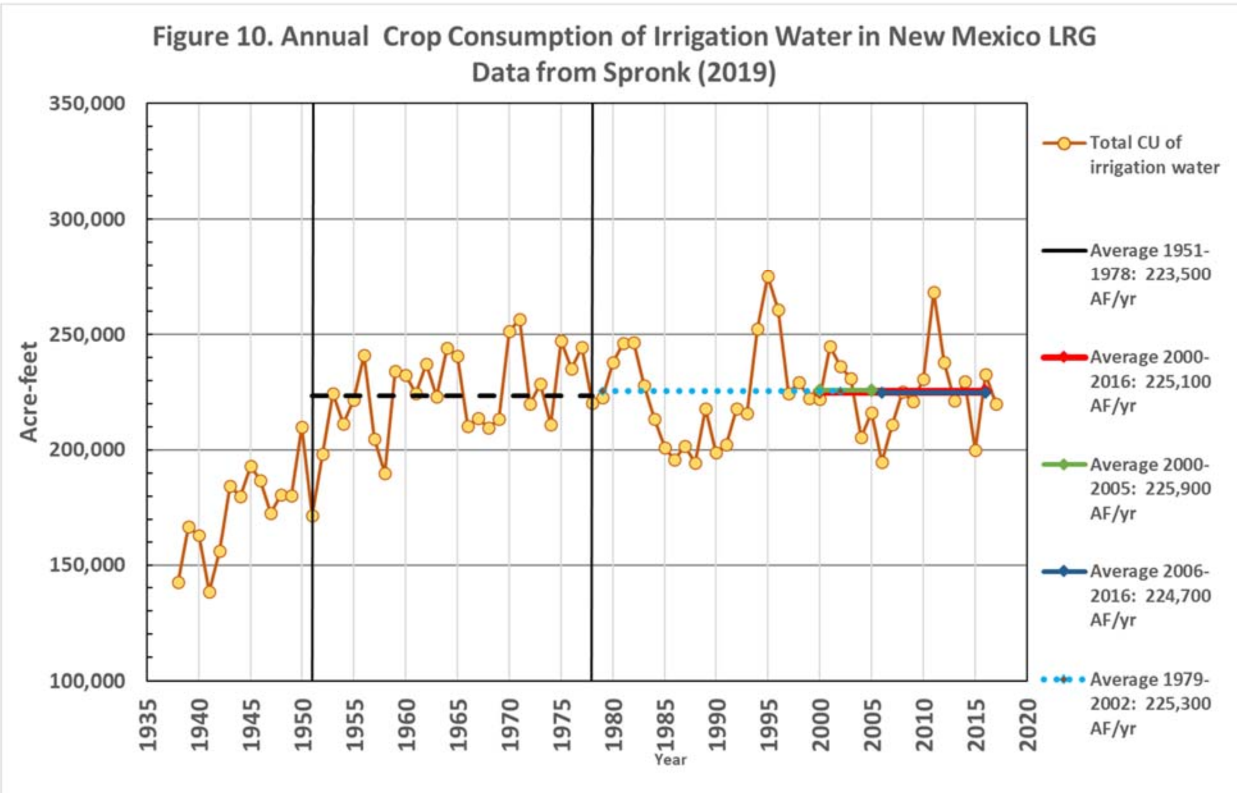


US_MSJ_00000965

In Figure 10 I plot the total crop consumption of irrigation water calculated by the New Mexico experts, and summarized in Spronk (2019). This plot shows a relatively stable level of irrigation consumptive use in New Mexico over many years, and also shows how the "average" does not vary perceptibly based upon the range of years selected to average. Unlike irrigation well pumping, the level of agricultural depletions has remained relatively stable, and the average value obtained for different sub-periods does not differ by more than 2,000 acre-feet.

Figure 10. Annual Crop Consumption of Irrigation Water in New Mexico LRG Spronk (2019)



My conclusion, based on these data, is that total New Mexico irrigation demand is currently stable. New Mexico's best estimates (summarized in the Canal and Farm Budget spreadsheets produced by Spronk (2019) indicates that this demand has not increased over the demand occurring during the D2 period. While irrigation pumping does now occur during Project full-supply years, the estimated pumping amount did not systematically increase between 1979 (the end of the D2 period) and 2002 (the last full-supply years of a 24 year stretch of consecutive full-supply years). Variation in New Mexico irrigation pumping is driven by variation in EBID's Project water supply, and therefore recent levels of pumping in New Mexico are higher than they otherwise would have been because the 2008 Operating Agreement has reduced EBID's share of Project Supply. New Mexico's best estimates of the total consumption of irrigation water in New Mexico also indicates that the consumption of irrigation water in New Mexico has not increased compared with the D2 period.

These data do not support the contentions of Drs. Ferguson, King or Blair that the large reallocation of Project Supply effected by D3 Allocation is a necessary or appropriate response to increased levels of depletion or groundwater pumping in New Mexico. Deposition testimony by Drs. King and Ferguson show that the 2008 Operating Agreement itself was a compromise reached to in order to achieve settlement of a legal dispute; the 2008 Operating Agreement was a product of consensus, and was not founded in technical analysis.

R2. The United States Experts Claim that the D3 Method Allocation Adjustments are not Strictly Negative for EBID.

Dr. Ferguson states that the D3 Method *"increases EBID's annual diversion allocation compared with the "D1/D2 Method" in years when actual current-year Project delivery performance exceeds historical delivery performance as represented by the D2 Curve."* (Ferguson, page 4 paragraph 1 and page 10 first full paragraph)

Dr. Barroll Reply: Project delivery performance, as described by Dr. Ferguson, is a measure of the amount of water that can be delivered to District canal headings for a given release of water from Caballo Reservoir. In **theory** the D3 Method can increase EBID's diversion allocation compared with the "D1/D2 Method" when current-year Project delivery performance exceeds historical delivery performance as represented by the D2 Curve. Under the 2008 OA, if Project performance defined by the Diversion Ratio exceeds D2 Curve levels, EBID is awarded part of the surplus, while when Project performance falls short of D2 Curve levels, EBID must bear the entire shortfall.

In **practice** this has not actually benefitted EBID and is not likely to ever do so. Since 2006, Project performance defined by the Diversion Ratio has only exceeded D2 Curve levels one (1) time, in the year 2011. In that year, EBID's allocation was calculated by adding 12,325 AF (57% of the 21,708 AF Supply "surplus") to EBID's "D2 Current-Year Diversion Allocation." However under the 2008 OA, EBID's "D2 Current Year Diversion Allocation" is calculated using the "Usable Water Available for Current Year Allocation," which can be much smaller than the total amount of Usable Water in storage[11] because the Carryover Obligation,[12] has been subtracted. In the end of 2010, EPCWID's carryover account was 224,347 acre-feet, and this large amount of Carryover had a significant impact on allocation as

[11] Which was the historic starting point for calculation.

[12] Carryover Obligation is another creature of the 2008 Operating Agreement as fully explained in Barroll (2019) at Appendix D, page D21-D22. Each year, a District can now carry unused Allocation over into the next. Allocation is determined and measured at canal headings. In order to determine how much reservoir release will be required to deliver that amount of Carryover to canal headings in the following year, the total amount of Carryover is divided by the new Diversion Ratio to obtain the Carryover Obligation. Since the Diversion Ratios occurring since 2008 have mostly been less than 1.0, this means that the Carryover Obligation is greater than the amount of Allocation carried over. Under the order of operations in the Allocation spreadsheet, this Carryover Obligation is subtracted off from the Usable Water before determining Current-Year Allocations.

described in Barroll (2019), Appendix D, Section 2.4, and in this report, Section R6. In essence, approximately 60,000 of off-season inflows to Elephant Butte had to be dedicated to making up for the paper part of EPCWID's Carryover Account and Carryover Obligation, reducing the amount of reservoir water available for "Current-Year Allocation" by that same amount.

If the historic 57:43 allocation had been applied to the entire amount of Project water available in 2011 ("Total Usable Water Available for Release" in the allocation spreadsheet) EBID would have been allocated far more water than they were allocated under the D3 Method, even including the additional 12,325 AF. I estimate that if the total Usable Water available in 2011 (426,821 AF) had been allocated according to the historic 57:43 split between EBID and EPCWID, EBID would have been allocated approximately 195,000 AF[13], as compared with the 77,000 AF that EBID was actually allocated under the D3 method in that year. I also estimate that if the D3 Method had been applied to the total Usable Water, with no reduction for Carryover, EBID would have been allocated 148,000 AF, still much more than the amount EBID was allocated (77,000 AF) using the D3 Method with Carryover.

The predictable effect of this reduced allocation on EBID was an increased need for groundwater pumping. In 2011 metered groundwater pumping in New Mexico was 303,000 AF. If EBID's allocation had been 195,000 AF, using Figure 7 I estimate that irrigation pumping in New Mexico would have been 209,000 AF, approximately 2/3 (two-thirds) of the actual amount.

Furthermore, the extra water EBID received in 2011 as a result of Project performance exceeding D2 levels was only 57% of the amount of extra supply associated with this performance level.[14] This is in contrast to what happens when Project performance **falls short** of D2 levels. When Project performance is below D2 levels, EBID's allocation under the D3 method is reduced by the **entire** supply deficit. For example, in the full-supply year of 2008, D3 allocation reduced EBID's allocation by 170,000 AF, the full amount of the negative departure from the D2 Curve; in full-supply year 2017, D3 allocation reduced EBID's allocation by 227,000 AF.

The largest allocation changes associated with the D3 method occur in these full-supply and near full-supply years. In such years it would be necessary for the Diversion Ratio to exceed 1.2 in order for EBID to obtain the touted benefits of a D3-method allocation higher than the D2 allocation. This is extremely unlikely to ever happen. One of the factors that makes this prospect so unlikely is the change in accounting that has occurred since the D2 period (1951 – 1978) by which significant components of water diverted by EPCWID which formed part of the D2 data set are no longer counted as part of its

---

[13] I calculate Project Supply for 2011 as total Usable Water (427,000 AF), adjusted by the Diversion Ratio (0.87). Then I subtract Mexico's share (calculated as 26,000 AF using the D2 curve) and split the remainder 57:43. Using this calculation, I find that New Mexico's 57% share would be 0.57 × [427,000 AF × 0.87 – 26,000 AF] = 195,000 AF.

[14] When Project performance exceeds D2 levels, EBID's Diversion Ratio allocation is greater than its D2 allocation. Under these circumstances, EBID is awarded its D2 Allocation plus either 57% of the difference between the D2 allocation and the Diversion Ratio allocation if Current Usable Water is below 600,000 AF, or 100% of the difference between the D2 allocation and the Diversion Ratio Allocation if Current Usable Water exceeds 600,000 AF. This is in opposition to what happens when the Project Performance is below D2 levels, in which case EBID is always awarded its Diversion Ratio allocation, and thus is always docked for 100% of the difference between the D2 allocation and the Diversion Ratio allocation.

charged diversion, and therefore are not part of the Diversion Ratio calculation. These components include City of El Paso effluent in the El Paso Valley, off-season diversions[15] and El Paso Valley drain flow.

For a concrete example, I include my analysis of 1969 Project diversions,[16] which are a part of the D2 data set. This analysis is also set forth in Barroll (2019), pages 57 through 60. In Table 2 I show the results of my analysis of 1969 diversion. The column labeled “WDR Values” shows the diversions obtained from those Reclamation records from 1969, and Mexican Diversion and Caballo release data. The total of these diversions, 802,000 AF, is part of the D2 data set. When this value is divided by the Caballo release of 667,700 AF a contemporaneous “Diversion Ratio” of 1.2 is calculated.

The next column in Table 2 breaks down those WDR diversions into some of their component parts: (a) the amount of the WDR diversion occurring outside of the Project release season, (b) the amount consisting of El Paso Valley drain flows, and (c) the estimated amount of accounted diversion that would be reduced by other accounting credits, if current accounting methods had been used in 1969[17].

The next column (Estimated Charged Diversions using Post-1979 Accounting) takes the 1969 WDR data and subtracts off the diversion components that would not have been included under current accounting protocols ((a) off-season diversions, (b) El Paso Valley drain flows, and (c) the net effect of credits). The resulting “1969 Charged Diversion”, estimated using current accounting methods is only 727,708 AF, a reduction of 74,292 AF from the Total WDR Diversion. The Diversion Ratio that is calculated using the “1969 Charged Diversion” is [727,708/667,669] which equals 1.09. **Therefore even the diversion data from 1969, a year from the D2 period which actually falls directly on the D2 Curve, falls well below the D2 Curve when employing current accounting methods**. This effect of changes in accounting makes it extremely unlikely that the Diversion Ratio calculated for any future year using current accounting procedures will ever exceed the “D2 delivery performance predicted by the D2 Curve” and thus the benefit to EBID claimed by Dr. Ferguson is a chimera.

---

[15] Off-season diversions are diversions occurring at times when there are no releases being made from Caballo Reservoir, typically because it is outside of irrigation season. Historically, up to about 40,000 AF of off-season diversions were made during the D2 period (1951 – 1978), largely by EPCWID, (Barroll, 2019 Appendix E, Table E.7). These diversions were included in the D2 data set that is now used to determine EPCWID’s allocation. Such off-season diversions are no longer charged or accounted as Project water.

[16] I chose 1969 for analysis for two reasons: 1) the 1969 release and diversion data point lies on the D2 curve, 2) there is a recent year (2008) with almost exactly the same Reservoir release that can be readily compared with 1969. Analysis of other years during the D2 period provided similar results.

[17] The effect of other accounting credits is estimated by analysis of data from 2008, a year of approximately the same release from Caballo, in which current accounting methods have been applied.

Table 2. Analysis of 1969 WDR Diversions

Table 2. (Modified Table 7.1 from Barroll (2019) Components reordered, Calculated Diversion Ratio added). Analysis of 1969 WDR Diversions				
	WDR Values *	WDR Values broken down by Component	Estimated Charged Diversion using Post-1979 Accounting	Difference in Total Accounted Diversions: WDRs vs. Post-1979 Accounting
EBID Diversion	421,000	404,000	404,000	17,000
EPCWID Diversion	321,000	263,708	263,708	57,292
(a) Off-Season Diversions		38,000		
(b) EPV Drain to Canal		2,292		
(c) Estimated Post-1979 Credits EBID **		17,000		
(c) Estimated Post-1979 Credits EP#1**		17,000		
Mexico	60,000	60,000	60,000	
Total Accounted Diversions	802,000	802,000	727,708	74,292
Caballo Release	667,700	667,700	667,700	
Diversion Ratio	1.20		1.09	
* WDR Values adjusted so that Mesilla Dam Diversions are split between the Districts Pro-Rata				
** Total Estimated Post-1979 Credits calculated as the difference between total diversions and charged diversion in 2008, a year of similar water supply to 1969. This total was split 50:50 between EBID and EPCWID				

Next, Table 3 shows the effect such a difference in Diversion Ratio would have on EBID's allocation under the D3 method. A Diversion Ratio of 1.2 would result in a D3 allocation to EBID of 480,000 AF, while the Diversion Ratio of 1.09 (calculated using "1969 Charged Diversion") would result in a D3 allocation of only 396,000 AF. In this example, this difference in accounting method to calculate the Diversion Ratio results in 84,000 AF less water to EBID than calculating a Diversion Ratio from the same type of Water Distribution Report data and accounting methods that were used to develop the D2 curve.

Table 3. Illustration of the Effect of Variation in the Diversion Ratio

Table 3. Illustration of the Effect of Variation in the Diversion Ratio Example			
Compare D3 Allocation with Diversion Ratio Calculated Using WDR Diversions, to D3 Allocation with Diversion Ratio Calculated Using Post-1978 Accounting			
(Values rounded to nearest 1000 AF)			
	D3 Allocation		**Difference**
Diversion Ratio (unitless)	1.20	1.09	0.11
Usable Water (AF)*	764,000	764,000	
Mexican Allocation (AF)	60,000	60,000	
EPCWID's Allocation (AF)	377,000	377,000	0
EBID's Allocation (AF)**	480,000	396,000	-84,000
* 1969 was a full-supply year (final allotment = 3.0 AF/A) and so I assume the amount of Usable Water available to the Project that year is at least 764,000 AF.			
** Calculation: EBID's Allocation = (Usable Water x Diversion Ratio) – Mexican Allocation – EPCWID Allocation]			

R3. TEXAS AND THE UNITED STATES CLAIM EPCWID'S SHARE OF WATER UNDER THE D3 METHOD APPROXIMATES ITS SHARE UNDER D2 ALLOCATION.

Dr. Blair contends (in his 10th Opinion, on page 8, last sentence) that the D3 Method is "*a reasoned attempt to return EPCWID's share of the Project Water supply to the amounts based upon the 1951-1978 conditions represented by the D2 Curve.*"
Dr. Ferguson states in his opinion in the middle of page 6 "*The annual allocation to EPCWID may be greater under the 'D3 Method' than under the 'D1/D2 Method' only in years when the Usable Water available for current-year allocation is between 763,842 acre-feet and 790,000 acre-feet. In all other years, the annual allocation to EPCWID under the 'D3 Method' is the same or less than under the 'D1/D2 Method.' During multi-year droughts, the annual allocation to EPCWID is less under the 'D3 Method' due to the Drought Correction Factor in the OA.*"
Also Dr. King in his 3rd opinion, page 7, states "*Under the D3 Allocation, deliveries to EPCWID and Mexico are consistent with historical conditions*."

Dr. Barroll Reply: The 2008 OA allocation procedures do not "return EPCWID's share of Project Water supply to the amounts based on the 1951 – 1978 conditions represented by the D2 Curve," nor do these three US experts provide any data supporting their conclusory contentions. Rather, the 2008 OA results in EPCWID getting a much larger share and larger amount of water under similar conditions than at any time during the D2 period.

While EPCWID's D3 allocation amount is based on the D2 Curve, changes in Project Accounting since the D2 period allows EPCWID to divert and use more Project Water than EPCWID received during the D2 period. The D2 Curve includes off-season diversions, and the diversion of El Paso Valley drain flow and effluent (items a, b, and c in Table 2). See Barroll (2019), section 7. EPCWID's D2 allocation is based on its past diversion and use of that water. Current Project accounting does not charge EPCWID for diversion or use of these sources of water (i.e. off-season diversions, and El Paso Valley drain flows and effluent), and so EPCWID is now entitled to divert its D2 share **plus also use** any off-season flows, El Paso Valley drain flows, and municipal effluent **free of charge.**

The addition of the Multi-Year-Drought Correction Factor to the Operations Manual in 2012 was a welcome admission by the Districts and Reclamation that the original 2008 OA was too extreme in its reallocation of Project water away from EBID during severe drought conditions. Even with that change, however, EBID's Total Allocation in these drought years is less than 57% of the water allocated to the Districts. Furthermore, this one change does not alter the much larger reallocation of Project water away from EBID during full-supply years.

Furthermore, in full-supply years, EPCWID's Current-Year Allocation (excluding Carryover) has been as high as 405,000 AF (Barroll (2019) Table A.10). This is a significant increase from EPCWID's full-supply allocation prior to 2006 of 376, 862 AF. This comparison does not even take include the effect of Carryover, which has increased EPCWID's Total Allocation to over 500,000 AF in some years.

As a result of this, and the large reductions in EBID's allocations, **EPCWID now gets a far larger share of Project water than ever before.**

R4. The United States Arbitrarily Minimizes the Effects of Texas Groundwater Pumping in the Mesilla Basin, and Equates the Reallocation of the Operating Agreement with New Mexico Pumping Effects Based on Unproven Assumptions.

Drs. Ferguson and King contend that groundwater pumping in the Rincon Basin by New Mexico and in the Mesilla Basin by both New Mexico and Texas impact the surface water supply, and can impact the operations of the Rio Grande Project. Dr. Ferguson suggests that Texas pumping in the Mesilla Basin is relatively small compared to the amount pumped by New Mexico. Furthermore, Dr. Ferguson suggests that the effects of Texas Mesilla Basin pumping on the Project do not need to be considered in Project allocation because Texas pumping in the Mesilla Basin has not increased substantially (<10%) since the D2 period (1951 – 1978) (see Ferguson pages 3 and 11).

<u>Dr. Barroll Reply:</u> I agree that groundwater pumping in the Mesilla Basin by both New Mexico and Texas impacts the surface water supply and can impact the operations of the Rio Grande Project by depleting the flows of surface water features. I also agree with Dr. Ferguson that the total amount of Texas groundwater pumping in the Mesilla basin is less than the total amount of New Mexico groundwater pumping in the Rincon and Mesilla Basins. However, because little meter data is available from Texas, the exact relationship between the pumping amounts can only be estimated. Texas irrigation well pumping in the Mesilla Basin can be estimated based on irrigation demand calculations for the Texas Mesilla lands. There is no recent data on commercial or industrial pumping in the Texas Mesilla.

Groundwater pumping can impact the flows in streams or other surface water features (such as drains and canals) by lowering the groundwater table in the vicinity of that surface water feature. The effect is either to intercept groundwater that would otherwise have discharged into that stream, or to increase the amount of seepage from that stream into groundwater. These negative impacts can be offset by the effects of return flow associated with the groundwater pumping such as effluent from a municipal use or deep percolation associated with use of wells for irrigation. The net impact of all these factors is the stream depletion associated with the groundwater pumping.

In theory, if the top of the groundwater surface (the water table) is sufficiently deep below the base of the stream, the rate of seepage from that stream achieves a maximum amount and will no longer increase as a result of additional pumping. When additional groundwater pumping has no additional effect on stream flows, that is referred to as hydrologic disconnection; that is to say, the stream is disconnected from the water table or aquifer. This has happened in the El Paso Valley, and occurs intermittently within the Mesilla Basin. Where stream disconnection occurs, the impacts of groundwater pumping can be displaced onto other streams or other, connected parts of the same stream. In addition, the impacts of groundwater pumping on disconnected parts of stream system can be delayed, depleting stream flows long after pumping has ceased.

In this situation, if adjustment to the Project Allocation is justified by reference to increases in pumping or increases in stream depletion caused by pumping, these adjustments should be based on technical analysis of the actual amounts of increase in pumping or stream depletion. At present, EBID's allocation is adjusted downward by the entire negative departure from the D2 Curve, resulting in decreases in EBID's allocation as great as 227,000 AF (in 2017[18]). The magnitude of this reduction is not supported by any comparable estimates of increases in New Mexico groundwater pumping or increases in depletion within New Mexico**.** For more details on comparison of estimated pumping and depletions between the D2 period and recent years, see section R1 above. None of the U.S. experts has provided any technical evidence quantifying the increase in groundwater pumping or depletions in New Mexico that support this massive downward adjustment of EBID's allocation. Nor can Dr. Ferguson's assertion that Texas Mesilla pumping has increased less than 10% be the basis for completely discounting any impacts of Texas Mesilla pumping. There is no scientific or technical basis to use a 10% increase in pumping, or a 15% increase, or a 5% increase as the standard for evaluation of impacts.

[18] This value is obtained by subtracting EBID's allocation in 2017, a full supply year, from the allocation EBID was given in full-supply years prior to 2006. EBID's allocation in 2017 was 267,523 AF, while before 2006 EBID's full-supply allocation was 494,979 AF. The difference between these two values is 227,456 AF.

R5. WITHOUT FULL EXPLANATION OR TECHNICAL ANALYSIS, THE U.S. MINIMIZES THE EFFECTS OF GROUNDWATER PUMPING IN THE HUECO BOLSON

Dr. Ferguson indicates that groundwater pumping in the Hueco Bolson has no impact on Project operations. In Dr. Ferguson's first opinion (under heading A, on page 3) he cites modeling results by New Mexico experts and "*the construction of the American Canal Extension ("ACE"), which eliminates the effects of groundwater/surface-water interactions on Project deliveries in the El Paso Valley.*" Dr. King (page 10) also appears skeptical that pumping in the Hueco can impact Project operations.

Dr. Barroll Reply: Current pumping in the Hueco Bolson aquifer probably has little ***additional*** impact on current Project Supply. However, the United States ignores why this is so. Groundwater pumping by Texas and Mexico in the Hueco Bolson has caused over 100 feet of drawdown in a large area[19] and largely disconnected the Hueco Bolson aquifer from the surface water system in the upper El Paso Valley. While current pumping can no longer increase stream depletions in a disconnected stream, that does not change the fact that earlier groundwater pumping increased stream losses until these losses reach their maximum rate and actually disconnected the Rio Grande from its aquifer so that it no longer acts as an integrated stream system.

Historical pumping in the Hueco Bolson reduced Project Supply in the El Paso Valley through:

a. depleting drain flows that had been part of Project Supply, and
b. increasing seepage losses from the canals, laterals and the Rio Grande.

Thus, pumping by Texas in the Hueco Bolson depleted the part of Project Supply that had historically originated in the Hueco Bolson, that had been historically relied upon for Project delivery. Depletions to EPCWID surface flows upstream of Project delivery points force Reclamation to release more water in order to meet orders for Project water. These increased releases reduce the reservoir supply available for subsequent allocation to the Districts, including EBID. Texas pumping reduced Project efficiency and performance in the El Paso Valley below the levels obtaining at the time of the signing of the Rio Grande Compact and conditions obtaining during the D1/D2 period (1951-1978). ***In short, Texas disconnected its aquifer through over-pumping and thereby substantially altered the sources of Project Supply, increasing its need for releases from the Reservoir, and now requires New Mexico to pay for Texas's own behavior.***

Sources of Project Supply arising in the Hueco include El Paso Valley drain flows generated above Fabens. The 1938 Rio Grande Joint Investigation noted that 57% of the water diverted at Fabens (Tornillo Canal) consisted of drain flow, while on 35% of the water diverted upstream at Franklin consisted of drain flow. The difference between those two percentages represent drain flows generated within the El Paso Valley itself, between Franklin and Fabens, that were diverted into Tornillo Canal. Diversion and use of this El Paso Valley drain flow by the Project continued after the Compact was signed, as reported in Reclamation drainage and diversion records as "Drain to Canal" diversions (Barroll (2019), Appendix C). During the D1/D2 period (1951 – 1978), up to 30,000 AF/yr of water was diverted

[19] See the dramatic interactive representation contained in Expert Report of Charles P. Spalding and Daniel J. Morrissey, McDonald Morrissey Associates, LLC, October 31, 2019, hereinafter MMA (2019), at Appendix Q.

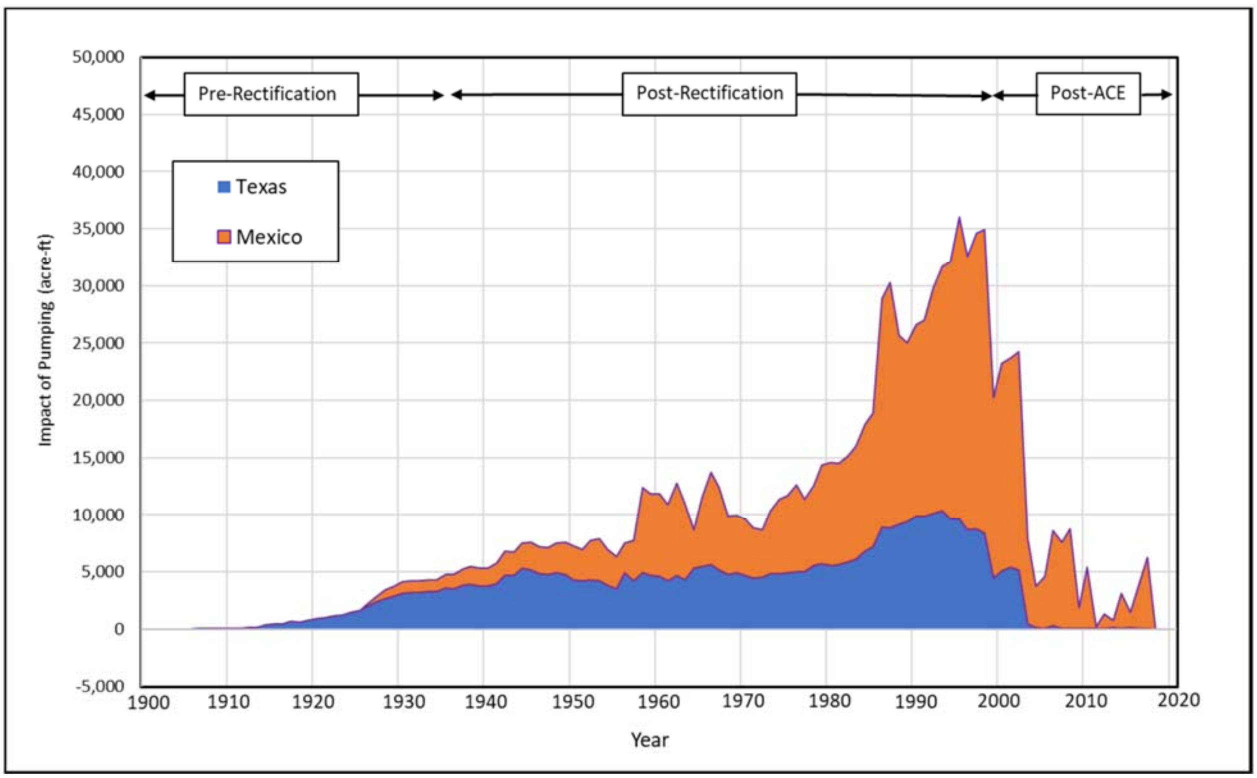
from the River Drain into the Riverside Canal Extension for delivery to the Tornillo Canal Heading in EPWCID.

A description of EPCWID's historical use of El Paso Valley drain flows can be found in Kirby (1994). Kirby was an engineer with the Project starting in 1949, and he served as Project Superintendent from 1966 until his retirement in 1980. As a consultant to EBID in 1994, Kirby wrote:

> *It is my remembrance that this admission [of the Tornillo Division into the Project] was only agreed to by EBID provided that the Tornillo Division would divert and use, as part of their water supply, the drain waters that accumulated into a collection channel at Fabens. There was a pumping station at this location later changed to a gravity diversion that moved water into the Tornillo Canal.* (Emphasis in the original)

The effects of Hueco pumping on the surface water system in the El Paso Valley is simulated by New Mexico's Hueco Model (MMA (2019), Figure 9.2 and 9.3), which shows increasing seepage losses in the reach of the Rio Grande between American Dam and Riverside from about 10,000 AF/yr in 1938 (when the Rio Grande was rectified) to about 40,000 AF/yr in the years before the American Canal Extension bypassed this reach of the river in 1998. Further analysis by MMA (2019) (MMA Figure 9.5, reproduced here as Figure 11) indicate that between 1940 and 1998 impacts to the Rio Grande caused by Texas and Mexico pumping increased by almost 30,000 AF/yr, and between 1980 and 1998 impacts to the Rio Grande caused by Texas and Mexico pumping increased by almost 20,000 AF/yr. That is, the El Paso Valley pumping was drawing down the groundwater table further and further such that surface water from the river – Project Supply – was seeping into the riverbed at a greater and greater rate.

Figure 11. (MMA (2019) Figure 9.5) Graph showing impact of pumping by Texas and Mexico for the Rio Grande from American Dam to the Riverside Diversion for the non-reoperated runs, 1903 to 2017



This effect of this Hueco pumping increasing the seepage from the Rio Grande in the El Paso Valley is described in Blair (2000),[20] who cites a USGS study indicating the "withdrawals from the Hueco for El Paso and Juarez … may have caused seepage to increase from 15,000 ac-ft/year in 1968 to 39,000 ac-ft/year in 1992." That is: Hueco pumping increased seepage loss from the Rio Grande by 24,000 AF per year from 1968 to 1991, thereby increasing the amount of water lost to the Project. Dr. Blair also cites a 1975 joint USGS/Texas Water Development Board study by Meyer suggesting that as a result of groundwater pumping "*the Rio Grande between American and Riverside dams changed from a gaining reach to a losing reach between 1936 and 1948.*" Modeling by New Mexico experts MMA (2019) does not support the conclusion that the Rio Grande actually gained water (i.e. the flow in that stretch of the river was augmented by inflow from groundwater) in the reach above Riverside Dam during the 20th century, but it does support the conclusion that losses from that reach increased due to groundwater pumping in the Hueco Bolson by Texas and Mexico.

The effect of Hueco groundwater pumping was to reduce the Project delivery efficiency in the El Paso Valley, and thereby reducing the total Project Supply. Since 1938, there have been changes in the El Paso Valley that act to partially mitigate these negative effects. The discharge of El Paso municipal effluent into EPCWID's conveyances largely offsets the effect of El Paso municipal pumping on EPCWID itself. However, this effluent is not considered Project water,[21] and use of the effluent by EPCWID is not charged against its allocation. Another mitigating change was the construction of the American Canal Extension (ACE) which allows EPCWID to bypass the bed of the Rio Grande when delivering water to the Riverside heading, avoiding the Rio Grande seepage losses caused by groundwater pumping in Texas and Mexico. However, EPCWID is then awarded a credit (the ACE Credit) for this bypass operation, and so gets a credit for resolving a problem that Texas helped create. In effect, municipal effluent and the ACE help to mitigate the effects of Hueco pumping on EPCWID, but the failure to treat this effluent as Project water, and the imposition of ACE Credit, act to the detriment of EBID.

The problems caused by the ACE Credit will be discussed in more detail in Section R8.

R6. THE UNITED STATES IGNORES THE REAL EFFECT OF CARRYOVER UNDER THE 2008 OA

Dr. Ferguson argues that Project Allocations, and thus Carryover Allocations, do not represent water in Project Storage, and therefore there is no need to reduce Carryover to reflect evaporation losses (Ferguson (2019), second half of page 14).

[20] Blair, A. W. 2000, page 8 of 18. *Salvage of Water in El Paso County Water Improvement District No. 1 Canal System.* Prepared for District No. 1, Draft Report, January 26, 2000. Al Blair is the long-time consulting engineer to both EPCWID and Hudspeth County Conservation and Reclamation District No. 1 ("HCCRD), and is another non-retained expert proffered by the United States.
[21] See Barroll (2019), at page 49-50 and D-25, D-26, and Section R7 of this report for a complete discussion of this anomaly.

<u>Dr. Barroll Reply:</u> Dr. Ferguson misses the points I fully explained in Barroll (2019) at pages D-21 through D-23. While Project allocation is not strictly equivalent to water in Project storage, Project allocations are ***supplied*** by Project storage. Part of the problem in the Project operations in 2011 was that unused allocation under the 2008 OA is now allowed to be "carried over" without reference to the water in Project Storage, and without reference to the physical processes such as evaporation that impact storage. As a result, in the 2010-2011 time frame, the amount of Carryover allocation (that is, allocation calculations on paper) exceeded the amount of Usable Water in storage (that is, actual wet water), and over 60,000 AF of the inflows during that very dry winter went directly into "liquifying" the paper water in the Carryover accounts, 90% of which belonged to EPWCID. As a result, there was 60,000 AF less water available for that current-year allocation, and EBID's allocation suffered proportionally. The data supporting this conclusion is shown in Table 4, reproduced from Appendix D of Barroll 2019.

Table 4. 2010-2011 Example of New Inflow to Reservoir Needed to Fulfill Existing Carryover Accounts and Obligation. Reproduced from Barroll, 2019, Table D.4.

Table D.4. 2010 – 2011 Example of New Inflow to Reservoir Needed to Fulfill Existing Carryover Accounts and Obligation

2010 - 2011 Example of when Carryover Accounts Required Additional Inflows			
		Storage, Carryover and Credit Conditions as of October 15 2010	Storage, Carryover and Credit Conditions as of January 1, 2011
Total Water in Reservoir Storage	(AF)	386,735	497,789
CO Compact Credit	(AF)	800	2,700
NM Compact Credit	(AF)	100,500	164,700
San Juan Chama Water	(AF)	60,796	64,250
Usable Water In Storage	(AF)	224,639	266,139
EBID 2010 Unused Allocation (Carryover from 2010 to 2011)	(AF)	20,014	
EBID 2010 Unused Allocation (Carryover from 2010 to 2011)	(AF)	224,348	
Total Carryover (Carryover from 2010 to 2011)	(AF)	244,362	
Diversion Ratio	(unitless)	0.98	0.85
2011 Carryover Obligation (divide total Carryover by 2011 Diversion Ratio	(AF)		287,485
Inflows after October 15 required to fulfill Carryover Obligation			62,846

Furthermore, EPCWID's allocation in full-supply or near full-supply years exceeds EPCWID's Project demand by approximately 100,000 AF/yr. That is, in full supply years, EPCWID's current-year allocation including ACE credit has been approximately 400,000 AF. In these years, and other years in which EPCWID's total allocation has exceeded 400,000 AF, (2007 through 2010) the amount of Project EPWID has ordered, and had charged against its allocation has averaged 295,000 AF, approximately 100,000 AF less than it's full-supply allocation.[22]

It is true that eventually EPCWID may make use of the allocation carried over on paper in subsequent low-supply years. However, historically the Project was operated on an annual basis, as was the case when the Compact was negotiated and signed, and the water in Project storage associated with any unordered allocation or allotment "returned to the pool" and was available for allocation proportionally to both Districts the following year. This changed in 2006, when EPCWID convinced Reclamation to institute Carryover allocation. Now any unused allocation is carried over for EPCWID into the following year, and that amount of water plus the additional water needed to deliver it,[23] is subtracted from the total Usable Water early in the allocation process, when calculating the amount of "Total Usable Water Available for Current Year Allocation". The amount of water available for current-year allocation consists of the Usable reservoir water that remains **after** this Carryover Obligation has been subtracted.

The Carryover Obligation is calculated as the total Carryover divided by the Diversion Ratio. This introduces its own effect. Typically, Carryover is accumulated in high-supply years, when the Diversion Ratio tends to relatively high (0.9 - 1.0). Carryover is then used in lower supply years, when the Diversion Ratio is typically much lower (0.6 – 0.8). Dividing the total Carryover by a smaller Diversion Ratio leads to an even higher Carryover Obligation. Thus, a large amount of Carryover requires an even larger amount of Carryover Obligation, which is subtracted out before any calculation of Current-Year Allocation begins. Another way of looking at this is that delivery of an allocation amount in a good-supply year requires release of reservoir water that is approximately equal to that allocation amount. When the same amount of allocation is Carried over to a low-supply year, a significantly greater amount of reservoir release is going to be required to deliver it. That extra release is taken out of the water available to the other District.

No adjustment is made to Carryover accounts for evaporation, which further aggravates this problem.[1] A rough estimate of the amount of evaporation associated with EPCWID's Carryover in 2010 can be obtained by looking at the Rio Grande Compact Commission (RGCC) determination of Compact Credit evaporation during that year (in Compact Accounting, evaporation is applied pro-rata to Compact Credits, San Juan Chama water, and Usable water pools). According to the 2010 Report of the RGCC,[24] New Mexico had 180,500 AF of Compact Credit in Elephant Butte that year, and the RGCC determined that 20,800 AF evaporation were associated with that Credit. EPCWID started 2010 with a Carryover balance of 232,914 AF, and ended 2010 with 224,347 AF, effectively maintaining a Carryover balance of 224,347 AF throughout the entire year. Presumably, the evaporation associated with that amount of water would have exceeded the 20,800 AF associated with 180,500 AF of Compact Credit water.

Because no adjustment is made to reduce the Carryover obligation for the effects of evaporation, or the effects of "paper water" allocation, of the amount of water available for current year allocation is

---

[22] The data used to make this calculation can be found in Barroll (2019) Appendix A, Table A.14.
[23] The "water needed to deliver" the Carryover depends on the Project Performance in the following year, and is calculated by dividing the amount carried over by the Diversion Ratio.
[24] RGCC 2010 Annual Report, Records of Releases and Deliveries, page 5.

further reduced. This reduction negatively impacts EBID more than EPCWID because EBID is not able to take advantage of Carryover to the extent that EPCWID can and does.[25]

R7. Texas Employs Technicalities to Avoid Being Charged for their Diversion and Use of the Municipal Effluent Component of Project Supply

Dr. Ferguson (last full paragraph of Page 9) and Dr. Blair (Opinion # 11, page 9) state that EPCWID is not charged for its diversion and use of treated municipal effluent, including effluent that has its origin in the diversion and use of Project Supply, because that effluent does not meet the definition of Project Water in Section 1.6 of the 2008 OA; that is, because that water does not *"reach the bed of the Rio Grande."*

Dr. Barroll Reply: Nothing in the opinions by Drs. Ferguson or Blair changes my opinion that the Project should charge EPCWID for the diversion and use of all municipal effluent by EPCWID and its members. The restrictive interpretation of Project Water -- and thus Compact water – applied by Texas to El Paso Valley effluent has resulted in a significant and one-sided change to Project accounting. The fact that the Project **currently does not** charge EPCWID for the diversion and use of that effluent constitutes an important change in Project accounting and is a direct cause of part of the current negative departure of Project performance from the D2 Curve.

At the present time, EPCWID is **not charged** for the diversion and use of an average of 24,000 AF/yr of treated effluent discharged from the City of El Paso wastewater treatment plants ("WWTPs") in the El Paso Valley during the Caballo release season.[26]

The El Paso Water Utility ("EPWU") obtains Project water for municipal use through EPCWID pursuant to several contracts between El Paso or EPWU, Reclamation, and EPCWID.[27] EPWU diverts its part of

[25] EBID makes less use of Carryover because EBID's allocation under the D3 Allocation Method is insufficient to meet its irrigation demand, even in years when the Project has a full supply. See Barroll 2019, page 71.

[26] The total annual discharge of El Paso Valley effluent into EPCWID conveyances is even greater, but current Project Accounting does not charge for the diversion and use of **any water** unless releases from Caballo are in progress or have recently ceased. Off-season diversions, however, were included in the D2 Curve, which is the standard against which current Project Performance is measured. The elimination of off-season diversion accounting itself constitutes part of the current discrepancy from D2 as demonstrated in Barroll 2019 Section 7 and Appendix E.

[27] All City of El Paso surface water treatment plants (WTPs), which divert water from the Project (and prepare it for human and other municipal use) and WWTPs (which treat municipal water after its use and discharge that effluent into the Project) are operated by El Paso Water Utility.

EPCWID's allocation during the Caballo release season at two water treatment plants: Robertson/Umbenhauer[28] and Jonathan Rogers.[29] These diversions are charged to EPCWID in Project Accounting. EPWU also pumps groundwater in the Hueco Bolson, but Project water constitutes the larger part of its supply in the El Paso Valley part its system, and therefore most of EPWU's El Paso Valley effluent originates as Project Supply. This effluent should most certainly be characterized as return flow from a Project beneficiary, and the diversion and use of this water should be charged to the Project beneficiaries as any other Project return flows would be.

Starting in 1923, and for many years, all of the City of El Paso's municipal effluent was discharged from the Haskell R. Street WWTP into the Rio Grande above Riverside. EPCWID's diversion of Haskell R. Street WWTP effluent water at the Riverside heading was consistently counted as part of Project Supply until 1999, when the newly built ACE intercepted Haskell R. Street WWTP effluent before it reached the "bed of the Rio Grande."

Additional WWTPs in the El Paso Valley (Socorro, superseded by Bustamante) came online starting in the late 1960's, and these plants discharged water into EPCWID's Riverside Canal. This use of the effluent from these WWTPs was apparently not ever charged against EPCWID's allocation.

EPWU operates another WWTP in the southernmost Mesilla Valley which treats and discharges effluent that largely originated as groundwater pumped by the Canutillo well field in Texas part of the Mesilla Valley. The diversion and use of this effluent **is** charged as Project Supply, and this effluent is used in Project Accounting as an offset against the stream depletion effects of Canutillo pumping. The treatment in Project Accounting of effluent from this WWTP is not at issue.

The amounts of treated effluent discharged from the El Paso Valley WWTPs into EPCWID conveyances, both during the Project release season, and for the entire calendar year, are tabulated in Table 5.

---

[28] Robertson/Umbenhauer Water Treatment Plant (aka the Canal Street Water Treatment Plant) was initially opened in 1943 and expanded in 1967. "The plant treats Rio Grande water to drinking water standards during the irrigation season (March-September) for distribution to customers. The plant can also blend and treat water pumped from wells during the non-irrigation season." https://www.epwater.org/cms/one.aspx?portalId=6843488&pageId=7421580.)

[29] Jonathan Rogers Water Treatment Plant became operational in 1993 and expanded in 2002. "This plant, along with the Robertson/Umbenhauer Water Treatment Plant operates during the seven-month irrigation season when Rio Grande Project water is available." https://www.epwater.org/cms/one.aspx?portalId=6843488&pageId=7421563.)

Table 5. Tabulation of EPWU Discharge of Treated Effluent into EPCWID Conveyances, 1999-2017

Table 5. El Paso Water Utilities (EPWU) Effluent Discharge in El Paso Valley

	Haskell Credit for Discharge to ACE during Release Season	Total Annual Haskell Discharge to ACE	Bustamante to Riverside during Release Season	Total Annual Bustamante Discharge to Riverside	Total EPWU Effluent in El Paso Valley During Release Season	Total EPWU Effluent in El Paso Valley During Calendar Year
1999	12,732	17,150	21,775	22,984	34,507	40,134

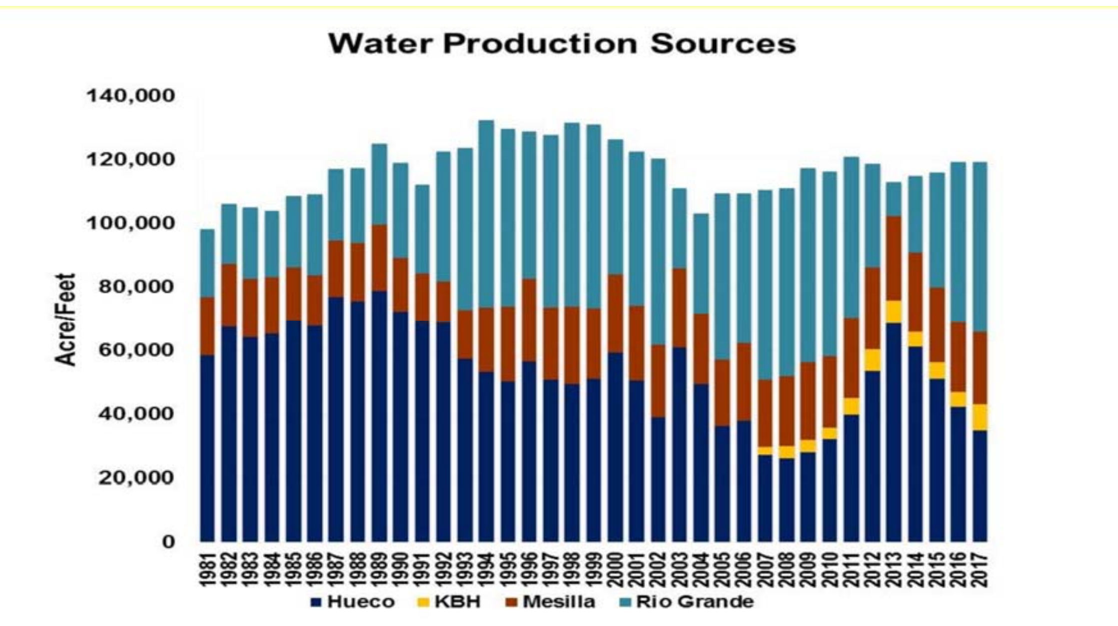
Figure 12 is a graphical summary of EPWU Water Production Sources that I downloaded from EPWU's website. The City of El Paso gets water from three main sources[30] as labeled in Figure 12[31]:
1) Mesilla: groundwater pumping from the Canutillo well field in the Mesilla Basin,
2) Hueco: groundwater pumping from the City's well field in the Hueco Bolson,
3) Rio Grande Project diversions in the Rio Grande Valley:
    a. Project Supply diverted from the American Canal at the Robertson/Umbenhauer WTP, and
    b. Project Supply diverted from Riverside Canal at the Jonathan Rogers WTP.

Figure 12. City of El Paso's Water Production Sources
https://www.epwater.org/our_water/water_resources Accessed by Peggy Barroll 3/5/2019



The water diverted in the Mesilla Basin at the Canutillo well field is generally delivered to business and residential customers in western El Paso, in the Mesilla Basin. Return flow from this use is treated at the Northwest WWTP and discharged into the Rio Grande above American Dam. Under past and current accounting methods, EPCWID is charged for the diversion and use of this water during the Caballo release season.

[30] EPWU claims that 40% of its water comes from the Rio Grande, 38% from Hueco wells, 17% from the Mesilla, and 5% from desalination. (https://www.epwater.org/our_water/water_resources.) EPWU admits: "Heavy aquifer pumping up to the late 1980s resulted in significantly reduced water levels in most of the Hueco Bolson and some of the Mesilla… El Paso Water has taken steps to reduce pumping in recent decades through major conservation efforts, increasing use of river water and using treated wastewater …." (https://www.epwater.org/cms/one.aspx?portalId=6843488&pageId=7416446; emphasis mine.) See Section R5 regarding the result of Texas's "heavy aquifer pumping up to the late 1980s".
[31] A minor source of EPWU supply is the saline groundwater pumped to supply the Kay Bailey Hutchinson desalination plant ("KBH" in Figure 12).

However, this reasonable and fair accounting treatment is not applied to municipal effluent in the El Paso Valley. EPWU combines its Project Supply with the groundwater it pumps in the Hueco Bolson, and the return flow from these sources, in the form of treated effluent, is returned to the American Canal Extension and the Riverside Canal. This water is diverted by EPCWID, and according to Dr. Ferguson[32] is used by EPCWID farmers, **but EPCWID is not charged for the diversion and use of this water.** Other evidence indicates that EPCWID considers this effluent to be an important component of its water supply. Blair (2001) (which comprises part of the 2001 Third Party Implementing Contract between EPCWID, the US and EPWU) contains a table (reproduced here as Table 6) which tabulates all the sources of water that EPCWID delivers to its farmers. The sources include 376,860 AF of "Project Water" **plus** "Usable Haskell Effluent – Non-Project Water" and "Usable Bustamante Effluent – Non-Project Water"[33].

Note that the 2001 Third Party Implementing Contract contains a substantial amount of language regarding the water quality requirement and standards for "Usable" EPWU effluent. This is part of Contract language that gives EPWU credit that allows it additional Project Supply in exchange for the discharge of "Usable Effluent" into the EPCWID system. EPCWID uses this effluent as "District Water" (but not Project Water). Or it may be that EPCWID is selling this water outside of the Project altogether under Contracts with Hudspeth[34].

---

[32] Deposition of Dr. Ian Ferguson 2/2020, page 250, line 7: "A. Yes. My understanding is that effluent discharged into EP1's [EPCWID's] conveyance system is delivered to irrigators to meet irrigation demands."

[33] EPCWID's "Project Water" amount of 376,860 AF was calculated using the D1 and D2 curves, and **included** municipal effluent, off-season diversions, and El Paso Valley drain flows. Now EPCWID requires these sources of water **in addition to** an even larger Project Water amount. (EPCWID full-supply allocation under D3 Allocation is 388,000 AF plus ~20,000 ACE allocation credit.)

[34] 2001 Agreement for the Sale of Sewage Effluent for Irrigation entered into between Hudspeth County Conservation and Reclamation District No. 1 ("HCCRD") and the El Paso County Water Improvement District No. 1 ("EPCWID") *and* 2010 Agreement for the Sale of Sewage Effluent for Irrigation entered into between HCCRD and EPCWID.

Table 1 - Sources and Quantities of District Water Including a Conservation Credit

Item	DISTRICT WATER SUPPLY and DELIVERY REQUIREMENTS (Maximum Effluent Diversions and Conservation Credit)	acres	Delivery ac-ft/ac	Diversion ac-ft	Delivery ac-ft
1	EPCWID's Diversion Allocation of Project Water	69,010		376,860	275,551
2	Conservation Credit from American Canal Extension Project			29,928	21,883
3	Usable Bustamante Effluent - Non-Project Water			13,333	9,749
4	Usable Haskell Effluent - Non-Project Water			15,000	10,968
5	Total District Water (Project and Non-Project Water)			435,121	318,150
6	Estimated Difference (Diversion to Delivery)			-116,971	
7	City 1941 and 1962 Contract Deliveries (max. of 3.5 ac-ft/ac)	7,241	-3.50		-25,344
8	LVWD 1988 Contract Delivery (4.0 ac-ft/ac)	2,922	-4.00		-11,688
9	Irrigated Land Delivery (4.0 ac-ft/ac)	57,847	-4.00		-231,388
10	2001 Contract 1,000 acres City Owned Land >2000 acres	1,000	-4.00		-4,000
11	2001 Contract Deliveries under section 7A2				0
12	2001 Contract Other District Water 7A1				-24,116
13	2001 Contract Total				**-28,116**
14	Non-Project Water (sum of items 3 and 4)				20,716
15	Reserve Balance of District Project Water				**899**
16	Reserve Balance of District Water				21,615
17	District Delivery Efficiency	73.1%			

NOTES:

The numbers in this table are based on the following assumptions:

1) execution of the 2001 Contract,
2) the present allocation and accounting methodology of Reclamation, and
3) acreage in Column A for rows 7, 8, and 10 was obtained from EPCWID Authorization for Water Service Report date 1/22/2001

The composition of EPWU's water supply in the El Paso Valley, which is the origin of Haskell and Bustamante WWTPs effluent, is shown In Table 7. This table provides EPWU diversion data for Project water in the El Paso Valley, and EPWU groundwater pumping in the Hueco Bolson. The amount of groundwater pumping occurring during months in which Project releases were occurring has been calculated, and is tabulated here.

The relative proportions of groundwater and surface water in the EPWU Hueco/El Paso Valley supply varies depending on EPCWID's allocation of Project Supply. In relatively high supply years, Project water constitutes up to 84% of EPWU's supply for the City of El Paso municipal use during the Project release season (Figure 13 and Figure 14). In years of low Project supply, Project water still constitutes 40% to 60% of EPWU's supply during the Caballo release season.

Table 7. Composition of EPWU Municipal Supply in the El Paso Valley

Table 7. Percentage of EPWU Supply Consisting of Project Water Release Season in the El Paso Valley

Year	Total EPWU Hueco Groundwater Pumping	EPWU Hueco Groundwater Pumping during Release Season	Total EPWU Diversion of Project Water	Total EPWU Diversion during Release Season	% EPWU Project Water during Release Season (El Paso Valley)

Figure 13. Project Release Season Municipal Diversions by EPWU in the Hueco Bolson/El Paso Valley

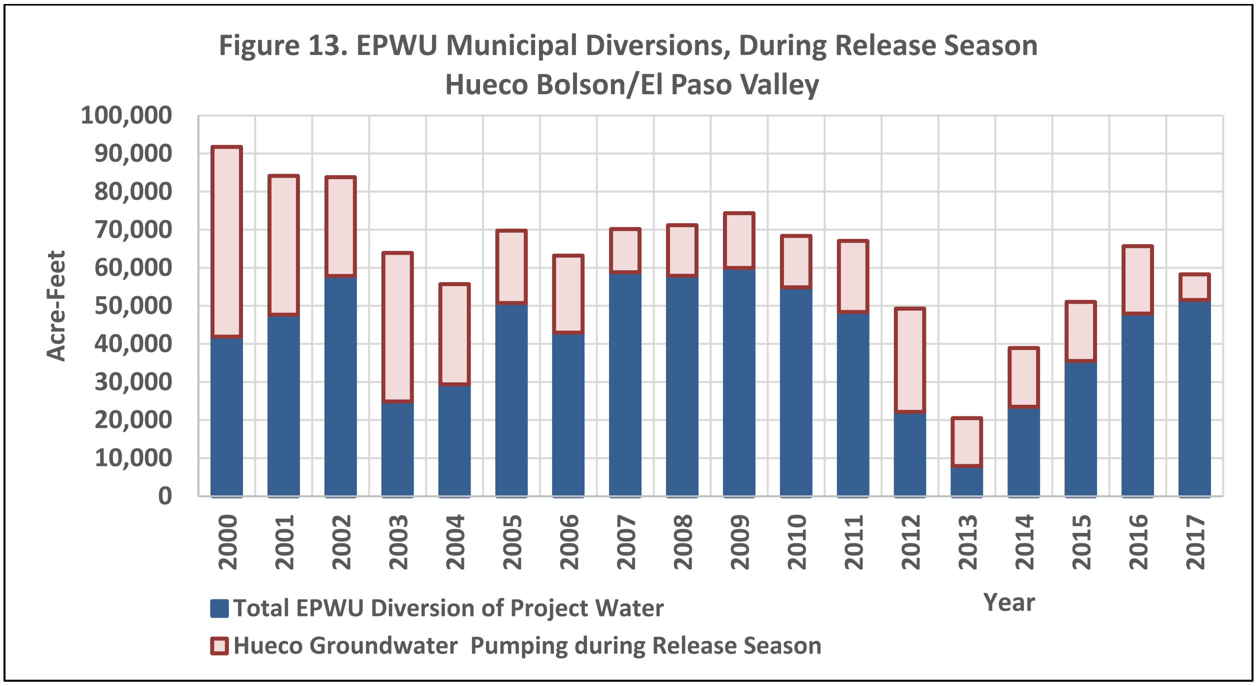

Figure 14. Project Release Season Municipal Diversions by EPWU in the Hueco Bolson/El Paso Valley

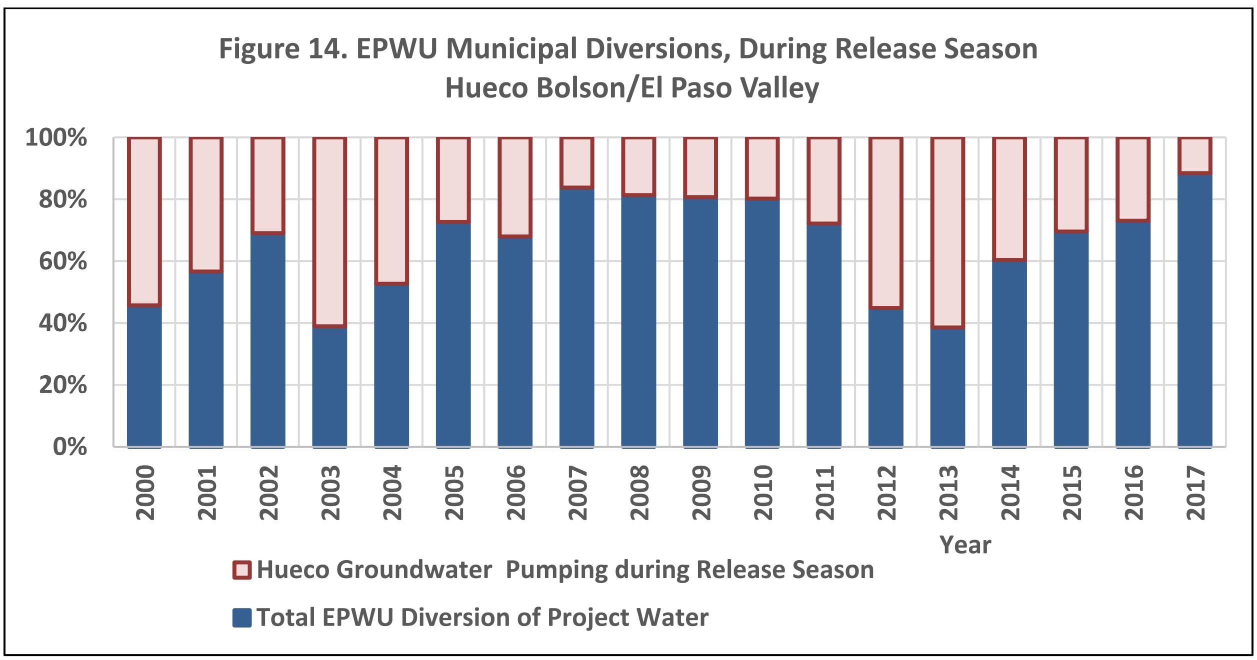


Haskell R. Street Wastewater Treatment Plant Treated Effluent

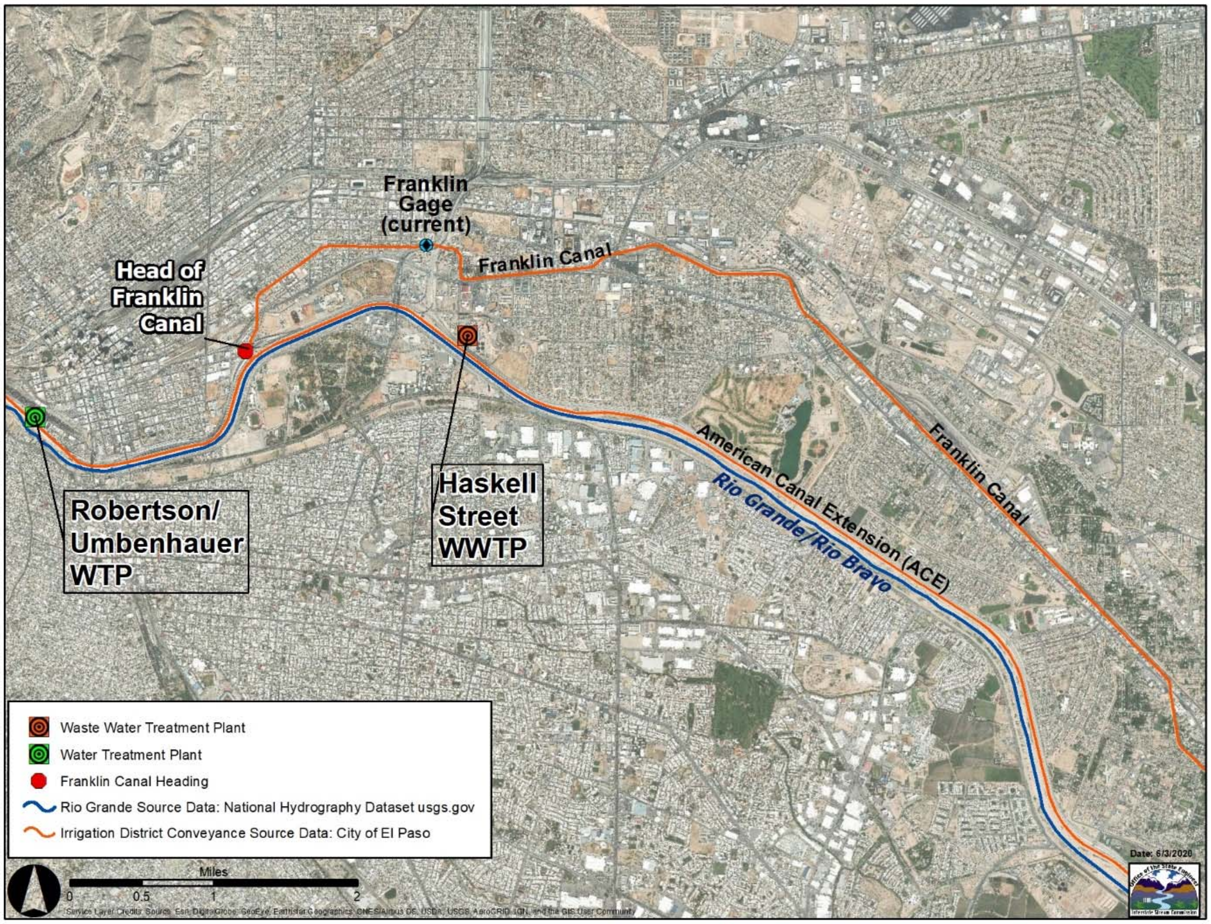
The City of El Paso's first wastewater treatment plant was the Haskell R. Street WWTP,[35] which for many decades was the City's only wastewater treatment plant. Treated effluent from this plant discharged into the Rio Grande until 1999, and the diversion of this water at Riverside Dam was counted as Project Supply both in early Project WDRs, and as part of post-1978 accounting. (*See* Barroll (2019), page 30, pages 49-50 and D-25 through D-27.)

In 1998 the American Canal Extension ("ACE") was completed, a lined conveyance **located immediately adjacent to the Rio Grande river.** In the vicinity of the Haskell plant the ACE is less than 200 feet away from the Rio Grande. The ACE conveys Project water diverted from the Rio Grande at American Dam directly to the Riverside Canal heading. The Riverside Canal now diverts water directly from the ACE, which now substitutes for the nearby Rio Grande riverbed. See Figures 15, 16 and 17.

Since early 1999 the effluent discharged from the Haskell R. Street plant has been intercepted by the ACE before it reaches the bed of the Rio Grande, and the ACE conveys the effluent to the Riverside Canal heading where it is diverted, passes the Riverside gage, and is then used for irrigation within EPCWID. Project accounting, however, **no longer charges EPCWID for this diversion and use even though this water is gaged at EPCWID's Riverside charge point**.

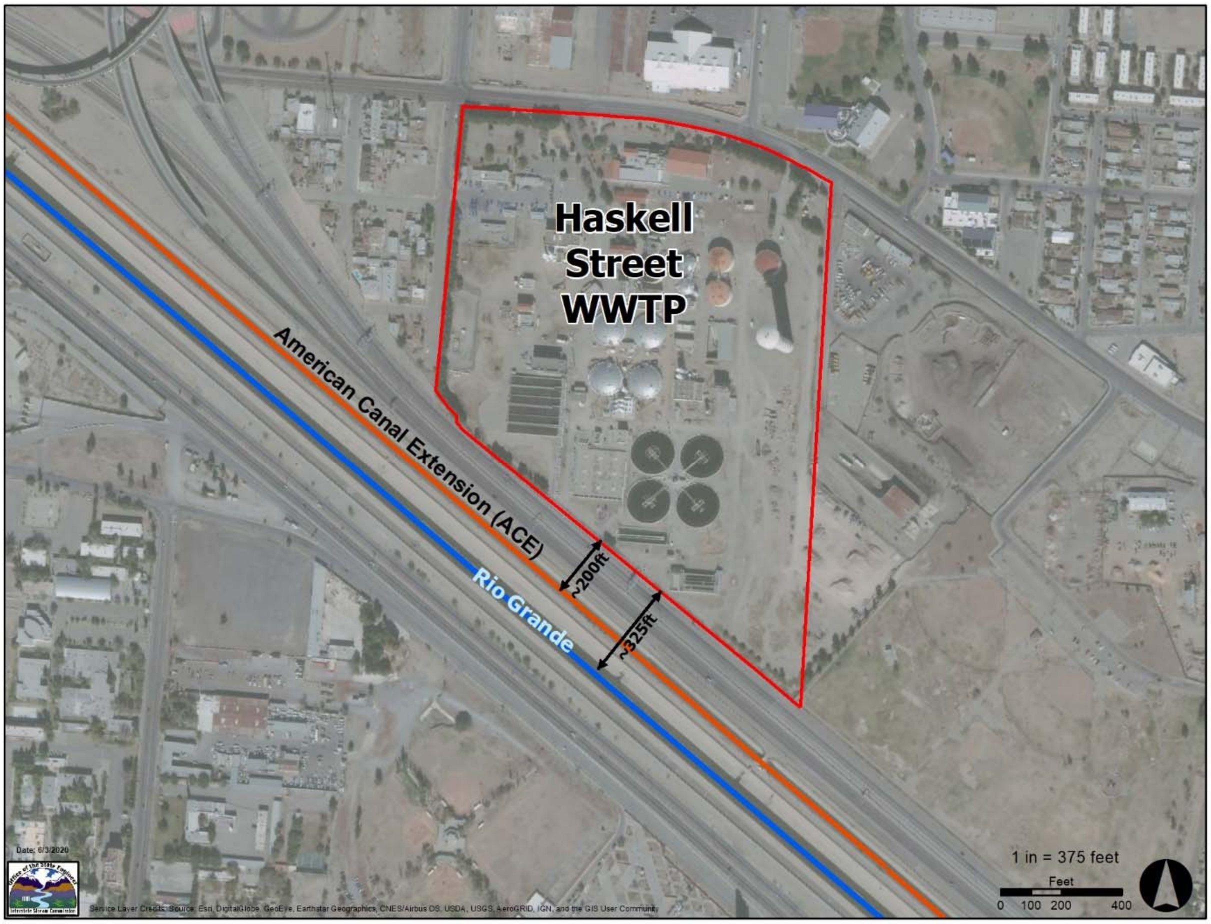
[35] Haskell R. Street WWTP became operational in 1923. "This plant is designed to treat wastewater and discharge it to either the Rio Grande or the American Canal. The preferred discharge point is to the American Canal in order to provide irrigation water to farmers in the Lower Valley. In exchange for this irrigation water, El Paso Water obtains valuable water credits for surface water that is treated to drinking water standards, reducing our dependence on groundwater." (https://www.epwater.org/cms/One.aspx?portalId=6843488&pageId=7422911; emphasis mine.)

Figure 15. Haskell R. Street Wastewater Treatment Plant Area Map



US_MSJ_00000988

Figure 16. Haskell R. Street Wastewater Treatment Plant Detail map



The decision to no longer charge EPCWID for diversion and use of this water was made in a 1999 meeting between EPCWID staff and Reclamation staff that was summarized by Reclamation's F. Cortez,[36] and in which the parties making the decision did not mention the potential impact of this accounting change on the Project as a whole. Instead of continuing to charge the diversion of this effluent as it passed the Riverside gage, as had previously been the practice, EPCWID and Reclamation agreed that the diversion and use of this effluent would continue, but now the amount discharged from Haskell into the ACE ten (10) miles upstream of the Riverside Canal heading, is now **subtracted** from the Riverside Canal heading diversion in the form of an accounting credit. As a result, not only does EPCWID divert and use Haskell R. Street effluent free of charge, but that effluent gets to "ride on top" of the rest of the Project water conveyed in the ACE, arriving at the Riverside heading intact, not reduced for evaporation or other losses, thus maximizing the amount of the Haskell Credit. This accounting anomaly has the ultimate result of reducing the Diversion Ratio, in essence causing EBID to pay for EPCWID's "free" Project supply water. EPCWID's Haskell R. Street Credit has been awarded since 1999 and has averaged 8,700 AF/year.

---

[36] Cortez Letter Summary of June 25, 1999 Meeting to Discuss Water Accounting Procedures at Riverside Canal and Haskell Street Waste Water Treatment Plant Discharge.

Since the entire amount of Haskell effluent discharged into the ACE is credited to EPCWID when diverted at Riverside, it is implicitly assumed that no water is lost from the ACE between the Haskell Plant discharge point, and the Riverside heading. This implicit assumption is inconsistent with the results of seepage study performed and documented by Blair (Blair, 2000), which measured "a seepage loss of 3.23 +/- 1.5 cfs for the 5.25 mile reach of the ACE upstream of the Riverside Canal Heading metering bridge.[37]" Over the course of a 150 day irrigation season, this loss rate would result in about 1,000 AF of total loss.

EPCWID and Reclamation take the position that the discharge of effluent derived from Project supply into the American Canal Extension is fundamentally different than discharge of that same water into the Rio Grande. This is despite the fact that **the ACE simply substitutes for the Rio Grande** in the delivery of Project water to EPCWID. That is, EPCWID is now charged for diversions from the ACE instead of from the Rio Grande, and the ACE was designed and constructed to take the place of the Rio Grande specifically for that purpose.

Bustamante Wastewater Treatment Plant Treated Effluent

The Bustamante WWTP is located downstream of Haskell, and discharges EPWU municipal effluent into the Riverside Canal system during the irrigation season, and into a drain leading to the Rio Grande during a few winter months. See photo, Figure 17. According to Dr. Ferguson, effluent discharged into Riverside Canal is used to supply farm demand within EPCWID just as the rest of the Project water is but is not charged against EPCWID's allocation[38]. There is no explicit Project accounting credit for Bustamante effluent, because since it enters Riverside below the gage, it is not included in the gaged diversions. Dr. Ferguson testified that because the Bustamante effluent enters the Riverside Canal system below the Riverside gage, "it would not be charged as Project water"[39]. The amount of water discharged from Bustamante into the Riverside Canal during the Project Release season has averaged approximately 15,500 AF/yr since 1999.

Essentially, approximately 24,000 AF/yr of Project return flow mysteriously loses its character as Project supply[40] through the agreement of Reclamation and EPCWID; although it is diverted and used during the Project release season it is not charged against EPCWID's allocation. **This contributes to the fact that EPCWID's charged diversions are generally much less than its full-supply allocation, allowing EPCWID to carry over large amounts of unused allocation under the 2008 OA. Under the current D3 Allocation method this results in corresponding decreases in EBID's allocation having nothing to do with actions by New Mexico actors.**

---

[37] Blair, A.W., 2000. Salvage of Water in El Paso County Water Improvement District No. 1 Canal System. Prepared for EPWCID No.1 Draft Report January 26, 2000.

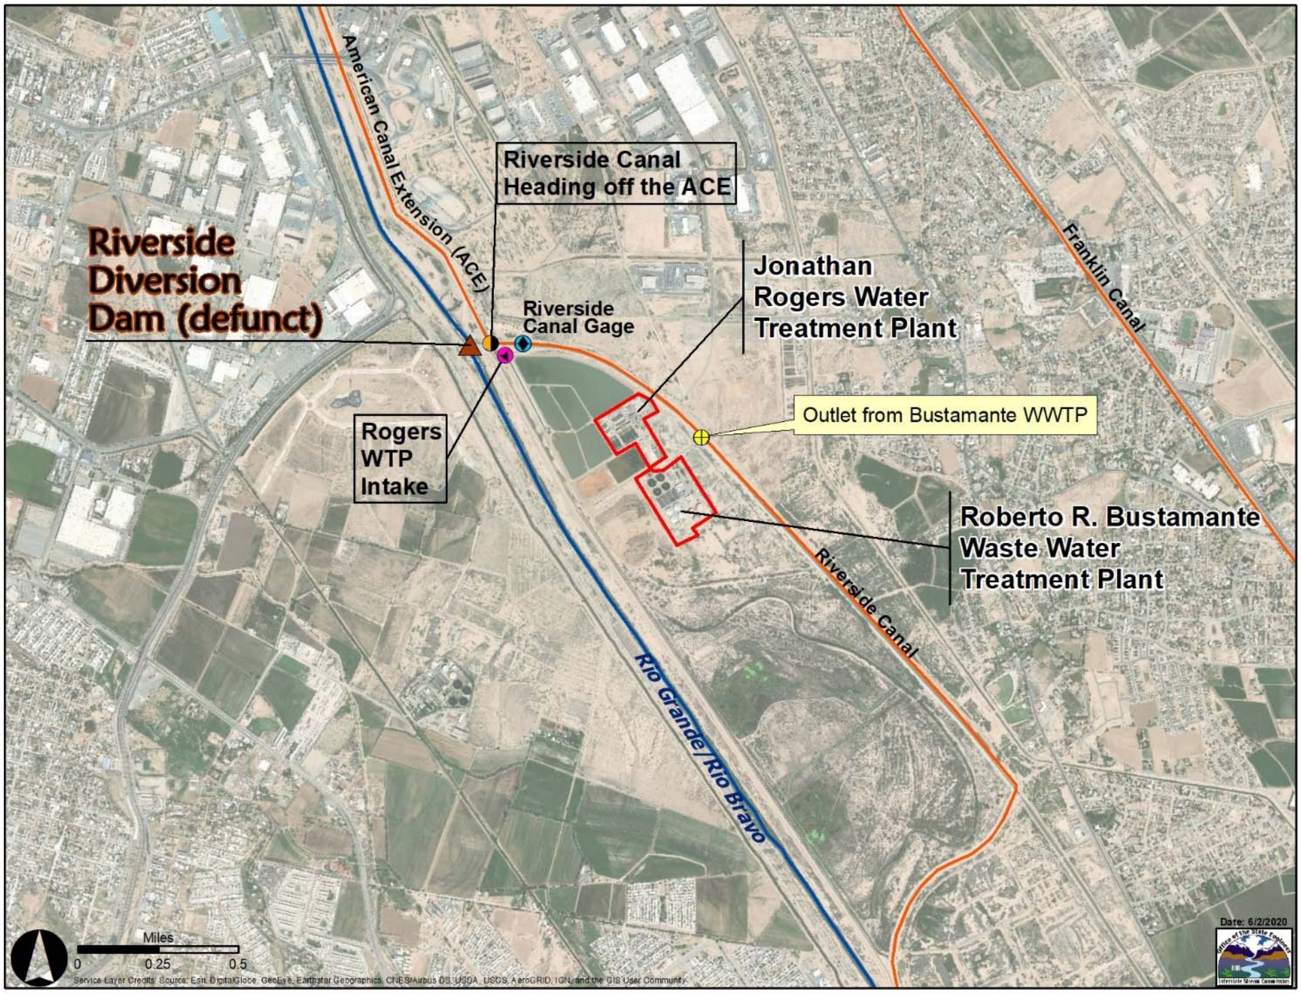
[38] Deposition of Dr. Ian Ferguson, 2/19/2020, page 151, line 21.

[39] Deposition of Dr. Ian Ferguson, 2/19/2020, page 151 line 25, page 152 line 1.

[40] Further, while EPCWID asserts that it has earned the benefit of Carryover due to the laudatory water conservation measures it employs, for at least this approximately 24,000 AF/yr the "conservation" is actually a result of accounting sleight-of-hand.

See Barroll (2019), Appendix C, for more detailed discussion of the structure of the El Paso Valley conveyance system and changes thereto.

Figure 17. Bustamante Wastewater Treatment Plant Location near the Riverside Canal and Heading



US_MSJ_00000991

R8. ACE CREDIT

Dr. Blair defends the ACE Credit (18th Opinion, pages 13 and 14) stating:

> *EPCWID does not receive any greater benefit for the American Canal Extension under the 2008 Operating Agreement than prior to the Agreement; and in some years, EPCWID receives no use of the credit and in other years the credit accrues to the benefit of EBID. The ACE canal credit is less than the reduction in seepage losses in the Rio Grande resulting from the construction of concrete lined ACE canal. These seepage losses existed since 1938 until the ACE canal was completed in 1996. The ACE canal credit does not reduce the annual diversion allocation to EBID. It does allow an appropriate credit to EPCWID for water conservation associated with EPCWID's payment of the local cost-share for constructing the ACE canal, and for the cost to operate and maintain the ACE canal.*

Dr. Ferguson also defends the ACE Credit (his 13th Opinion, page 13) in similar language:

> *The ACE Conservation Credit is less than the estimated reduction in seepage losses. As a result, the ACE Conservation Credit does not reduce the annual diversion allocation to EBID; rather, it allows EPCWID to benefit from water conservation achieved by the district's investment in constructing the ACE. Also, Dr. Barroll does not acknowledge that the ACE Conservation Credit has not been applied in several recent years by agreement between EBID and EPCWID; these years include the extremely dry years of 2011, 2013, and 2016. Finally, Dr. Barroll does not acknowledge that, in the event that EPCWID's carryover reaches the limit specified in Section 1.11 of the OA, carryover in excess of that specified limit, including carryover resulting from the ACE Conservation Credit, is transferred to EBID's carryover balance.*

Dr. Barroll Reply: The American Canal Extension (ACE), completed in 1998, connects the end of the original American Canal, below the Franklin Canal heading, to the Riverside Canal heading (see Figures 15 and 17). The ACE allows EPCWID to divert all of the water needed by Franklin, Riverside, and EPWU at American Dam, and completely bypass the bed of the Rio Grande below American Dam when delivering water to the Riverside heading. See Barroll (2019) Section 6.4 and Appendix D, for more detailed description of the ACE and ACE related Project Accounting issues.

Use of the ACE to by-pass the bed of the Rio Grande for delivery to Riverside avoids the seepage losses occurring in the 15-mile reach of the Rio Grande above Riverside. The seepage losses in this reach, however, are a result of groundwater pumping in Texas and Mexico – see Section R5 for an explanation of the impacts of Texas groundwater pumping. Rio Grande Project accounting then awards EPCWID a credit (the "ACE Credit") for this bypass operation. The application of the ACE Credit reduces EBID's share of Project Supply as discussed below. In other words, Texas gets credit for resolving a problem it created, and EBID and New Mexico lose water as a result. See Barroll (2019) Section 6.4 and Appendix D for more detailed description of the ACE and ACE related Project Accounting issues.

It can be demonstrated through testing of the Allocation Spreadsheet (which is the heart of the 2008 OA) that the amount of the ACE credit awarded to EPCWID within that Spreadsheet is subtracted, 1:1 from EBID's allocation. This effect is illustrated in Figure 6.8 of Barroll (2019) which demonstrates that the effect of awarding EPCWID a 17,998 AF ACE Conservation Credit is to reduce EBID's allocation by that same amount: 17,998 AF. Therefore, the effect of the ACE credit, when applied through the Allocation Spreadsheet as described in the 2008 OA is to decrease EBID's allocation by the amount of EPCWID's ACE credit.

In recent years the ACE credit has sometimes been omitted, or been applied inconsistently. In some years the ACE credit has been applied by increasing the allocation at the end of the year during the accounting process, instead of through the Allocation Spreadsheet. When the ACE Credit is added on to EPCWID's allocation at the end of the irrigation season, the net effect is to increase EPCWID's Carryover to the subsequent year. Since the ACE Credit is not associated with any water in reservoir storage, this increase in Carryover is an increase in the amount of paper water in Carryover. In some years, this will mean that increased amounts of winter inflows to storage will be automatically converted into Carryover, in order to supply that Carryover account.

Allocation the subsequent year begins with calculation of the Carryover obligation (the total amount carried over from the previous years plus the amount of extra release needed to deliver that Carryover allocation to canal headings), and subtracting that off from Usable water before calculating Current-Year Allocations. In this way, the increase in Carryover caused by the ACE Credit reduces the amount of water available for Current-Year Allocation the following year, negatively impacting EBID's Allocation.

The issues that I raise related to the ACE Credit are independent of whether the ACE Credit has been awarded in every year. Similarly, the issues with the ACE Credit are independent of whether Carryover transfer has the potential to result in benefit to EBID (as suggested by Dr. Ferguson). As for Carryover transfer, New Mexico cannot depend on this benefit to EBID occurring in the future. Carryover Transfer to EBID only occurs if EPCWID has accumulated unused allocation in excess of its Carryover Limit, which is 232,915 AF, and such transfers would be greatly reduced or even eliminated if EPCWID increases its diversions in full-supply years.

R9. EPCWID CARRYOVER AND ITS CLAIMED "LINK TO CONSERVATION"

Drs. Ferguson and Blair argue that it is good management and conservation measures that have allowed EPCWID to carry over such large amounts of water since the inauguration of the D3 Allocation Method. Dr. Ferguson states (Ferguson's 9th opinion, pages 9 and 10):

> *Dr. Barroll incorrectly characterizes carryover accrued by EPCWID as "unused" and "unneeded." EPCWID implements water conservation measures to allow the district to accrue carryover when possible (e.g., in years when the district's diversion allocation is average or above average).*

Dr. Ferguson adds (in his 13th opinion on page 13)

> *EPCWID actively manages its allocation to accrue carryover when possible and to utilize carryover during drought periods, as part of the District's approach to improving water supply reliability during severe drought conditions. Dr. Barroll's opinion does not acknowledge that the OA provides EBID the opportunity to accrue and utilize carryover in the same manner as EPCWID. However, EBID chooses not to actively manage its*

allocation to take advantage of carryover; instead, irrigators within EBID increase their groundwater use to meet crop water demands during drought periods.

Dr. Blair states (in his Opinion #13 on pages 10 and 11):

> *EPCWID manages its use of allocated Project Water to meet the needs of its water users which includes the conservation of water for future use. EPCWID actively conserves water in years with full allocations for use in drought years, and uses all of its allocated water in the time and manner it deems most beneficial to the District and its water users. The corollary to Dr. Barroll's conclusion is that EPCWID and EBID must drain the reservoir every year so that no water is ever carried-over into the next year. There has been "carryover" of Rio Grande Project water since the first-year water was stored in Elephant Butte Reservoir in 1916. Storage and carry-over of water from year-to-year is an appropriate and prudent operation of a water supply reservoir.*

Dr. Barroll Reply: Since the implementation of D3 allocation in 2006, EPCWID's allocation in full-supply or near full-supply years exceeds EPCWID's charged diversion by approximately 100,000 AF/yr. Part of the discrepancy between EPCWID's allocation and its charged diversion is that part of the water EPCWID actually diverts and makes use of is not charged against its allocation. As discussed in section R7 above, under current Project accounting rules EPCWID can divert and use approximately 25,000 AF/yr of El Paso municipal effluent free of charge. This accounting maneuver does not constitute an "active conservation measure."

EBID's inability to take advantage of Carryover to the same extent as EPCWID is a result of the large reduction in EBID's full-supply allocation caused by D3 allocation, not a result of management decisions. EBID's allocation has been reduced below the level needed to supply the crops grown on its current irrigated acreage. EBID farmers currently irrigate approximately 70,000 acres, and within New Mexico there are also approximately 4,500 irrigated acres that are not part of EBID. Thus, the total irrigated acreage in the New Mexico part of the LRG is already much less than the 90,640 acres authorized by the Rio Grande Project.

Under the historical operations of the Project, prior to 2006, any unused allocation would return "to the pool" and be available for current-year allocation to both Districts. As described in Filberto (Bert) Cortez's 2007 affidavit, submitted on behalf of the **United States when it was arguing against** implementation of Carryover storage,[41] statement 19: "The practice for nearly 100 years of Project Operation was that any unreleased storage or unused diversion allocation from either district went back into the Project supply to be allocated anew the next year." During the years that led up to the adoption of the D3 method in 2006, both Districts often had unused allocation at the end of the irrigation season, and any reservoir storage that might be associated with this unused allocation, regardless of which district had the unused allocation, was returned to the pool for allocation (on a 57/43 basis) the following year, as shown in Table 8.

[41] Filberto (Bert) Cortez's 2007 Declaration in Cause No. EP07CA0017 (PRM), EPCWID v EBID, and the US DOI.

Table 8. Unused Allocation in the Years Leading up to Implementation of Carryover Comparison of Allocation and Charged Diversions 1999-2005

Table 8. Unused Allocation in the Years Leading up to Implementation of Carryover Comparison of Allocation and Charged Diversions 1999 - 2005						
	EBID Allocation	EBID Charged Diversion	EBID Unused Allocation	EPCWID Allocation	EPCWID Charged Diversion	EPCWID Unused Allocation
	Acre-feet	Acre-feet	Acre-feet	Acre-feet	Acre-feet	Acre-feet
1999	494,979	426,132	68,847	376,862	340,727	36,135
2000	494,979	460,278	34,701	376,862	306,375	70,487
2001	494,979	460,182	34,797	376,862	343,365	33,497
2002	494,979	431,521	63,458	376,862	376,926	(64)
2003	165,144	164,740	404	125,735	137,250	(11,515)
2004	185,507	164,572	20,935	154,265	144,005	10,260
2005	494,979	353,261	141,718	376,862	247,607	129,255
1999-2005 Average	403,649		52,123	309,187		38,294
District % of unused Allocation			58%			42%

Furthermore, Table 8 demonstrates that prior to the adoption of D3 allocation in 2006, EBID did not use all of its allocation in full supply years, leaving significant amounts of water behind in the reservoir to be reallocated the following year: in fact, in some years EBID contributed more to the “pool” than did EPCWID. This changed immediately in 2006 when EBID’s full-supply allocation was reduced dramatically, below the amount needed to supply its crops.

Finally, Dr. Blair’s “corollary” is a strawman argument. I do **not** contend that the Project cannot store water in Elephant Butte or Caballo reservoirs from year to year. Rather I contend that Project Carryover accounting under the 2008 OA is a significant change from historical Project operations, and that can and does harm New Mexico water users by reducing the current-year allocation to EBID in some years.[42]

[42] See Lopez (2019) Section 7 for his discussion on how Carryover impacts New Mexico’s Compact rights and obligations.

R10. THE UNITED STATES DOES NOT REFUTE MY EVIDENCE THAT UNTIL 2006, PROJECT ALLOTMENT AND ALLOCATION ENTITLED EBID AND EBID FARMERS TO 57% OF THE US SHARE PROJECT SUPPLY, AND THAT HISTORICAL PROJECT DELIVERY DATA INDICATES THAT THE ACTUAL DELIVERY OF PROJECT WATER TO THE DISTRICT WAS APPROXIMATELY 57% TO EBID AND 43% TO EPCWID.

Dr. Ferguson (5th Opinion on page 7 of Ferguson 2019) writes: "*Dr. Barroll's statement that 'from 1938 – 1978, Reclamation operated the Project so that EBID's farmers were entitled to 57% of the US share of Project Supply' is also incorrect*." Dr. Ferguson then contradicts himself by writing: "*From 1951-1978 Reclamation allotted water equally to all acres.*" Allotting water equally to all acres is exactly the same as giving every acre an equal entitlement to water, and since 57% of those acres were in EBID, EBID farmers were indeed entitled to 57% of the water. In his 6th opinion (page 7) Dr. Ferguson does not refute my assertion that "starting in 1979 Reclamation explicitly allocated Project Supply to the Districts in the ratio of 57% to EBID and 43% to EPCWID." Dr. King (in his 2nd opinion at the top of page 7 of King 2019) concedes that from 1979 to 2007 Reclamation allocated the US share of Project supply 57/43; he only differs with the details of my explanation. Dr. Blair does not refute the fact that EBID was allocated 57% from 1979 – 2006, but also quibbles about the description of the allocation method during that time in his 4th opinion (page 5 of Blair 2019).

On his page 7 Dr. Ferguson points out that prior to 2006 the percentages of Project water actually diverted by the Districts and delivered to District farmers varied from year to year, and writes that "*Reclamation did not guarantee equal **delivery** to all lands*" (emphasis mine.) This is correct, but it does not change the fact that Reclamation's equal-allotment-to-lands meant that EBID lands were **entitled** to order 57% of the US share of Project Supply. Dr. Ferguson himself explains the variability in actual delivery, writing: "*Actual deliveries to farms depended on the amount of water called for by farmers*", and "*The amounts of water diverted by the Districts and delivered to their farmers depended on the amounts of water called for by the districts and farmers respectively*." Again, this variation in actual delivery does not change the amount the District and their farmers were entitled to order. And while there was variability in actual delivery, on average the percentages of actual EBID diversions and farm deliveries were consistent with 57%. From 1951 through 1978, on average EBID's diversions were 56% and EBID' farm deliveries were 54% of total District diversions and farmer deliveries. From 1978 through 2005, on average EBID's diversions were 58% of total District diversions.

Dr. Blair (2019, page 4) states that "There is no requirement or documentation under the Rio Grande Compact or otherwise which directs that 'each Project acre was entitled to the same delivery of water.'" He does not, however, refute my conclusion that in practice the Allotment and Allocation procedures of the Project until 2006 entitled each acre to order the same amount of water.

In 2007, then Project Manager FIlberto (Bert) Cortez wrote in a formal Declaration:

The allocation has historically been equally divided to all Project lands on an acre foot per acre basis. Before 1980, Reclamation operated the Rio Grande Project in its entirety, combining storage and return flows so that each acre of farm land received and equal amount of water regardless of the source of the water or what district the land was located"

And

EBID is allocated 88/155 of the available Project water supply and EPCWID is allocated 67/155 of the available water supply.

R11. THE UNITED STATES IGNORES THE ACTUAL OPERATION OF THE 2008 OA AS WELL AS STATEMENTS BY ITS AUTHORS

Dr. Blair (Opinion 12, page 10) states that "*The 2008 Operating Agreement does not assume that all of the 'negative departures from historical performance are caused by New Mexico*.'" Dr. Ferguson agrees with Dr. Blair, as stated in Dr. Ferguson's 2nd opinion (Ferguson page 4) and 10th opinion (Ferguson page 10).

Dr. Barroll Reply:

I base my assertion that that "the 'D3 Method' is based on the assumption that any negative departure from historical Project performance is caused by New Mexico in part upon my understanding of Reclamation's allocation spreadsheet, and also from various written and verbal statements from the authors of the 2008 OA. For instance, the Reclamations EIS states: *"Moreover, it [the 2008 OA] ensures that deviations in performance relative to historical conditions would be accounted for by adjusting the annual allocation to EBID*." (FEIS page 7). Also, in a report by Dr. Ferguson himself[43] he states on page 9: "*The diversion ratio adjustment provision of the OA therefore mitigates potential negative effects of changes in Project performance, which result predominately from the actions of individual landowners within EBID, by ensuring that Project allocations and deliveries to EPCWID remain consistent with historical Project performance*." Since the 2008 OA assigns all "deviations in performance" to EBID, and ensures "*that Project allocations and deliveries to EPCWID remain consistent with historical Project performance"* it certainly appears that the OA is predicated on an assumption that all deviations are caused by EBID. **Regardless of whether the 2008 OA is actually predicated on such an assumption, because it reduces EBID's allocation by all deviations from historical Project performance regardless of their cause, it emphatically has that effect as a practical matter.**

Based on the calculation embedded into the 2008 OA Allocation Spreadsheet, it is clear that the effect of D3 Allocation is to reduce EBID's allocation in an amount equal to the entire negative departure from the D2 Curve (except under multi-year drought conditions, a modification that was added in 2012.) Meanwhile, EPCWID's allocation has not been reduced to account for the impacts of any pumping in

[43] Dr. Ferguson's own report (Memorandum No. 86-68210–2015-05 Simulation of Rio Grande Project Operations in the Rincon and Mesilla Basins: Summary of Model Configuration and Results, Appendix C of the Continued Implementation of the 2008 Operating Agreement for the Rio Grande Project Environmental Impact Statement, 2016) on page 9.

Texas, or changes in Project accounting that except some EPCWID diversions from being counted as Project deliveries.

Drs. Ferguson, Blair and King all emphasize that the 2008 OA was a "negotiated settlement." However, it is unclear that EBID has obtained the bargain it attempted to obtain. In Dr. King's rebuttal he indicates that the deviation from the D2 curve in Project performance is caused by increased groundwater withdrawals ***"relative to the 1951 – 1978 D2 period"*** (King page 7), and that the 2008 OA is intended *"to offset groundwater depletions in New Mexico relative to the 1951 – 1978 D2 period."* (King page 8) These statements reflect an understanding that the 2008 OA was intended to grandfather-in New Mexico groundwater pumping levels from the D2 period, and that adjustments made to EBID's allocation were intended to offset **additional** amounts of pumping above and beyond the D2 period. Similarly, EBID presentations from the 2008 time-period reflect that same understanding. A 2008 presentation to the New Mexico State Legislature states "D2 level of groundwater pumping grandfathered into Project allocation."[44] This is the bargain that EBID apparently thought it was making in negotiating the 2008 OA; however, this is not what EBID got.

Instead, the 2008 OA takes large amounts of allocation away from EBID, far larger than any available estimates of increased pumping in New Mexico since the D2 period. Instead of reducing EBID's allocation solely to account for increased groundwater pumping in New Mexico since the D2 period, the 2008 OA also reduces EBID's allocation to compensate for changes in Project accounting that have benefitted EPCWID by allowing EPCWID to divert and use, without charge, sources of water that had previously been considered Project water.

R12. QUANTIFICATION OF D3 REALLOCATION

In this section I perform a first-order analysis to quantify the amount of Project Supply reallocated under the Operating Agreement through analysis of the reported Allocation data from 2006 through 2019. I use Current-Year Allocation data to avoid any potential "double counting" of allocations carried over for multiple years.

Table 9 contains Current-Year Allocation data for the Districts from 2006 through 2019, and calculates of the amount by which EPWID's Current-Year Allocation exceeds 43% of the Current Allocation to both Districts. The total reallocation calculated by this method is 693,408 AF, which is the amount EPCWID's allocation has been increased at the expense of EBID.

[44] Esslinger, G., 2008. Elephant Butte Irrigation District Update for the Water and Natural Resources Committee. Presentation to the New Mexico State Legislature, August 4, 2008.

Table 9. EPWID Current-Year Allocation in Excess of 43% of Current-Year Allocation to Districts

Table 9. EPCWID Current-Year Allocation in Excess of 43% of Current-Year Allocation to Districts						
	Current-Year Allocation from Reclamation Allocation Records

Total					**531,389**	

However, under current Project Accounting, EPCWID diverts and uses an average of 24,000 AF of EPWU effluent, essentially Project return flow, without charge. If the amount of EPWU effluent that is provided to EPCWID during the Caballo Release season is included with EPCWID's Charged Diversions, as shown in Table 11, the total amount that EPCWID diverts in excess of 43% is 708,000 AF.

Table 11. EPCWID Diversion (including Effluent) in Excess of 43% of Total District Diversions

Estimated Values of Release Season El Paso Valley Effluent Discharge 2018 and 2019

Thus, analysis of the actual Allocation and Diversion data indicate that over the past 14 years, EPCWID has obtained approximately 700,000 AF of Project water in excess of its rightful 43%. Note that prior to 2006, Project Allocation methods either explicitly allocation 43% of the US share of Project Supply (from 1979 – 2005) or allotted water equally to all Project acres, so that EPCWID farmers, with 43% of the Project acreage, was entitled to order 43% of the US share.

This analysis presented above is a first-order analysis, in that it does not attempt to calculated the change to the hydrologic system that would occur under a different distribution of Project Supply. In all likelihood, if the upper part of the Project (EBID) were allocated and received more surface water, the delivery performance of the Project would increase, as a result of improved aquifer conditions, to the benefit of the Project.

The physical mechanism that would improve Project delivery performance is as follows: improved allocation and supply to EBID would lead to:

- An increase in recharge to the Rincon and Mesilla valley aquifer from canal seepage, and
- Reduced groundwater pumping within EBID.

These benefits would result in higher-than-otherwise groundwater levels within the Rincon and Mesilla valleys within New Mexico. This change in groundwater levels would lead to:

- Reduced seepage losses from the Rio Grande, and
- Increased drain flows above Courchesne.

As a result of these hydrologic improvements, it would not be necessary to release as much Project water to meet District orders and the Mexican delivery schedule, and the Project Diversion Ratio would be proportionally increased. These processes can only be simulated with an integrated groundwater and surface water operations model. The ILGM has already performed preliminary runs of this nature (Sponk 2019), but that model is currently undergoing revision in response to rebuttal criticism, and the revised model results will be completed after this report is concluded.

The increase in Project Diversion Ratio would lead to a further increase in the amount of Project Supply available for allocation and delivery. Under D3 Allocation rules, that increase would go to EBID; under 57:43 Allocation, the extra water would accrue to both Districts. In either case, EBID would reap some of the benefit, which would result in further improvement to the hydrologic system within EBID, and further improvements to Project delivery performance.

This process is the flip side of the “vicious cycle” I describe in Barroll (2019) Section 9.7, and also the flip side of the “double whammy” and “positive feedback effect” that Dr. King describes in his 2019 rebuttal on page 11 and 12. **In summary, any improvement to EBID’s Allocation will help start a “virtuous” cycle, in which greater surface water supplies to EBID improve the Project delivery performance, leading to a greater total Project Supply.**

This result is consistent with the general operating principles of large irrigation systems: water is applied upstream provides return flows for downstream parts of the system. Diversion of these return flows (recycling), allows the same water to diverted 2 or 3 times as it passes downstream. In our case, the extra water to EBID also improves aquifer conditions in the upper part of the Project by reducing stream flow losses and improving drain flows, contributing to an increase in the total amount of deliverable Project Supply.

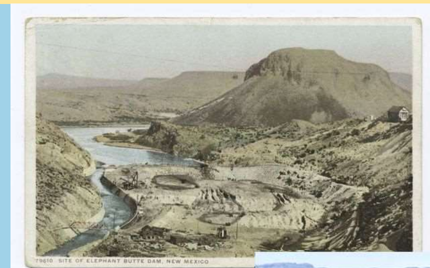
1. Introduction to Rio Grande Project

- Basics:
  - Origin and Scope
  - Districts
  - Geography
  - Infrastructure
- Sources of Water:
  - Reservoir Release
  - Return Flows
  - Inflows below Caballo
- Project Water Users
  - Farmers (irrigation)
  - City of El Paso (drinking water/other municipal use)



New York Public Library

Las Cruces Sun

Rio Grande Project

- The Project was designed to deliver water in New Mexico and Texas, and to Mexico.
  - Authorized by Congress in 1905
  - Construction began 1912
  - Began deliveries of water in 1915 (while still under construction)
- New Mexico farmers district: Elephant Butte Irrigation District (EBID)
- Texas farmers district: El Paso County Water Improvement District #1 (EPCWID or EP1)
  - Texas has added the City of El Paso under Miscellaneous Purposes Act Contracts

Rio Grande Project

- The Project was already in place at the time of the 1938 Rio Grande Compact.
- A 1938 Contract between the Districts sets forth a division of Project water supply between the Districts in accordance with the proportions of Project acreage: 88,000 of 155,000 Project acres (57%) to EBID, and 67,000 of 155,000 Project acres (43%) to EPCWID.
- The 1938 Compact limits Project Supply to “Usable Water in Storage” not including Compact Credits

Sources of Project Supply

- **Project Storage**: Water released from Caballo and diverted at Project canal headings
- **Return Flows**: Water that had been diverted by a Project user and then returned to the Project (drain flows, Project waste, effluent)
- **Drain Flows**: Water discharged from drains that can be diverted within Project
- **Municipal Effluent**: Treated municipal wastewater that can be diverted within the Project
- Any other usable inflows below Caballo Dam (storm flows)

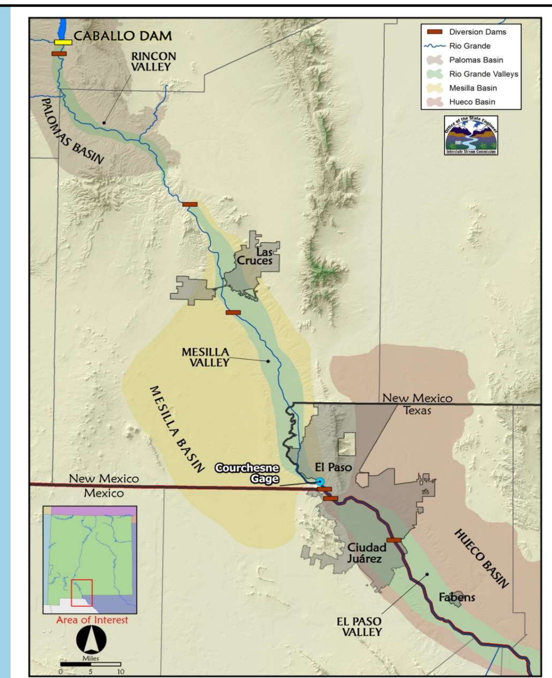
Geography

Project lands are within river valleys, with thin alluvial aquifers

- Rincon Valley
- Mesilla Valley
- El Paso Valley

These valleys are within larger Sedimentary Basins

- Palomas Basin
- Mesilla Basin
- Hueco Bolson



Barroll Rebuttal, App A June 15, 2020 7

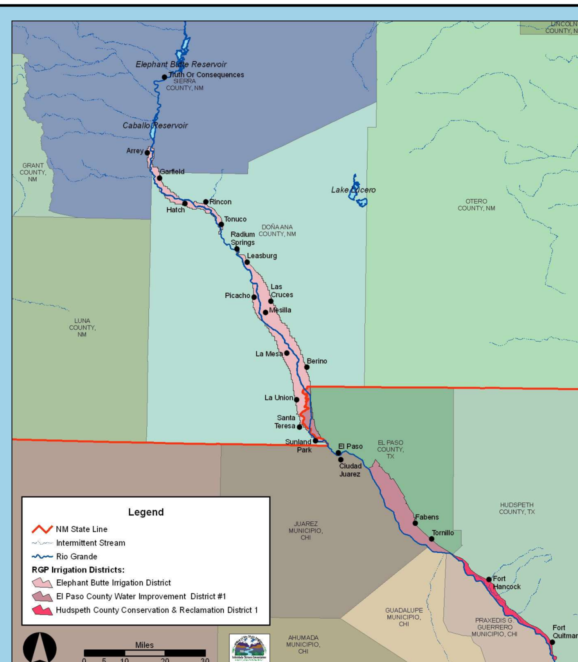
7

RGP Map

Districts limited to Authorized Acreages:

EBID: 88,000 acres
(+ 3% Cushion: 90,640 acres)
~57% of Project Authorized Acreage

EPCWID : 67,000 acres
(+ 3% Cushion: 69,010 acres)
~43% of Project Authorized Acreage

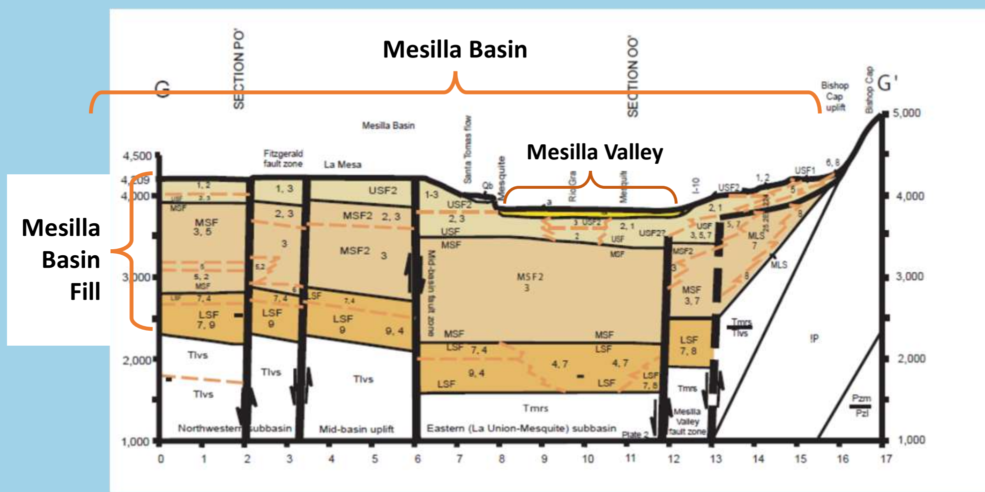


Barroll Rebuttal, App A June 15, 2020 8

8

Cross Section: West to East

River valleys, with thin riverine alluvial sediments, incised into larger deep basins

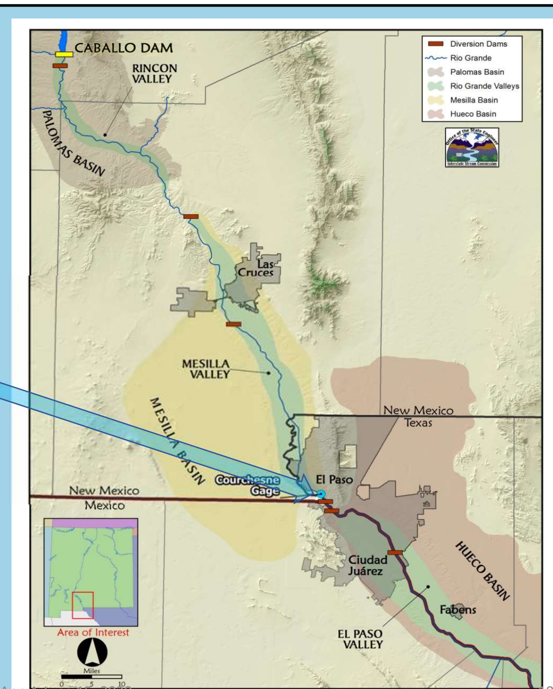


9

Geography

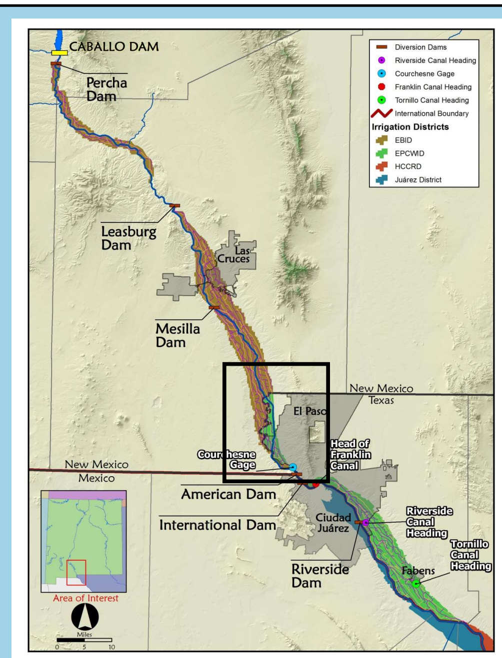
Natural dividing point at El Paso: Courchesne Gaging Station

Separates:
Mesilla Basin from Hueco Bolson
and
Mesilla Valley from El Paso Valley



10

Part of EPCWID is located above Courchesne, in the Mesilla Valley.



11

These Broad Areas Will be Explained in Detail

- Operations
  - Reservoir release calculated to meet orders, including gains and losses between reservoir and delivery points.
  - Districts order water to be delivered to their canal headings
  - Operational history: change in 1979, change in 2006
- Groundwater Pumping
  - 1950's drought: irrigation wells drilled throughout Project by farmers in response to insufficient Project Supply
- Project Allocation and Accounting
  - Before 1979 Reclamation allotted Project water directly to farmers
  - 1979 to present Reclamation allocates Project water to Districts
    - Districts allot water to farmers
  - Formal Project Accounting was created (post-1978 Accounting)

12

2. Entitlement and Delivery of Project Water Between Districts From Early Project until 2006

- Early Project through 1978
  - Each authorized acre equally entitled to order Project Water
  - Authorized Acreage split between Districts 57:43
  - Implicit split in Project water entitlement: 57:43
  - Actual District deliveries varied but were generally consistent with 57:43
- 1979 – 2005: Reclamation allocated water to Districts:
  - No formal operating agreement in place
  - Total Allocation based on D1/D2 Curve, developed using WDR delivery data from 1951 – 1978
  - Allocation split explicitly 57% to EBID, 43% to EPCWID
  - Actual District deliveries varied but were generally consistent with 57:43

Project Allocation and Accounting

Allocation determines how much water each District is entitled to order each year (prior to 1979 this took the form of allotment to farmers defining their order entitlement).

Accounting is a "post-fact" determination of how much of its Allocation each District actually received each year.

3. Change of Project Allocation in 2006

- Concerns about reduced Project delivery performance and the effects of NM groundwater pumping resulted in new Allocation Procedure:
  - EBID proposed D3 Allocation in 2006
  - EPCWID demanded Carryover of unused Allocation
  - Partially implemented starting in 2006
- Negotiation between Districts and US led to a settlement: the 2008 Operating Agreement (2008 OA)
- 2008 OA includes D3 Allocation plus Carryover
  - EPCWID is guaranteed Allocation consistent with D2 levels
  - All negative departures from the D2 Curve are taken out of EBID's Allocation
  - Any unused District Allocation (up to set limits) can be carried over into following year

4. Allocation and Delivery Amount Changes under D3 Allocation plus Carryover

- EBID's Allocation and diversion in full-supply years dropped by approximately one-third - more than 150,000 AF
- EPWCID's Allocation in full-supply years increased by approximately 20,000 AF, plus any allocation "carried over"
- On average, the split of Current-Year Allocation between the Districts changed from:
  - Pre-2006: 57% to EBID; 43% to EPCWID
  - 2006 – 2019: 43% to EBID; 57% to EPCWID
- On average, the split of Charged Diversions between the Districts changed from:
  - 1979 – 2006: 58% to EBID; 42% to EPCWID
  - 2006 – 2019: 47% to EBID; 53% to EPCWID

5. Cause of EBID's Allocation Reduction

EBID's Allocation is reduced for any negative departure from historical Project performance as defined by the D2 Curve.

- The US and TX argue that the negative departure from D2 is caused predominantly or entirely by excess groundwater pumping (or depletions) in New Mexico.
- New Mexico argues that part of the negative departure from D2 may indeed be caused by NM actions, but not ALL of that departure is caused by NM.
- Instead, NM argues that a significant part of the problems with Project Performance are caused by non-New Mexico factors.

17

6. Accounting Factors that Effect Project Performance

- The D2 Curve was developed from diversion data from 1951 – 1978.
- This diversion data is calculated very differently than current Charged Diversions. Charged Diversions omit diversions that were included in the D2 Curve.
- Under D3 Allocation, EBID's Allocation is reduced when total Charged Diversions fall short of the D2 Curve.

18

7. Accounting Factors

a) Off-Season Diversions

b) El Paso Valley Effluent

c) c) El Paso Valley Drain Flow

8. How do these Accounting Factors Affect the Distribution of Project Supply?

- Off-Season diversions: The D2 Curve is artificially inflated by the inclusion of flows that are no longer counted. Under D3 Allocation, EBID's allocation is reduced for any negative departure from the D2 Curve, therefore EBID's allocation is being artificially reduced.
- EPWU effluent: EPCWID diverts and uses the effluent it gets from EPWU in the El Paso Valley. Because this water use is not charged to EPCWID, the sum of the Charged Diversions is lower than it should be, increasing the discrepancy between Charged Diversion and the D2 Curve.
- El Paso Valley drain flow: Again, the D2 Curve is artificially inflated by the inclusion of flows that no longer exist or are no longer counted as Charged Diversions.

9. Effects of Pumping in the Hueco Bolson / El Paso Valley

- As in New Mexico, Texas groundwater pumping can
  - Reduce discharge of groundwater into drains, reducing Project Supply
  - Increase seepage from streams and canals, reducing Project efficiency

10. American Canal Extension Credit

- American Canal Extension (ACE) built to bypass a losing reach of the Rio Grande between American Dam and Riverside Canal heading.
- Losses in the reach of the Rio Grande were caused/exacerbated by groundwater pumping in the Hueco Bolson, largely by Texas.
- ACE mitigates these losses, but then EPCWID gets a credit for having done so (up to ~20,000 AF).
- ACE Credit applied under 2008 OA reduces EBID's Allocation.
- ACE Credit gives EPCWID (and thus Texas) a credit for mitigating a problem caused by Texas.

11. Effects of Carryover on EBID and New Mexico

- EBID's Allocation is now so low it can make little use of Carryover.
- EPCWID's Allocation in full-supply years is much higher than its demand, and so it can carry over large amounts of unused Allocation.
- Under the 2008 OA, Carryover plus water needed to deliver it is subtracted from Usable Water before performing Current-Year Allocation.
- Carryover accounts are never reduced for evaporation and may include paper water.
- EPCWID's large Carryover accounts have acted to reduce Current Year Supply and the amount of water allocated to EBID.

12. Net Effect of 2008 OA on EBID and New Mexico

- D3 Reduces Allocation to EBID
  - Reduces aquifer recharge from canal seepage
  - Increases need for groundwater pumping to meet demand
- Groundwater levels in Rincon and Mesilla valleys decline further
  - Drain flows decrease
  - River losses increase
- Further reduction in Project performance
- Further reduction in EBID's Allocation

Net Result: Vicious Cycle
(Double Whammy/Positive Feedback Loop as stated by Dr. Phil King)

13. US Claim: D3 Reallocation is Necessary to Offset NM Pumping Impacts on EPCWID and Protect EPCWID's Project Supply

- US provides no technical analysis to quantify the effect of NM pumping on Project Supply or EPCWID deliveries
- New Mexico pumping has not greatly increased since D2 Period
- A significant part of the apparent discrepancy from D2 is caused by factors other than New Mexico pumping

14. Neither TX nor US Refute Barroll Analysis Showing:

- Before 2006 EBID and EBID farmers were entitled to order 57% of US Project Supply.
- Before 2006 the actual distribution of Project Supply between the Districts was approximately 57% to EBID and 43% to EPCWID.
- Starting in 2006 there was a large reduction in the share of Project Supply allocated to EBID and the share of water EBID received.
- The large reallocation that began in 2006 is due to the new D3 Allocation method plus Carryover,
  - D3 Allocation reduces EBID's Allocation for all negative departures in Project performance from historical levels defined by the D2 Curve.
- A significant part of the negative departure from D2 is caused by changes in Project Accounting and other factors not related to New Mexico.

15. Neither TX nor US Refute Barroll Analysis Showing:

- EBID's Allocation is now so low that it is impossible for EBID to take advantage of Carryover.
- EPCWID has been able to create large Carryover accounts from its unused allocation in full-supply years. Part of the reason EPCWID can accumulate large amounts of unused Allocation is because it can now use El Paso municipal effluent in the El Paso Valley - free of charge.
- Carryover is never reduced for evaporation. Carryover may include paper water. EPCWID's large Carryover account can reduce the amount of water available for Current-Year Allocation, and thus the amount of water allocated to EBID.

37

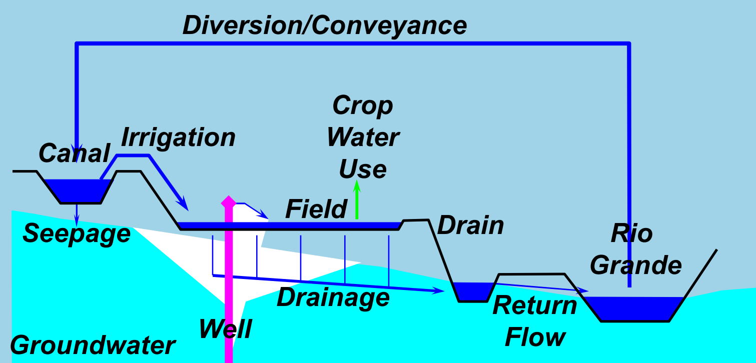
Project Infrastructure: Wasteways

Conveyances used to return unused water to the Rio Grande

- Waste: excess water needed to
  - Push deliveries throughout system
  - Keep level of water in canal high enough to allow gravity flow into farm ditches
- Bypass water historically transported through canals rather than in riverbed for reasons of efficiency
  - El Paso Carriage in New Mexico, Ascarate Wasteway in Texas.

38

Rio Grande Project Water Distribution Cycle (from King, 2003)

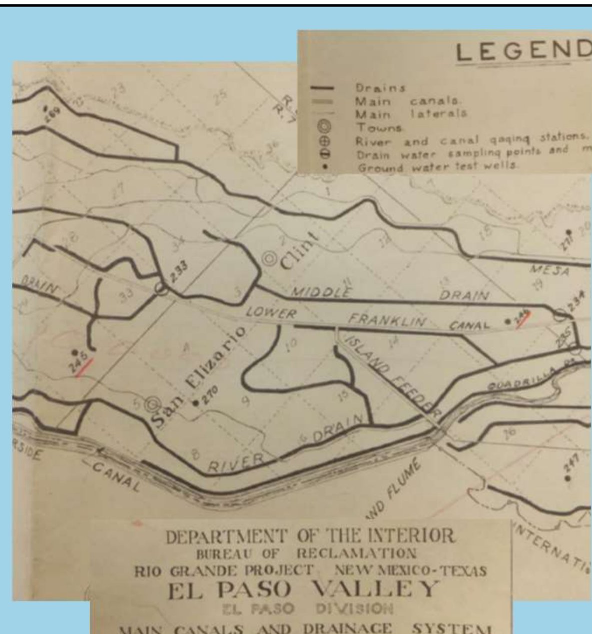


King 2003

39

Project Infrastructure: Drains

- Drains take in groundwater from water-logged lands, and return that water to Rio Grande
- Drains were installed from about 1918 – 1925 throughout entire Project
- Drain flow returning to Rio Grande above a Project canal heading is diverted and used within the Project (a form of Project return flow)

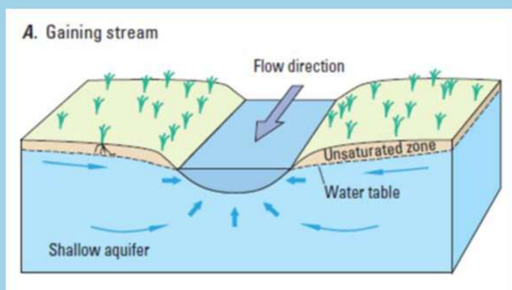


Map from the Papers of Raymond Hill

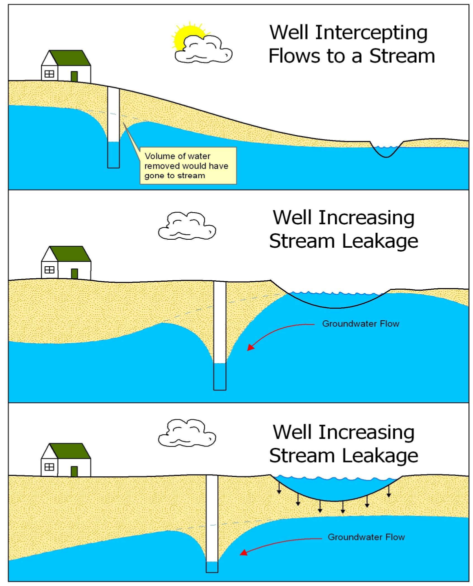
40

Drains

Active drains are "gaining streams"
Like streams, their flows can be depleted by groundwater pumping



MMA 2019



Importance of Drains

- Drains represent direct groundwater-surface water interaction
- Drain flows are a direct measurement of groundwater discharge
- Drain flows are directly dependent on groundwater levels

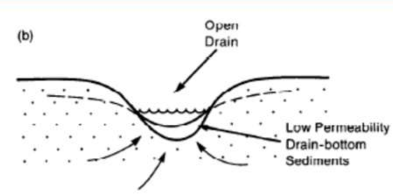


Figure 40.—Factors affecting head loss immediately around a drain: (a) buried drain pipe in backfilled ditch and (b) open drain.

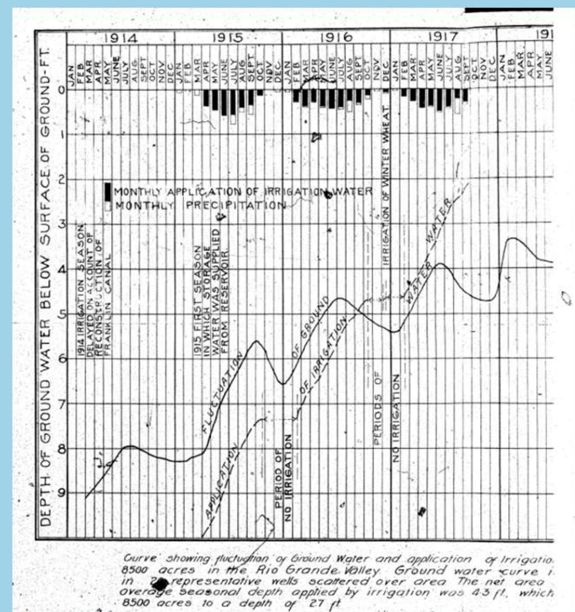
McDonald and Harbaugh, 1988, USGS Techniques of Water Resource Investigations, Chapter A1, A Modular Three-Dimensional Finite-Difference Groundwater Model (MODFLOW).

Importance of Drains to Project

- In the early years of the Project, excess application of irrigation water throughout the Project caused water levels to rise, waterlogging lands
- Eventually over 450 miles of drains were installed, salvaging and protecting these lands



Rio Grande Project History 1918

Importance of Drains to LRG Studies

- Accurate groundwater discharge/recharge measurements are vital to developing a well-supported groundwater measurement.
- Drain flows are a great measure of groundwater discharge (although minor amounts of waste or storm flow are included in measurements)
- Groundwater discharge to Rio Grande main stem, or seepage from the Rio Grande, is much more difficult to measure accurately due to the large amount of surface water that is flowing through “on top of” any surface water - groundwater interaction.

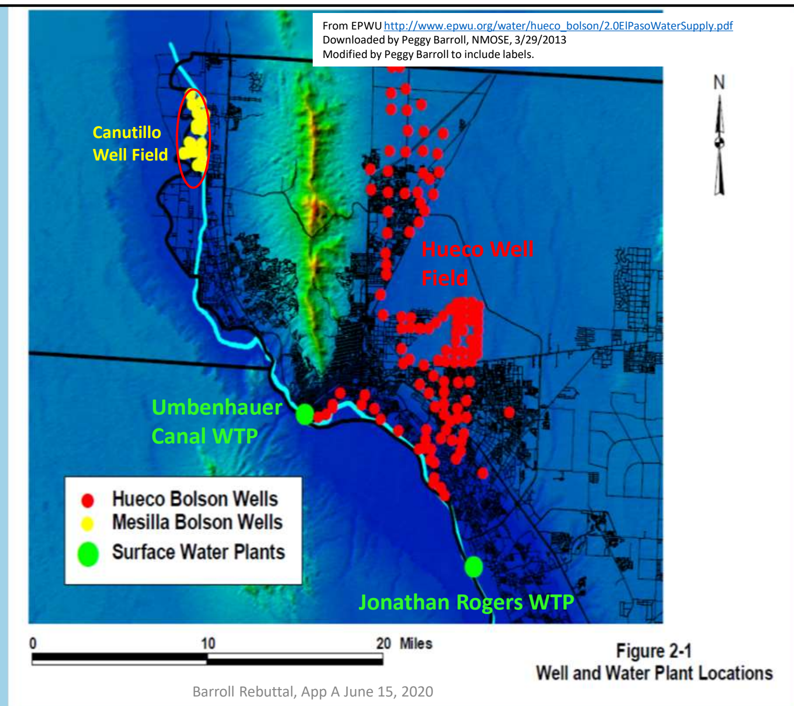

Figure 2-1
Well and Water Plant Locations

General Project Operations

- Reclamation allots or allocates water to Project beneficiaries and Mexico
- Mexico's Allocation is delivered according to a schedule provided by the US State Department
- EBID and EPCWID order water from Reclamation on an ongoing basis during the irrigation season
- Reclamation releases water from reservoir storage as necessary to meet orders
- Districts divert water at canal headings
- Ditch riders deliver water to farmers

Project Operations

District/Project Level

- Districts order water from Reclamation to be delivered to main canal headings
- A District may continue to order water until it has used up its Allocation
- Releases from reservoir Storage are made in response to orders
- Amount released is the amount needed to deliver District orders to the canal heading, considering Supply already in the system

Project Orders

- Districts order water in terms of cubic feet per second (cfs) at their canal headings
- Reclamation will adjust the gate at Caballo Dam as necessary for the release rate in order to get the orders to the canal headings
  - If there are losses along the way, Reclamation increases the Caballo release accordingly
  - If there are gains along the way, Reclamation decreases the Caballo release accordingly

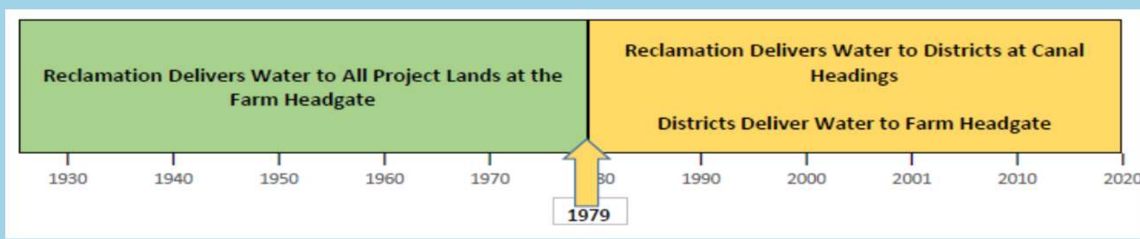
Overview of Operational History

Two major regimes:

- Pre-1979: Reclamation delivered water to farmers, operating Project as one entity
- 1979 forward: After the Districts payed off Project construction loans, Transfer Contracts were executed. Now Reclamation delivers water to Districts, and the Districts deliver water to farmers



59

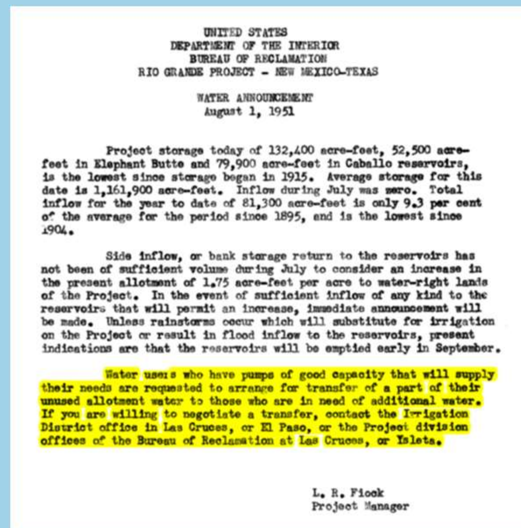
Irrigation Wells in the Rio Grande Project

- Farmers throughout the Project drilled irrigation wells during 1950's drought
- Irrigation wells drilled during 1950's drought:
  - EBID: ~1,200 wells
  - EPCWID: ~750 wells
- Reclamation encouraged farmers to use well water if possible
- Reclamation helped farmers use Project conveyances to distribute well water
- Probably (almost) all irrigated acres within Project received well water during 1950's drought

60

Quotes from Project Announcements

1951: “Water users who have pumps of good capacity that will meet their needs are requested to arrange for transfer of a part of their unused allotment water to those who are in need of additional water.”



UNITED STATES
DEPARTMENT OF THE INTERIOR
BUREAU OF RECLAMATION
RIO GRANDE PROJECT - NEW MEXICO-TEXAS

WATER ANNOUNCEMENT
August 1, 1951

Project storage today of 132,400 acre-feet, 52,500 acre-feet in Elephant Butte and 79,900 acre-feet in Caballo reservoirs, is the lowest since storage began in 1915. Average storage for this date is 1,161,900 acre-feet. Inflow during July was zero. Total inflow for the year to date of 81,300 acre-feet is only 9.3 per cent of the average for the period since 1895, and is the lowest since 1904.

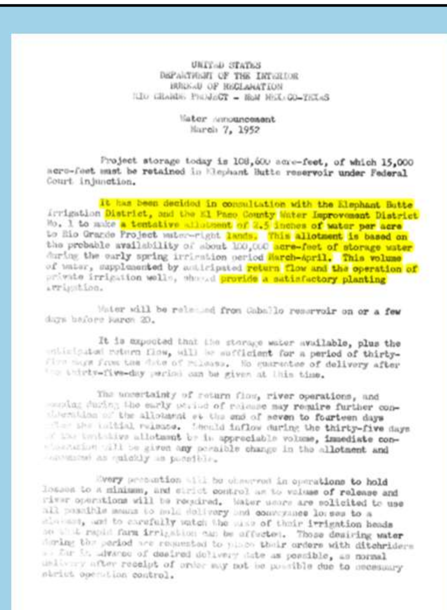
Side inflow, or bank storage return to the reservoirs has not been of sufficient volume during July to consider an increase in the present allotment of 1.75 acre-feet per acre to water-right lands of the Project. In the event of sufficient inflow of any kind to the reservoirs that will permit an increase, immediate announcement will be made. Unless rainstorms occur which will substitute for irrigation on the Project or result in flood inflow to the reservoirs, present indications are that the reservoirs will be emptied early in September.

Water users who have pumps of good capacity that will supply their needs are requested to arrange for transfer of a part of their unused allotment water to those who are in need of additional water. If you are willing to negotiate a transfer, contact the Irrigation District office in Las Cruces, or El Paso, or the Project division offices of the Bureau of Reclamation at Las Cruces, or Isleta.

L. R. Fiock
Project Manager

Quotes from Project Announcements

1952: “It has been decided … to make a tentative allotment of 2.5 inches of water per acre… This volume of water, supplemented by anticipated return flow **and the operation of private irrigation wells**, should provide a satisfactory planting irrigation.”



UNITED STATES
DEPARTMENT OF THE INTERIOR
BUREAU OF RECLAMATION
RIO GRANDE PROJECT - NEW MEXICO-TEXAS

Water Announcement
March 7, 1952

Project storage today is 108,600 acre-feet, of which 15,000 acre-feet must be retained in Elephant Butte reservoir under Federal Court injunction.

It has been decided in consultation with the Elephant Butte Irrigation District, and the El Paso County Water Improvement District No. 1 to make a tentative allotment of 2.5 inches of water per acre to Rio Grande Project water-right lands. This allotment is based on the probable availability of about 100,000 acre-feet of storage water during the early spring irrigation period March-April. This volume of water, supplemented by anticipated return flow and the operation of private irrigation wells, should provide a satisfactory planting irrigation.

Water will be released from Caballo reservoir on or a few days before March 20.

It is expected that the storage water available, plus the anticipated return flow, will be sufficient for a period of thirty-five days from the date of release. No guarantee of delivery after the thirty-five-day period can be given at this time.

The uncertainty of return flow, river operations, and [illegible] during the early period of release may require further consideration of the allotment at the end of seven to fourteen days after the initial release. Should inflow during the thirty-five days of the tentative allotment be in appreciable volume, immediate consideration will be given any possible change in the allotment and announced as quickly as possible.

Every precaution will be observed in operations to hold losses to a minimum, and strict control as to volume of release and river operations will be required. Water users are solicited to use all possible means to hold delivery and conveyance losses to a minimum, and to carefully watch the size of their irrigation heads so that rapid farm irrigation can be effected. Those desiring water during the period are requested to place their orders with ditchriders as far in advance of desired delivery date as possible, as normal delivery after receipt of order may not be possible due to necessary strict operation control.

Quotes from Project Operations and Maintenance Reports

Ysleta Branch (El Paso Valley) 1954 : "The year 1954 was one of the most favorable on record… reservoir storage … allowed only a 5 inch allotment to start the season… increased to a total of ½ acre foot by the end of the release period. This supply, together with several small storm flows…, drain return flow, **and water from 418 irrigation wells, installed since 1950, was enough irrigation water for almost normal requirements**."

Emphasis added

OPERATION AND MAINTENANCE OF IRRIGATION SYSTEM - 1954
YSLETA BRANCH

General Conditions

The year 1954 was one of the most favorable on record for growing cotton, and as a result the yields were record breaking. Gross farm incomes were only slightly less than the previous year. This was in spite of a reduction in cotton acreage, a very small water allotment, slightly lower cotton prices, poor alfalfa yields, and low alfalfa prices. The season started with reservoir storage at about 17 per cent of normal, which allowed only a 5 inch allotment to start the season. As very little additional inflow became available the allotment was increased to a total of 1/2 acre foot by the end of the release period. This supply, together with several small storm flows originating below Caballo Reservoir, during July and August, drain return flow, and water from some 418 irrigation wells, installed since 1950, was enough irrigation water for almost normal requirements.

The Ysleta branch of the Rio Grande Project is located along the Rio Grande River in the extreme Western tip of Texas, in El Paso County. It extends from the American Dam, which is 2 1/2 miles above the heart of the City of El Paso, to 41 miles below the city, in a Southeastern direction, to the El Paso-Hudspeth County line. The Branch is comprised of 63,739 acres of irrigable and highly productive land, it lies immediately North and East of the Rio Grande channel which marks the international boundary between the United States and Mexico.

The Branch headquarters are located at Ysleta, Texas, 12 1/2 miles East of downtown El Paso. It is comprised of an office building, machine shop, carpenter shop, storage buildings, sheds, caretakers house, and sufficient yard storage space for normal operation and maintenance activities.

The headquarters staff is comprised of an Irrigation Superintendent, two Maintenance Supervisors, two Watermasters, one Supervisory Engineering Aide, two Engineering Aides, two General Clerks, a Clerk-Stenographer, and a Storekeeper.

The elevation of the area is between 3,500 ft. and 3,650 ft. above sea level. The climate may be classified as mild, with a mean annual temperature of 61.6 degrees F., with winter temperatures varying from -6 degrees to a maximum of 86 degrees. Summer temperatures range from a minimum of 46 degrees to a maximum of 108 degrees. Average rainfall is 8.86 inches, of which more than half occurs in July, August, and September. The average frost-free period is 242 days; however, the minimum has been 176 days. Adequate storage capacity in Elephant Butte and Caballo reservoirs is a very favorable factor in providing irrigation water for the project.

Quotes from Project Operations and Maintenance Reports

Las Cruces Branch (Rincon/Mesilla Valley) 1954: "Storage water carryover was so limited that even the first irrigation had to be made with a combination of water pumped from wells and water from the storage supply…

So with the limited storage water**, water pumped from farm wells, and conveyed in part through the project canals and laterals**, and the summer showers, a combination that made possible the production of one of the best yielding crops ever produced by this Branch."

Emphasis added

OPERATION AND MAINTENANCE OF IRRIGATION SYSTEM - 1954
Las Cruces Branch

The water users and Bureau personnel again faced a severe year from the point of available water supply, in fact the storage water carryover was so limited that even the first irrigation had to be made with a combination of water pumped from farm wells and water from the storage supply.

This drought condition was greatly alloviated from mid summer on by some providential showers, that not only benefited the crops direct but also caused floods in the Rio Grande which were diverted and used to good advantage. So, with the limited storage water, water pumped from farm wells, and conveyed in part through the project canals and laterals and the summer showers, a combination that made possible the production of one of the best yeilding crops ever produced by this Branch.

The Las Cruces Branch consists of two long, narrow valleys bordered on each side by desert mesa land and in some places by low-lying hills. The Rio Grande flows through these valleys, dividing the farm lands and making it necessary to pass the irrigation water over the river through flumes and under the river through siphons.

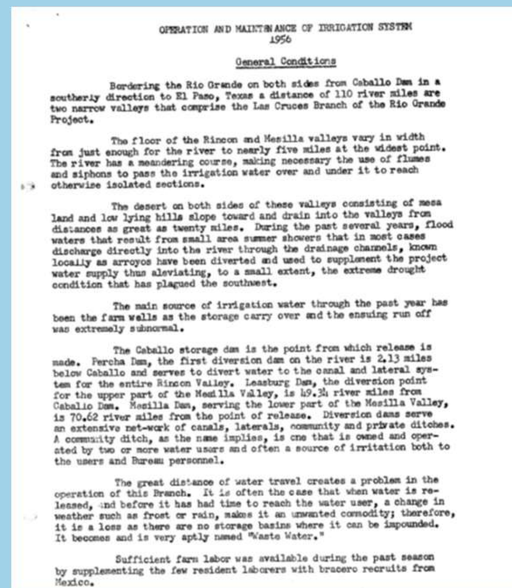
The Caballo storage dam is the point from which release is made. Percha Dam, the first diversion dam on the river, is 2.13 miles below Caballo and serves to divert water to the canal and lateral system for the entire Rincon Valley. Leasburg Dam, the diversion point for the upper part of the Mesilla Valley, is 49.34 river miles from Caballo Dam. Mesilla Dam, serving the lower part of the Mesilla Valley, is 70.62 river miles from the point of release. Diversion dams serve an extensive network of canals, laterals, community and private ditches. A community ditch, as the name implies, is one that is owned and operated by two or more water users and often a source of irritation both to the users and Bureau personnel.

The great distance of water travel creates a problem in the operation of this Branch. It is often the case that when water is released, and before it has had time to reach the water user, a change in weather such as frost or rain, makes it an unwanted commodity; therefore it is a loss as there are no storage basins where it can be impounded. It becomes and is very aptly named "waste water".

Transportation is sufficient in these two valleys; they are traversed by railroad, truck, and bus lines; also, there is an airport near Las Cruces with a daily schedule connecting with transcontinental travel to the north and south. The State and County highway systems have been improved during the past year and are now ample to care for all traffic and movement of crops from farm to market.

Quotes from Project Operations and Maintenance Reports

Las Cruces Branch 1956 : “The main source of irrigation water through the past year has been the farm wells as the storage carry over and the ensuing run off was extremely subnormal”



OPERATION AND MAINTENANCE OF IRRIGATION SYSTEM
1956

General Conditions

Bordering the Rio Grande on both sides from Caballo Dam in a southerly direction to El Paso, Texas a distance of 110 river miles are two narrow valleys that comprise the Las Cruces Branch of the Rio Grande Project.

The floor of the Rincon and Mesilla valleys vary in width from just enough for the river to nearly five miles at the widest point. The river has a meandering course, making necessary the use of flumes and siphons to pass the irrigation water over and under it to reach otherwise isolated sections.

The desert on both sides of these valleys consisting of mesa land and low lying hills slope toward and drain into the valleys from distances as great as twenty miles. During the past several years, flood waters that result from small area summer showers that in most cases discharge directly into the river through the drainage channels, known locally as arroyos have been diverted and used to supplement the project water supply thus aleviating, to a small extent, the extreme drought condition that has plagued the southwest.

The main source of irrigation water through the past year has been the farm wells as the storage carry over and the ensuing run off was extremely subnormal.

The Caballo storage dam is the point from which release is made. Percha Dam, the first diversion dam on the river is 2.13 miles below Caballo and serves to divert water to the canal and lateral system for the entire Rincon Valley. Leasburg Dam, the diversion point for the upper part of the Mesilla Valley, is 49.34 river miles from Caballo Dam. Mesilla Dam, serving the lower part of the Mesilla Valley, is 70.62 river miles from the point of release. Diversion dams serve an extensive net-work of canals, laterals, community and private ditches. A community ditch, as the name implies, is one that is owned and operated by two or more water users and often a source of irritation both to the users and Bureau personnel.

The great distance of water travel creates a problem in the operation of this Branch. It is often the case that when water is released, and before it has had time to reach the water user, a change in weather such as frost or rain, makes it an unwanted commodity; therefore, it is a loss as there are no storage basins where it can be impounded. It becomes and is very aptly named "Waste Water."

Sufficient farm labor was available during the past season by supplementing the few resident laborers with bracero recruits from Mexico.

Contemporaneous Estimates of Irrigation Well Pumping during 1950’s drought

- EBID:
  - Estimated maximum: 294,000 AF/yr
  - Gunaji 1961 (NM State University/EBID)

- El Paso Valley:
  - Estimated maximum: 125,000 AF/yr
  - Leggat 1962 (Texas Water Commission/USGS)

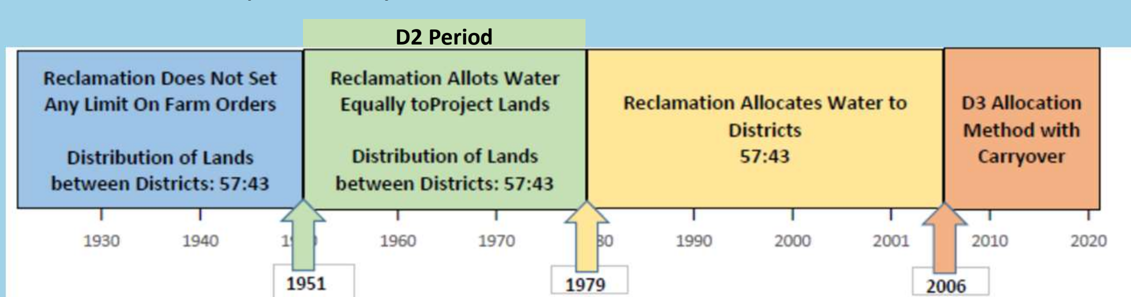
Project Allocation and Accounting

Allocation determines how much water each District is entitled to order each year (prior to 1979 this took the form of allotment to farmers defining their order entitlement).

Accounting is a "post-fact" determination of how much of its Allocation each District actually received each year.

Project Allocation

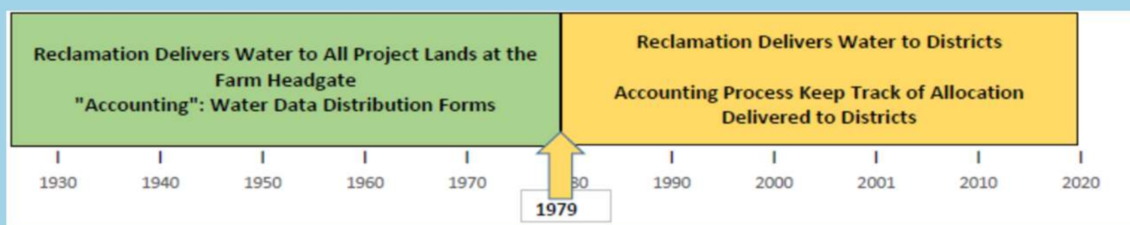
- Pre-1979: Reclamation allots equal water to all Project Acres
- 1979 – 2005: Reclamation allocates water to Districts 57:43
- 2006 – 2018: Reclamation allocates water to Districts using D3 Method plus Carryover



Project Accounting:
How the Project Keeps Track of Who Got What

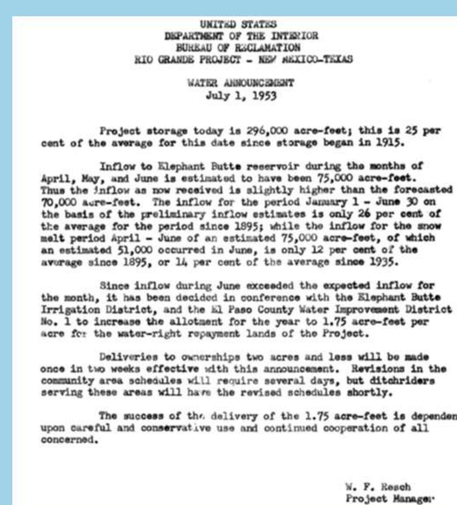
- Pre-1979: Reclamation kept track of diversions by "Units" or "Valleys" (not Districts) in Water Distribution Records (WDR)

- From 1979 on: Each District calculates its Charged Diversions using complex calculations determined by Accounting rules.



Early Allocation and Accounting: Before 1979

- Reclamation operated Project as one entity, and delivered water to farm headgates
- Allocation:
  - Starting in approximately 1951 Reclamation set limiting allotments for farm deliveries (in terms of acre-feet per acre)
  - Every authorized acre entitled to delivery of same amount water.
  - In the early 1950's Reclamation determined a full-supply allotment to be 3.024 AF/A based on data from 1946 – 1950.
- "Accounting":
  - Reclamation keep track of deliveries to "Units" or "Valleys"
  - Issued Water Distribution Reports (WDRs)



UNITED STATES
DEPARTMENT OF THE INTERIOR
BUREAU OF RECLAMATION
RIO GRANDE PROJECT - NEW MEXICO-TEXAS

WATER ANNOUNCEMENT
July 1, 1953

Project storage today is 296,000 acre-feet; this is 25 per cent of the average for this date since storage began in 1915.

Inflow to Elephant Butte reservoir during the months of April, May, and June is estimated to have been 75,000 acre-feet. Thus the inflow as now received is slightly higher than the forecasted 70,000 acre-feet. The inflow for the period January 1 - June 30 on the basis of the preliminary inflow estimates is only 26 per cent of the average for the period since 1895; while the inflow for the snow melt period April - June of an estimated 75,000 acre-feet, of which an estimated 51,000 occurred in June, is only 12 per cent of the average since 1895, or 14 per cent of the average since 1935.

Since inflow during June exceeded the expected inflow for the month, it has been decided in conference with the Elephant Butte Irrigation District, and the El Paso County Water Improvement District No. 1 to increase the allotment for the year to 1.75 acre-feet per acre for the water-right repayment lands of the Project.

Deliveries to ownerships two acres and less will be made once in two weeks effective with this announcement. Revisions in the community area schedules will require several days, but ditchriders serving these areas will have the revised schedules shortly.

The success of the delivery of the 1.75 acre-feet is dependent upon careful and conservative use and continued cooperation of all concerned.

W. F. Resch
Project Manager

Early Project "Accounting" Data
Reclamation Water Distribution Records (WDRs)

- Reclamation Records
- Until 1979 this was the only "Accounting" data.
- Reports delivery of Project Supply at the level of "Units" or "Valleys" (not Districts)
- Net Supply (or River Headgate diversion RGH): Diversion at canal headings adjusted for by-pass
- Additional terms in El Paso Valley

71

Later Allocation and Accounting: 1979 - Present

- Reclamation delivers water to District canal heads, Districts deliver water to farmers
- Allocation:
  - Reclamation allocates to Districts (in terms of acre-feet) for diversion into canal headings
  - Until 2006, D2 Allocation Method split between Districts explicitly 57:43.
  - 2006 to present: D3 Allocation Method (**not** 57:43)
- Accounting:
  - Complex Post-1978 Accounting developed to track deliveries to Districts
  - Assorted credits evolved through time
  - Districts perform this Accounting

72

Post-1978 Project Accounting

Each District performs its own monthly accounting

- Charged Diversions (Allocation charges) are based on amount ordered/diverted by each District at its charge points (canal headings)
- Complex accounting determines charges to each District for water delivered in southern Mesilla Valley
- Adjustments are made for credits
- When only one District is in operation, that District is charged for the amount released from Storage, not the amount it diverted
- Notes:
  - Districts do not always order their entire Allocation
  - Not all water diverted is charged

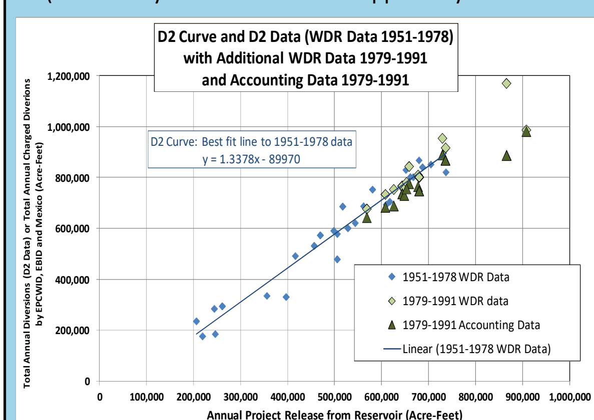
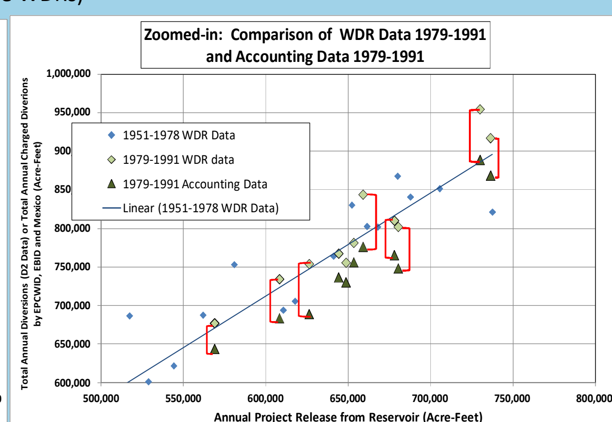
WDR Delivery Data is not Consistent with Post-1978 Accounting

There is a period of overlap, from 1979 – 1991 in which we have both kinds of data: Reclamation WDRs and post-1978 District Accounting.

(In the early 1990's the Districts apparently took over the WDRs)



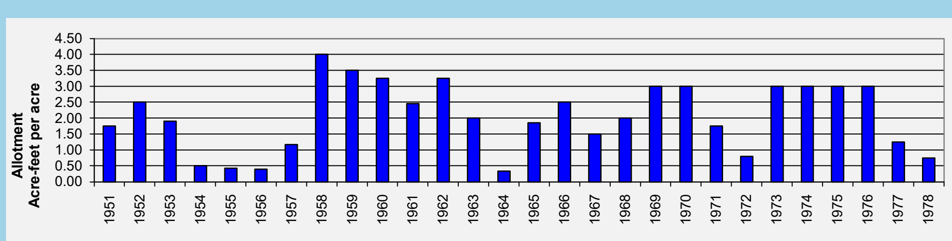


2. Entitlement and Delivery of Project Water between Districts From Early Project until 2006

- Early Project through 1978
  - Each authorized acre equally entitled to order Project Water
  - Authorized Acreage split between Districts 57:43.
  - Implicit split in Project water entitlement: 57:43
  - Actual District deliveries varied but were generally consistent with 57:43.
- 1979 – 2005: Reclamation allocated water to Districts:
  - No formal operating agreement in place
  - Total Allocation based on D1/D2 Curve, developed using WDR delivery data from 1951 – 1978
  - Allocation split explicitly 57% to EBID, 43% to EPCWID
  - Actual District deliveries varied but were generally consistent with 57:43

Pre-1979 Entitlement

- Reclamation allotted water to farms
- Every authorized Project acre entitled to equal water
  - No allotment limits set prior to 1951
  - 1951-1978 allotment (limit) set in terms of depth of water (acre-feet/acre or AF/A)
  - Authorized acreage breakdown
    - EBID: 88,000 Acres (+3% buffer, 90,640 acres) ~57%
    - EPCWID is 67,000 (+ 3% buffer, 69,010 acres) ~43%
  - <u>Thus the entitlement to water at the District level was 57:43</u>



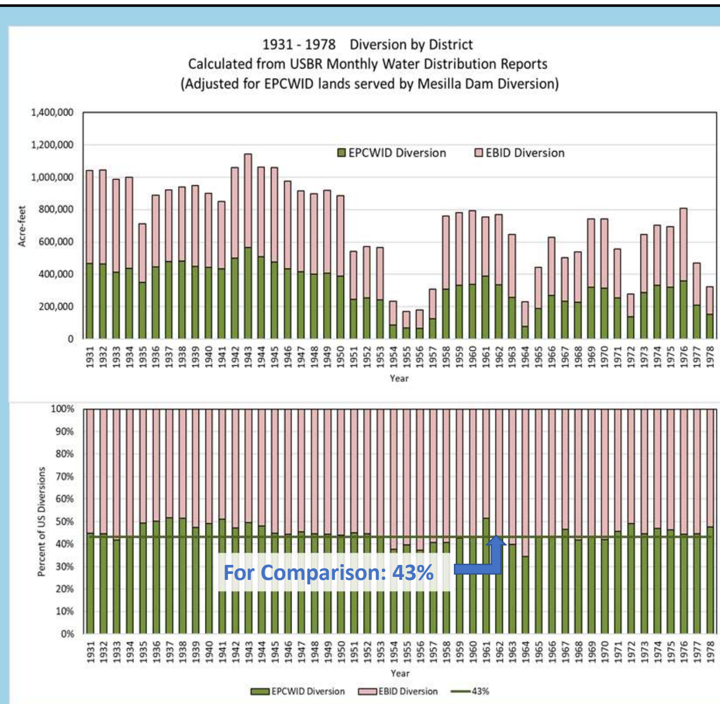
Allotment varied from year to year, but every authorized acre was entitled to the same amount.

Pre-1979 Diversions
(at Canal Headings)

Average 1931 – 1978
EBID: 55%
EPCWID: 45%

Average 1951 – 1978
EBID: 56%
EPCWID: 44%

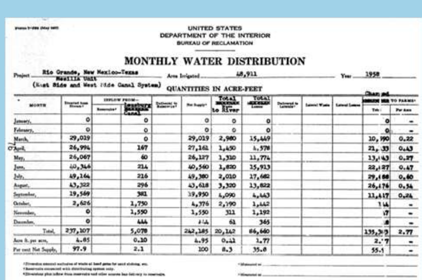
The amounts the Districts received from 1931 – 1978 was generally **consistent** with a 57:43 split.
Note: the amount a District received depends on the amount its farmers ordered.

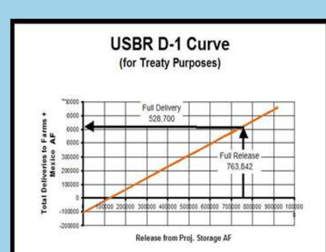


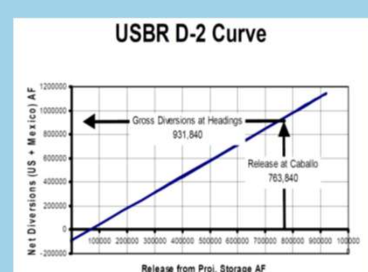
77

Post-1978 Project Allocation

- Reclamation starting allocating water to Districts in 1979
- Reclamation developed linear regressions between delivery data from WDRs for the period 1951 – 1978. These regressions are the D1 and D2 Curves.
- D1/ D2 Allocation method documented ~1990 in Water Supply Allocation Procedures document.





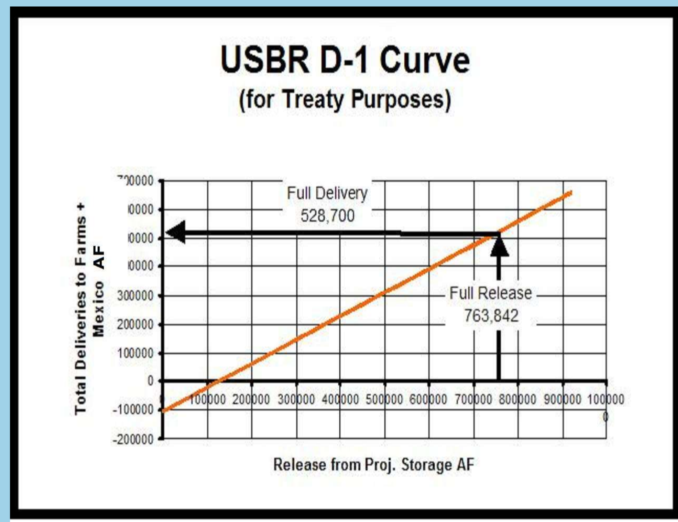


Barroll Rebuttal, App A June 15, 2020 78

78

D1 Curve

- Linear Regression of data from 1951 - 1978
- X-Axis: Release from Caballo
- Y-Axis: Delivery to Farm Headgates plus Mexican diversion
- Used to determine Mexico's share based on available water in reservoir Storage



From Cortez, 2003

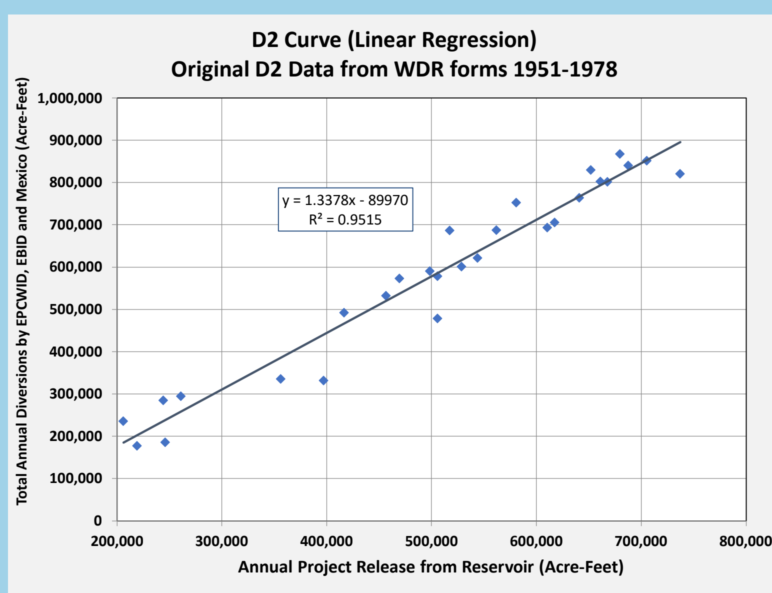
D2 Curve

A measure of Project performance or Project delivery efficiency

Linear Regression of Data from 1951 – 1978

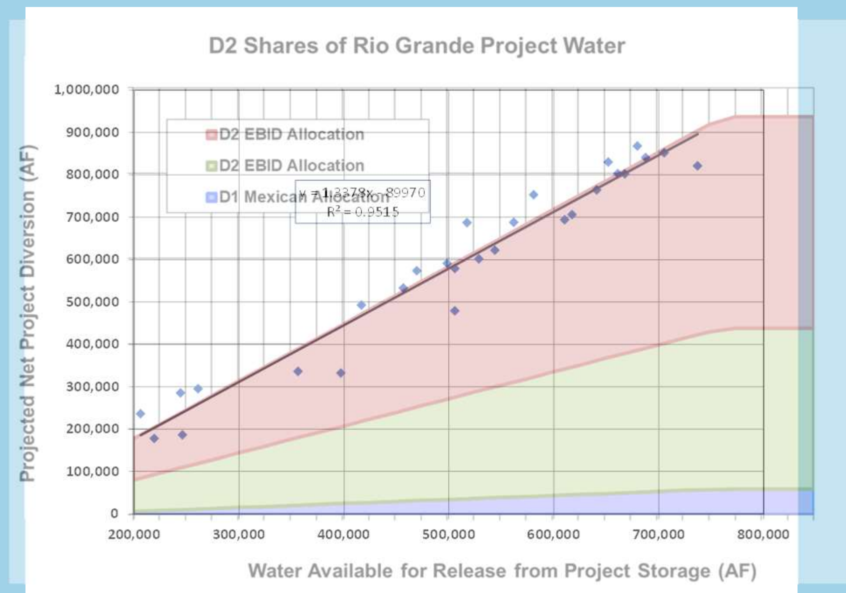
X-Axis: Annual Release from Caballo

Y-Axis: Annual Net Diversions by District and Mexico



Using the D2 Curve

Shares of Project Water to EBID, EPCWID and Mexico superimposed on D2 Curve



81

Using the D2 Curve

For a given Supply of Usable Water in Storage

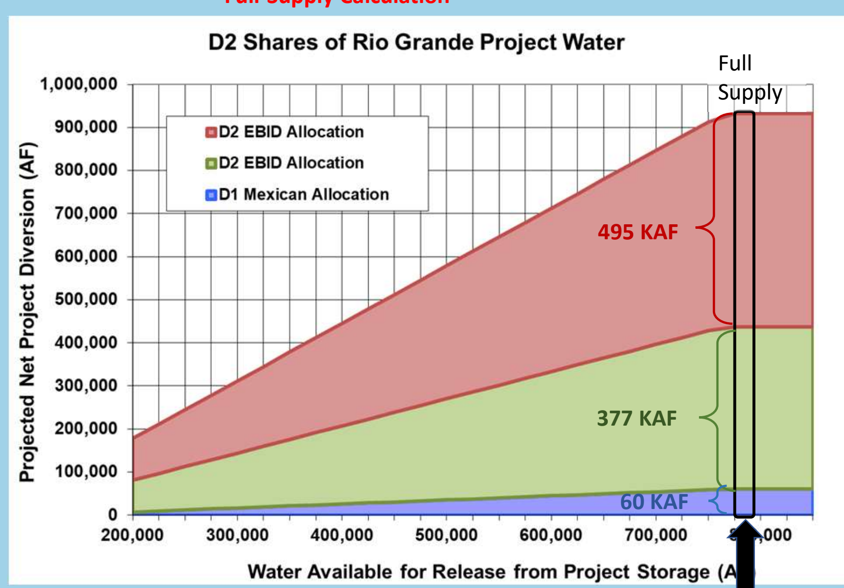
D2 Curve determines total Allocation amount (for diversion)

Mexico is assigned its share (using D1 Curve)

EBID and EPCWID split the rest 57:43.

Explicit 57:43 entitlement of Districts to order water

Full-Supply Calculation



82

Using the D2 Curve

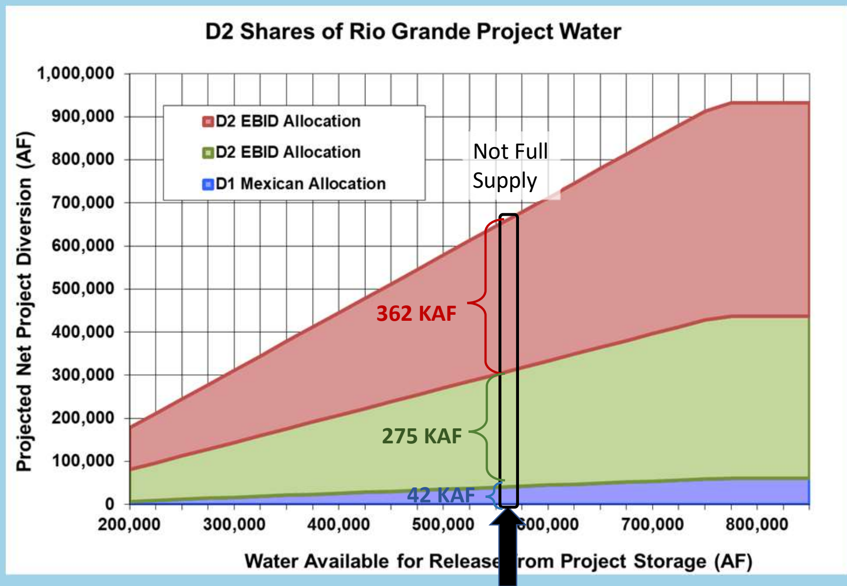
For a given Supply of Usable Water in Storage

D2 Curve determines total Allocation amount (for diversion)

Mexico is assigned its share (using D1 Curve)

EBID and EPCWID split the rest 57:43.

Explicit 57:43 entitlement of Districts to order water



Barroll Rebuttal, App A June 15, 2020 83

83

Using the D2 Curve

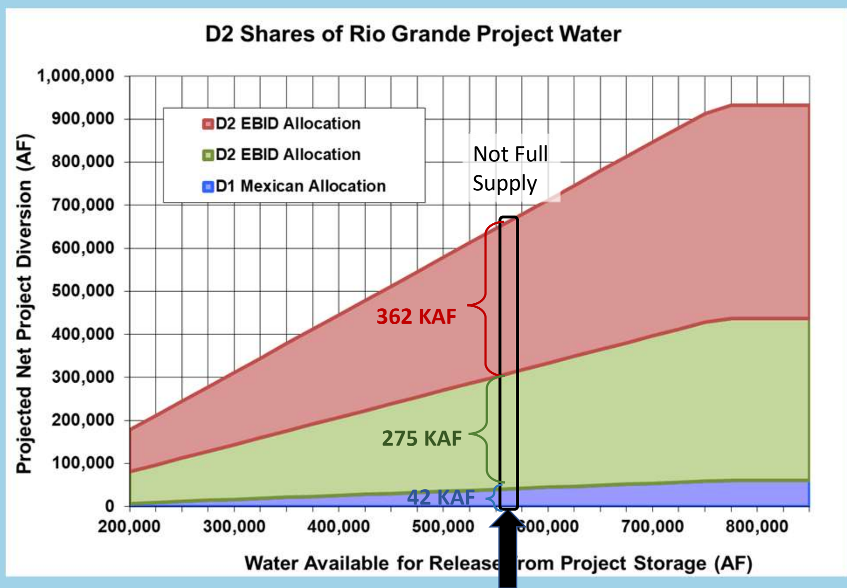
For a given Supply of Usable Water in Storage

D2 Curve determines total Allocation amount (for diversion)

Mexico is assigned its share (using D1 Curve)

EBID and EPCWID split the rest 57:43.

This works as long as the total amount of water you deliver for a given release falls close to the D2 Curve



Barroll Rebuttal, App A June 15, 2020 84

84

US_MSJ_00001045

3. Change of Project Allocation Method in 2006

- Concerns about reduced Project delivery performance and the effects on NM groundwater pumping resulted in new Allocation procedure:
  - EBID proposed D3 Allocation in 2006
  - EPCWID demanded Carryover of unused Allocation
  - Partially implemented starting in 2006
- Negotiation between Districts and US led to a settlement: the 2008 Operating Agreement (2008 OA)
- 2008 OA includes D3 Allocation plus Carryover
  - EPCWID guaranteed Allocation consistent with D2 levels
  - All negative departures from the D2 Curve are taken out of EBID's Allocation.
  - Any unused District Allocation (up to set limits) can be carried over into following year

Recap: Using the D2 Curve

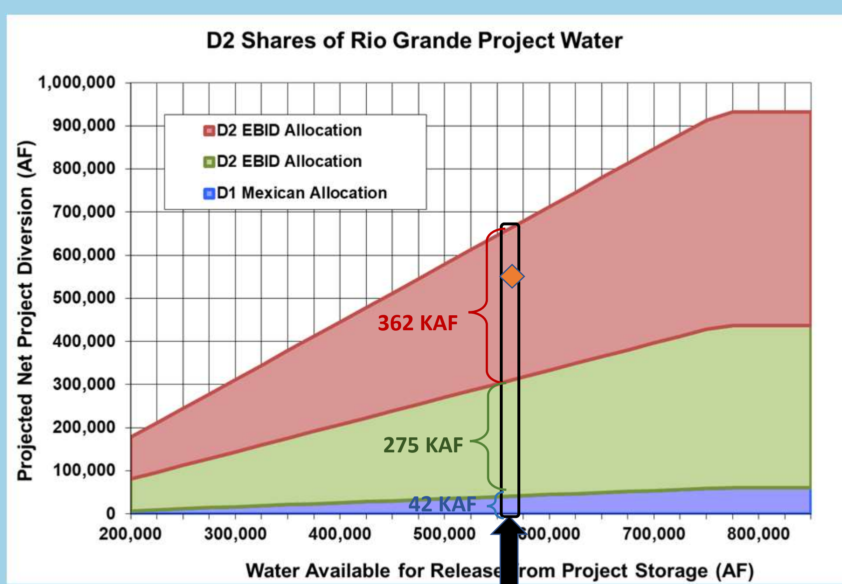
For a given Supply of Usable Water in Storage

D2 Curve determines total Allocation amount (for diversion)

Mexico is assigned its share (using D1 Curve)

EBID and EPCWID split the rest 57:43.

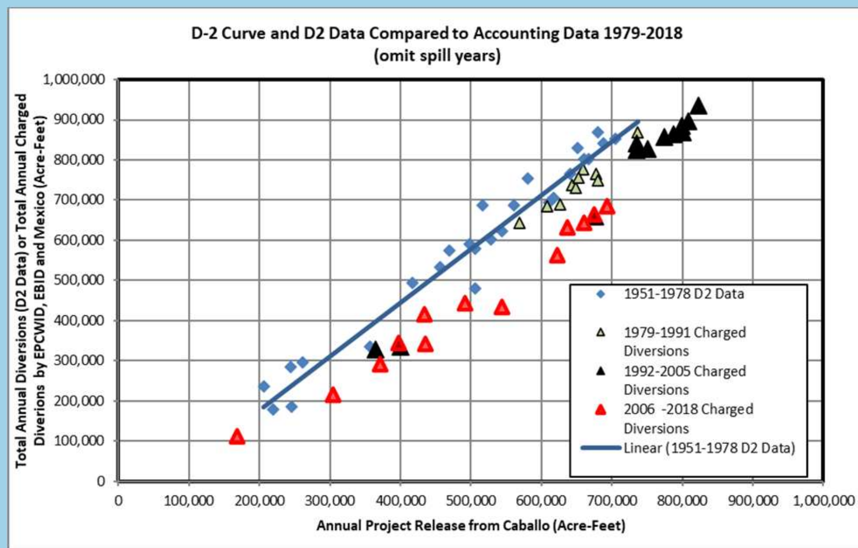
This works as long as the total amount of water you deliver for a given release falls close to the D2 Curve



Problem

Recent Total Charged Diversions calculated using Post-1978 Accounting Data all fall well below D2 line

This means that If Reclamation used the D2 Curve to determine total Allocations, it would be allocating more water than it can deliver (as Charged Diversions)



Barroll Rebuttal, App A June 15, 2020 87

87

District and Reclamation Solution to this Problem: D3 Allocation Method

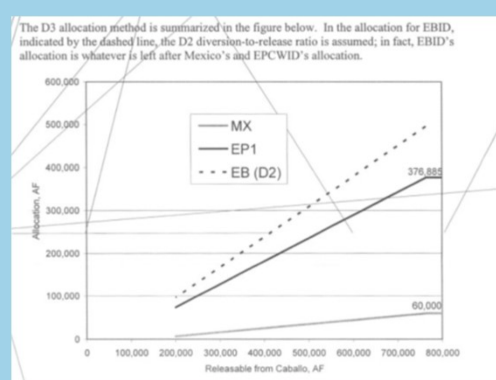
Connie Rupp, Area Manager
U.S. Department of the Interior
Bureau of Reclamation
555 Broadway Blvd. NE, Suite 100
Albuquerque, NM 87102-2352

Re: Allocation of Rio Grande Project Water.

Dear Ms. Rupp:

Our attorneys and consultants have been corresponding with the El Paso Water Improvement District No. 1 and your attorneys regarding the proposed "D-3 Curve". The Elephant Butte Irrigation District (hereinafter "EBID") hereby requests that the Bureau of Reclamation immediately implement a new allocation procedure that would assure equitable allocation of Project Water to El Paso County Water Improvement District No. 1 and the Republic of Mexico. We believe that the proposed D-3 Curve does this. EBID is concerned that the Bureau's current allocation method fails to ensure equity among Project Water users.

OFFICE OF THE
MAY 2006
STATE ENGINEER

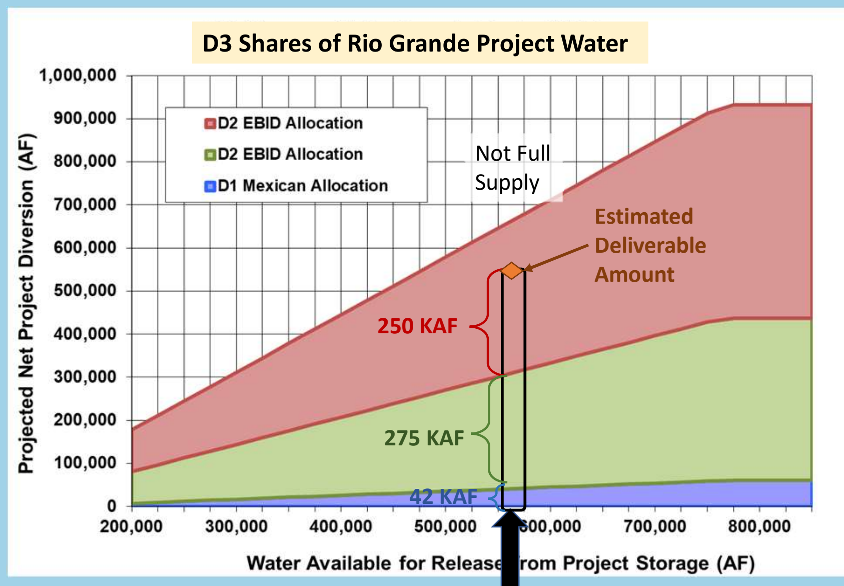


The D3 allocation method is summarized in the figure below. In the allocation for EBID, indicated by the dashed line, the D2 diversion-to-release ratio is assumed; in fact, EBID's allocation is whatever is left after Mexico's and EPCWID's allocation.

Barroll Rebuttal, App A June 15, 2020 88

88

D3 Allocation Method



For a given Supply of Usable Water in Storage:

- Mexico's Allocation still uses D1 Curve
- EPCWID's share is determined using D2 method
- Diversion Ratio is used to estimate how much water can really be delivered to canal headings as Charged Diversions
- Subtract Mexican and EPCWID Allocation
- EBID gets remainder

89

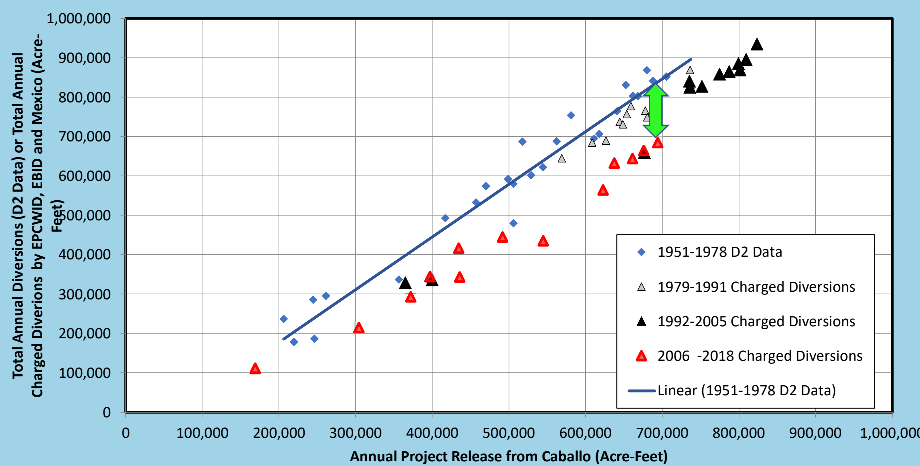
D3 Allocation using Diversion Ratio

- Diversion Ratio is calculated based on current Project performance
  - Used to estimate how much water can be delivered to Canal Headings as Charged Diversions
  - Determines EBID's Allocation
- Mexico still gets D1 Curve Allocation
- EPCWID Allocation approximately equal to what they did under D2
- EBID gets the remainder
- The entire discrepancy from D2 is subtracted from EBID's Allocation.

90

Under D3 EBID's Allocation is Reduced for the Entire Negative Departure from the D2 Curve

Recent Departures from D2 Curve are large



91

Carryover

- Demanded by EPCWID
- Ability for each District to keep unused Allocation from one year and carry it over into the next year
- Partially implemented in 2007
  - Litigation ensued

IN THE UNITED STATES DISTRICT COURT
FOR THE WESTERN DISTRICT OF TEXAS
EL PASO DIVISION

2007 JAN 22 AM 11:37

EL PASO COUNTY WATER IMPROVEMENT DISTRICT NO. 1, Plaintiff,

v.

ELEPHANT BUTTE IRRIGATION DISTRICT and the UNITED STATES OF AMERICA, DEPARTMENT OF THE INTERIOR, BUREAU OF RECLAMATION Defendants.

CAUSE NO. JUDGE PHILIP MARTINE

EP07CA002

COMPLAINT FOR DECLARATORY AND INJUNCTIVE RELIEF

TO SAID HONORABLE COURT:

NOW COMES Plaintiff, El Paso County Water Improvement District No. 1 (hereinafter, "EPCWID"), and files this Complaint for Declaratory and Injunctive Relief (the "Complaint") and would respectfully show the court as follows:

92

2008 Operating Agreement

- Arose from confidential Settlement Negotiations between Districts and US in 2007-2008
- Settled various on-going litigation
- Implemented D3 Allocation method using Diversion Ratio
- Implemented Carryover
  - Limits set on District Carryover: 60% of full supply Allocation
    - EPCWID: 232,915 AF
    - EBID: 305,918 AF
  - Any unused Allocation in excess of limit is transferred to other District

4. Allocation and Delivery Amount Changes under D3 Allocation plus Carryover

- EBID's Allocation and diversion in full-supply years dropped by approximately one-third, more than 150,000 AF/yr
- EPWCID's Allocation in full-supply years increased by approximately 22,000 AF/yr, plus any Allocation carried over
- On average, the split of Current-Year Allocation between the Districts changed from:
  - Pre-2006: 57% to EBID; 43% to EPCWID
  - 2006 – 2018: 44% to EBID; 56% to EPCWID
- On average, the split of Charged Diversions between the Districts changed from:
  - 1979 – 2006: 58% to EBID; 42% to EPCWID
  - 2006 – 2018: 47% to EBID; 53% to EPCWID

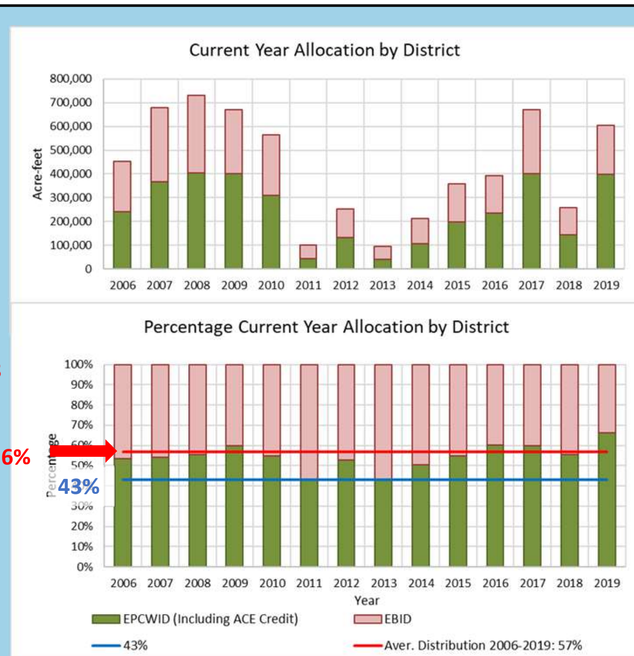
2006 – 2019 Entitlement:

Defined using new Allocation method

Allocation
(*Current Year, Omitting Carryover)

Average
EBID: 44%
EPCWID: 56%

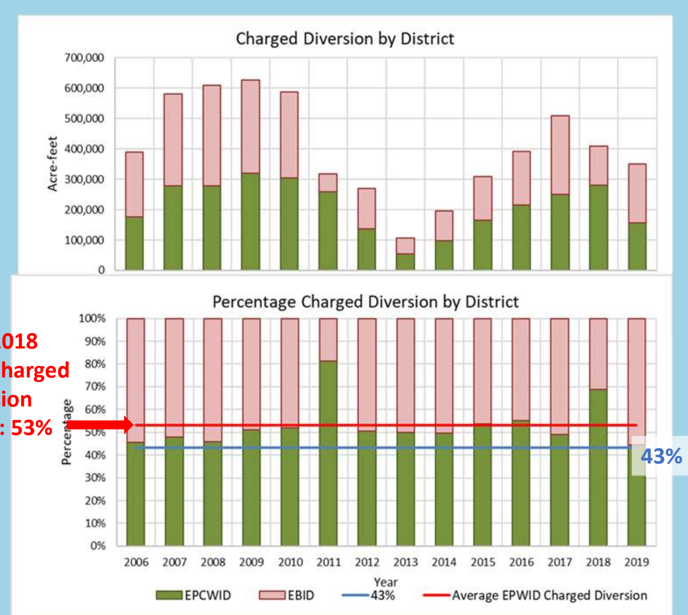
2006-2018 EPCWID Allocation Average: 56%



2006 – 2019 Delivery in terms of Charged Diversions

Averages:
EBID: 47%
EPCWID: 53%

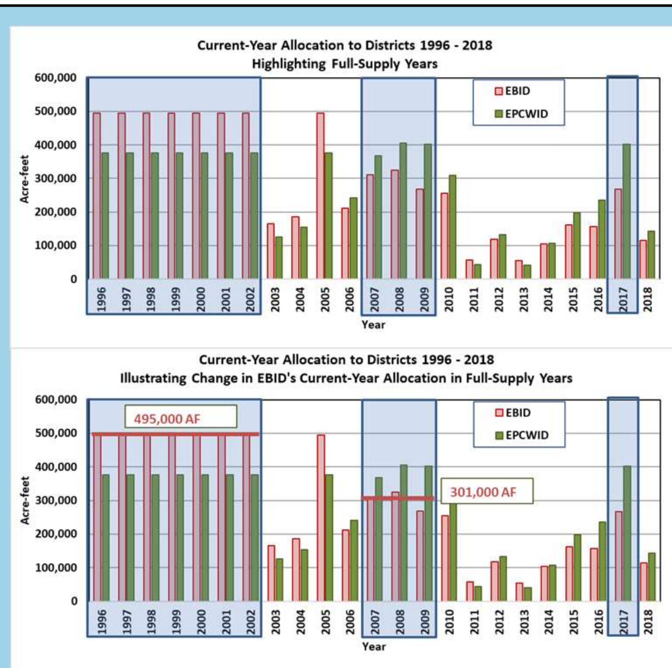
2006-2018 EPCWID Charged Diversion Average: 53%



Largest Redistributions Occur in Full-Supply Years

EBID's full-supply year Allocation* dropped from 495,000 AF to 301,000 AF
(Reduction: 194,000 AF)

*Current-Year Allocation



Barroll Rebuttal, App A June 15, 2020 97

97

EPCWID's Full-Supply Allocation

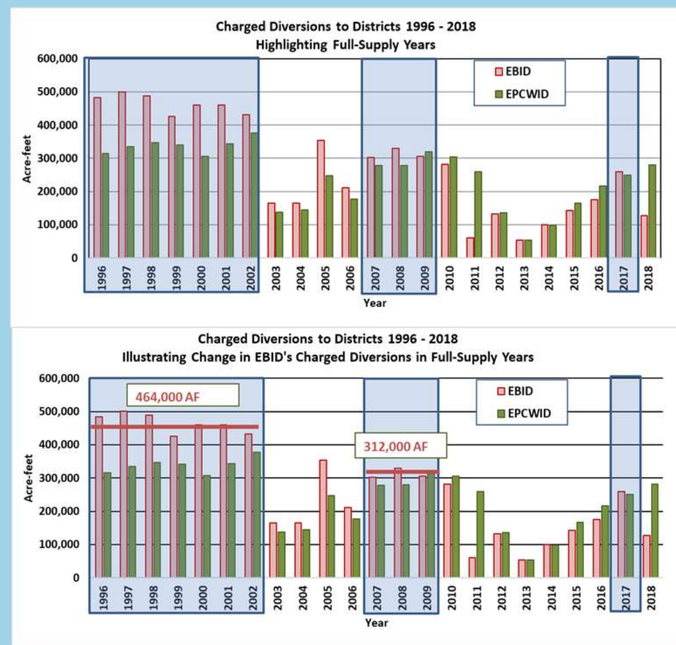
- Before 2006, Under D1/D2 Allocation, EPCWID's Allocation in full-supply years was **376,862 AF**
- Since 2006, under D3 Allocation, EPCWID's Allocation in full-supply years has been as high as **405,000 AF** (2008).
- Increase includes
  - Use of 790,000 as a Full-Supply Release values (instead of 763,800 AF previously)
  - American Canal Extension Credit (up to 20,000 AF)

Barroll Rebuttal, App A June 15, 2020 98

98

Largest Redistribution: Full-Supply Years

EBID's average diversion in full-supply years drops from 464,000 AF to 312,000 AF
(Reduction: 152,000 AF)



Barroll Rebuttal, App A June 15, 2020 99

99

EPCWID's Charged Diversion in Full-Supply Years

- 1996 – 2002 Average EPCWID Charged Diversion: **337,000** AF
- 2007 – 2009 Average EPCWID Charged Diversion: **293,000** AF
- Reduction in Charged Diversion in full-supply years may reflect reduction in demand, or desire to save water in EPCWID's Carryover Account

Barroll Rebuttal, App A June 15, 2020 100

100

How Much Water Does this Difference in Delivery Constitute?

If the actual Charged Diversions had been distributed 57:43, EBID would have diverted a total of 531,000 AF more water over these 14 years.

Table A.12.Rev1. Distribution of Charged Diversions between Districts
(Including revised 2018 and 2019 data, adding Totals, 57:43 Distribution, and Difference Calculations)

Year	Release from Caballo AF	EBID AF	EBID % of US Share	EPCWID AF	EPCWID % of US Share	Total US Diversions
2006	432,770	211,841	54%	177,183	46%	389,024
2007	636,993	302,665	52%	278,252	48%	580,917
2008	674,724	329,294	54%	279,173	46%	608,467
2009	693,289	305,475	49%	320,083	51%	625,558
2010	659,679	282,082	48%	304,937	52%	587,019
2011	396,444	59,771	19%	258,772	81%	318,543
2012	371,271	133,060	49%	136,380	51%	269,440
2013	168,201	54,002	50%	53,530	50%	107,532
2014	306,900	99,007	50%	97,418	50%	196,425
2015	435,483	143,404	46%	165,872	54%	309,276
2016	544,181	175,199	45%	216,309	55%	391,508
2017	622,467	259,510	51%	249,919	49%	509,429
2018	491,305	127,487	31%	280,674	69%	408,161
2019	453,564	194,510	56%	155,872	44%	350,382
Total Diversions		**2,677,307**	**47%**	**2,974,374**	**53%**	**5,651,681**
57:43 Distribution		**3,208,696**	**57%**	**2,442,985**	**43%**	**5,651,681**
Difference		**-531,389**		**531,389**		

But EPCWID Charged Diversions do not include their use of El Paso Effluent

- EPCWID diverts and uses a significant amount of treated effluent discharged by the El Paso Water Utility (EPWU) into Project canals.
- This effluent is largely Project return flow, and ordinarily would be considered Project Water, and EPCWID would be charged for its use.
- Owing to the technicality that this effluent doesn't "reach the bed of the Rio Grande", its diversion and use is not charged to EPCWID.
- If this water is included in the calculation as part of EPCWID's diversion of Project Supply, then the "difference" between what EBID got and 57% of Supply is 700,000 AF.

Data and Calculation of Project Supply Diversion Distribution, Including EPWU Effluent

Table A.12.Rev2. Distribution of Water between Districts

(Including revised 2018 and 2019 data, adding Totals, 57:43 Distribution, and Difference Calculations)

Year	Release from Caballo	EBID Charged Diversions	EBID % of US Share	EPCWID Charged Diversions	EPWCID Uncharged Effluent Use *	Total EPCWID Supply during Release Season	EPCWID % of US Share	Total US Diversions
Year	AF	AF		AF	AF

103

5. Cause of EBID Allocation Reduction

Under D3 Allocation Method, EBID's Allocation is reduced for any negative departure from historical Project performance as defined by the D2 Curve.

- The US and TX argue that the negative departure from D2 is caused predominantly or entirely by excess groundwater pumping in New Mexico.
- New Mexico argues that part of the negative departure from D2 may indeed be caused by NM actions, but not ALL of that departure is caused by NM.
- Instead, NM argues that a significant part of the problems with Project Performance are caused by other factors.

Barroll Rebuttal, App A June 15, 2020 104

104

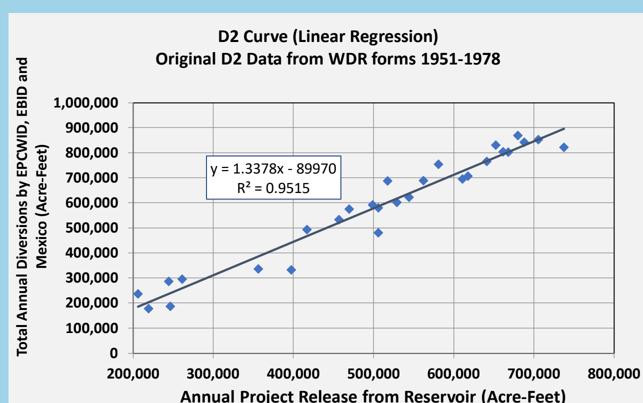
Mechanism by Which EBID's Allocation has been Reduced: D3 Allocation Method

- Adopted by Project in 2006
- Incorporated in to 2008 Project Operating Agreement (2008 OA)
- Intended to reduce EBID's Allocation in order to
  - **Offset effect of New Mexico pumping (King 2019, Ferguson 2019)**
  - **Protect EPCWID's Project Allocations from the impacts of New Mexico groundwater pumping (King 2019)**
  - **Account for Project Water "captured" by New Mexico groundwater pumping (Blair 2019)**

105

D3 Allocation Method

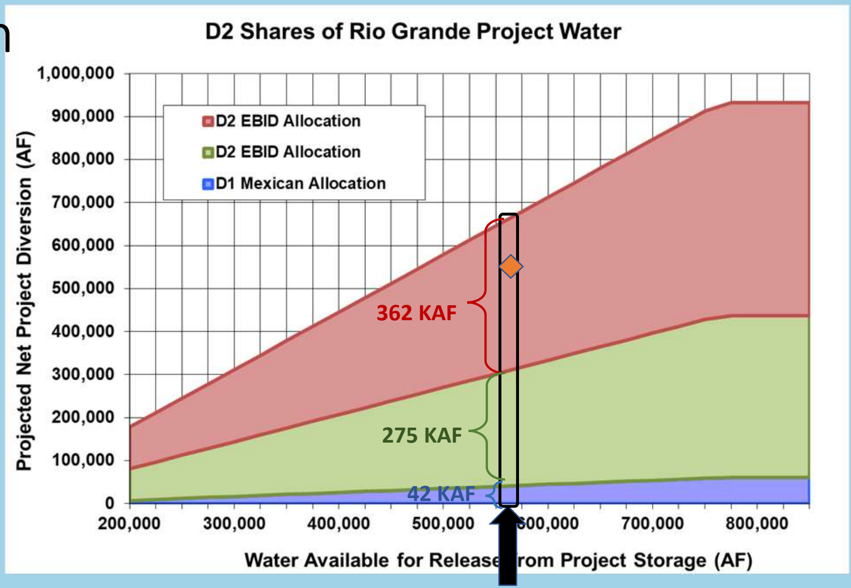
- Based on historical data from 1951 – 1978
  - Releases from Caballo
  - Net diversions
  - D2 "curve" (a linear regression of this data)
- EPCWID's Allocation is based on this historical data
- Mexico's Allocation is based on Treaty
- EBID gets remaining Allocation



106

US_MSJ_00001056

D2 Allocation

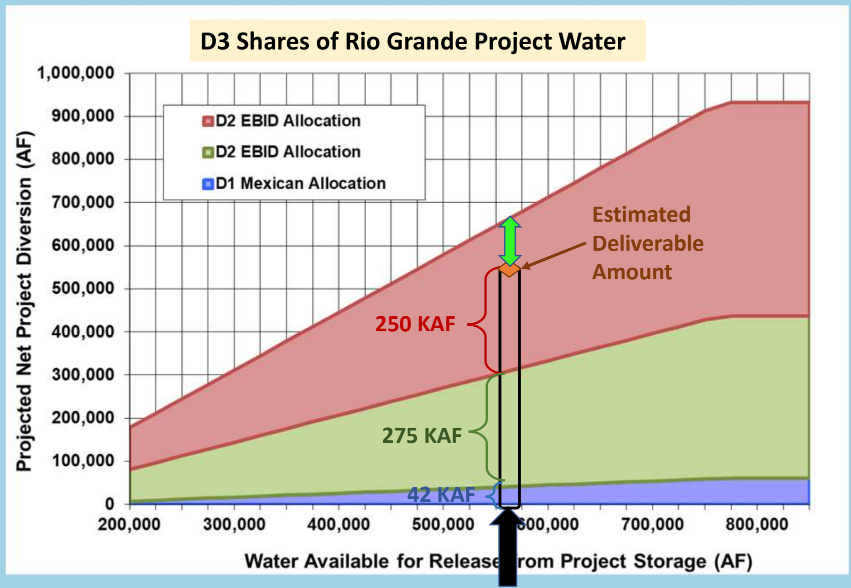


Allocates full amount determined by D2 Curve

Barroll Rebuttal, App A June 15, 2020 107

107

D3 Allocation Method



Entire negative departure (vertical distance) between D2 Curve and current Total Charged Diversion is taken out of EBID's Allocation

Barroll Rebuttal, App A June 15, 2020 108

108

EBID Gets "Remainder of Allocation"

- EBID's Allocation is reduced for the **entire negative** departure of current Charged Diversions from the D2 Curve
- Ferguson (page 4): "D3 Method" is not "based on the assumption that any negative departure from historical Project Performance is caused by New Mexico."
- Nevertheless, D3 Allocation <u>does in fact assign all negative departure from historical Project performance (D2 Curve) to New Mexico</u>, with a few exceptions (multi-year drought).

109

Causes for Negative Departure from D2

1) Increased groundwater pumping/depletions within Project
2) Changes in Project Accounting
    A. Off-season diversions in D2 Curve: Average 23,000 AF
    B. Diversion of EPV drain flow in D2 Curve: Average 8,200 AF
    C. Diversion/use of EPV effluent <u>not</u> counted: Average 24,000 AF

New Mexico is responsible for **part of** the increased groundwater pumping/depletions

New Mexico is **not** responsible for changes in Project Accounting

Yet EBID's Allocation is reduced for the total negative departure from D2

110

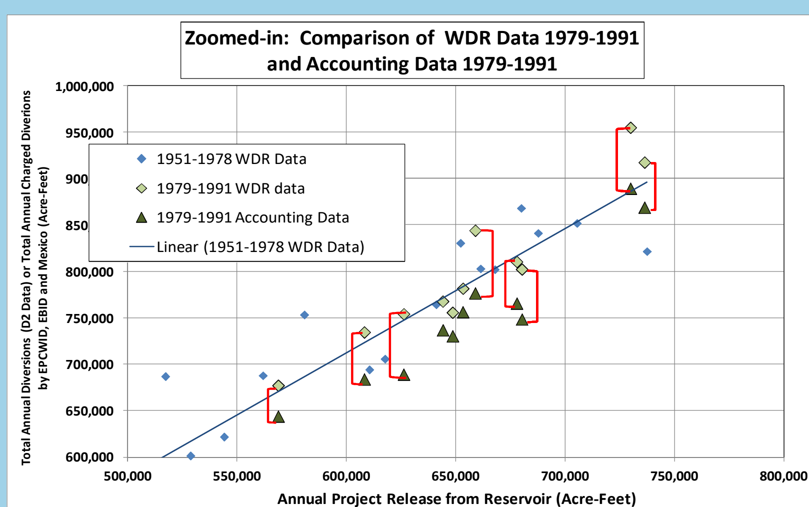
6. Accounting Factors that Impact Project Performance

- The D2 Curve was developed from diversion data from 1951 – 1978.
- This diversion data is calculated very differently than current Charged Diversions. Charged Diversions omit diversions that were included in the D2 Curve.
- Under D3 Allocation, EBID's Allocation is reduced when total Charged Diversions fall short of the D2 Curve.

111

Problems with D3 Allocation Method

- Net Diversions from D2 period (1951 – 1978) are calculated differently than today's Charged Diversions (apples to oranges problem)
- Some of the current apparent discrepancy from the D2 Curve is caused by those differences in calculation (differences in Project Accounting)



112

How Has Project Accounting Changed Since the D2 Period (1951 – 1978)?

1. Off-Season Diversions
   - D2 data includes diversions of return flows during the winter, during months when no releases were made from Caballo
   - Post-1978 Accounting only counts diversion made during the Caballo Release period
2. EPWU Effluent
   - During D2 period, effluent from EPWU Haskell R. Street Plant reached the Rio Grande, and when it was diverted at Riverside it was counted as diversion of Project Supply
   - Currently effluent from both the Haskell and Bustamante plants discharge into EPCWID conveyances where it is used by EPCWID farmers. The diversion and use of this water is **not** charged to EPCWID.

Barroll Rebuttal, App A June 15, 2020 113

113

How Has Project Accounting Changed Since D2 Period (1951 – 1978)? (continued)

3. Diversion of El Paso Valley Drain Flows
   - D2 data explicitly includes diversions of water from the River Drain into the Riverside Canal Extension near Fabens, Texas.
   - Post-1978 Accounting does not include any consideration of drain flows in the El Paso Valley
4. Other Project Accounting Credits

Barroll Rebuttal, App A June 15, 2020 114

114

7. Accounting Factor (a) Off-Season Diversions

- The D2 data set is based on Reclamation records that include diversions made throughout the calendar year.
- Current Project Accounting (since ~1979) does not count any diversions made during times when Caballo is not releasing water.
- EPCWID's guaranteed Allocations are based on 12-months of diversion, but they are only charged for diversions made during 4 to 8 months of the year.
- The D2 data includes an average of 22,400 AF/yr of off-season diversions. In full-supply years, off-season diversions were 30,000 - 40,000 AF.

Accounting Issue: Off-Season Diversions

Current Accounting (Post-1978 Accounting) does not include any diversions made outside of the Caballo release season

2008 Operating Agreement Operations Manual, Page 3:

Non-Allocated Water: water in the Rio Grande, during non-irrigation season and after the closing of the Caballo Dam release gates and prior to opening of the Caballo Dam release gates for the subsequent primary irrigation season, which originates from drain flows and other sources which may be diverted by the irrigation districts for application to irrigable land area within their boundaries. All diversions made by the Districts during the non-irrigation season utilizing return flow waters shall not be charged against the District's respective allocations.

Accounting Issue: Off-Season Diversions

The WDR's from the 1951 – 1978, upon which the D2 Curve is based, include diversions from the entire calendar year.

- An average of 23,000 AF/yr of off-season diversions occurred during that time, mostly in the El Paso Valley.

3 Diversions plus inflow from reservoirs and other sources less delivery to reservoirs.

a Measured at
b Measured at

Off-Season Diversions Example: 1968

- Caballo Reservoir Releases
  - Began: February 27 (first deliveries from these releases occurred in March)
  - Ended: September 20 (last deliveries from these releases occurred in late September
- Under current Accounting rules, diversions made in January, February, October, November and December **would not be counted.**

Off-Season Diversions: 1968		
	Diversion in New Mexico	Diversion in Texas
Month	Acre-feet	Acre-feet
January	0	3,757
February	0	3,125
October	0	5,834
November	0	4,615
December	0	3,290
Total	0	25,041

Impacts of Off-Season Accounting Issue

- The D2 Curve, and EPCWID's Allocation, are inflated by significant amounts of off-season diversions (averaging 22,400 AF) that are not considered part of Project Water.
- Off-season diversions largely consisted of drain flows, effluent, and base-flow gains to the bed of the Rio Grande.
- Currently, the amount of water available in the off-season is probably not large, but if the hydrologic system recovers, and off-season flows become significant again, **the use of these flows would still not be counted.**
- Since diversion of off-season diversions will not be charged, that will permanently depress the Diversion Ratio (which is calculated based on Charged Diversions).
- A low Diversion Ratio mean low Allocation to EBID

7. Accounting Factor (b) El Paso Valley Effluent

- The City of El Paso Water Utility (EPWU) supply in the El Paso Valley includes Project water and a smaller amount of Hueco groundwater.
- Municipal effluent from EPWU in the El Paso Valley consists of Project return flow and return flow from groundwater pumping.
- This effluent is discharged into a conveyance parallel to and close to Rio Grande that effectively takes the place of the Rio Grande.
- EPCWID diverts and uses this effluent but is no longer charged for it.
- Approximately 24,000 AF of this effluent is discharged during the Caballo release season, which EPCWID thus uses free of charge.

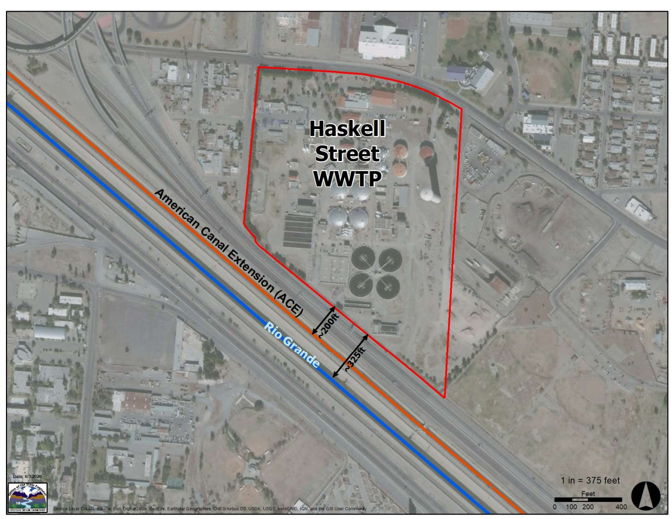
Change in Disposition of Haskell R. Street Effluent

- Until 1999, Haskell effluent discharged into the Rio Grande, and diversion of that effluent at Riverside was counted as Project Supply.
- The ACE, completed in 1998, allows EPCWID to by-pass the bed of the Rio Grande when making deliveries to Riverside.
- Starting in 1999, Haskell effluent is discharged into ACE, less than 200 feet from the bed of the Rio Grande.



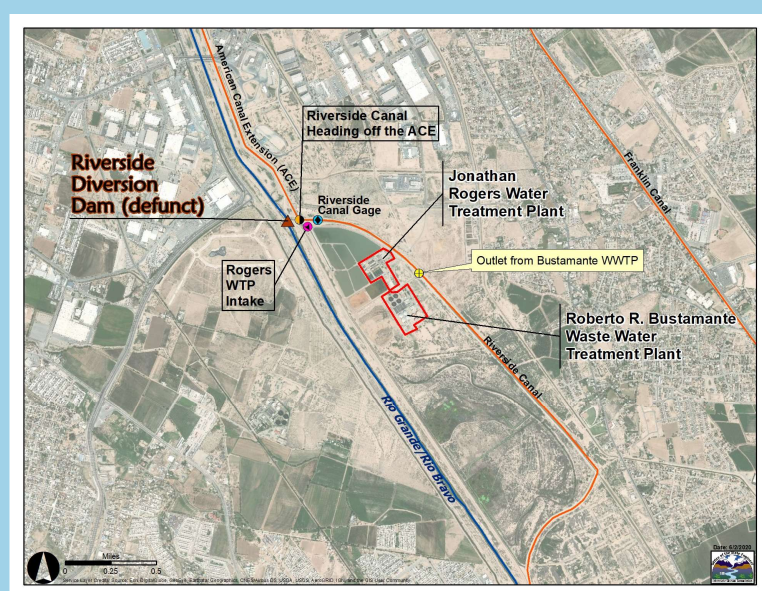
Change in Accounting of Haskell R. Street Effluent

- Haskell effluent is currently diverted into the Riverside Canal heading from the ACE and is used by EPCWID, but the diversion of this water is not included in EPCWID's Allocation Charges.
  - This effluent passes the Riverside gage with the rest of the Project water diverted at Riverside. Current EPCWID accounting **subtracts off the amount of Haskell effluent EPCWID as a Credit** during the release season
- Average annual discharge Haskell to ACE: 16,255 AF
- Average Haskell discharge during release season: 10,470 AF
- EPCWID now uses this water free of charge.

125

Bustamante Wastewater Treatment Plant

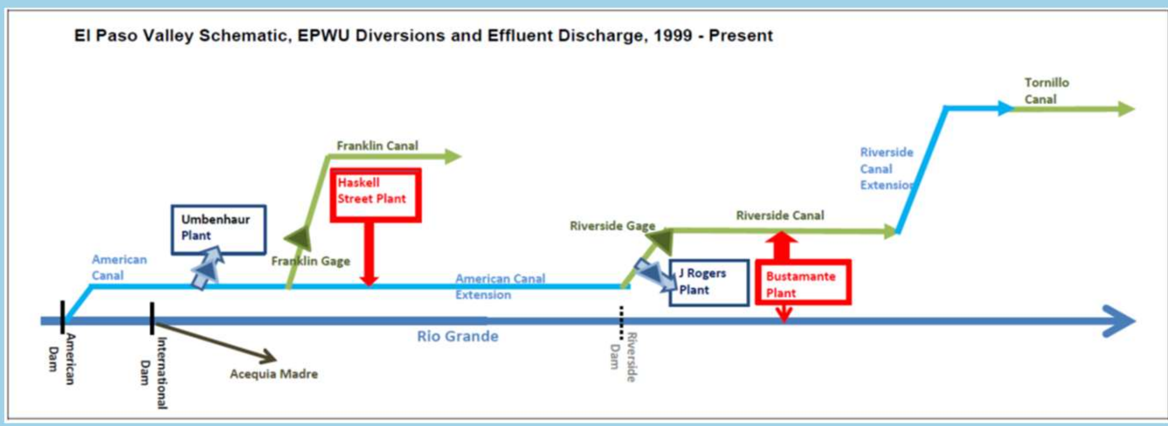
- Came on-line: 1960
- Effluent is discharged into Riverside Canal, 0.5 miles below the Riverside Gage
- EPCWID use of this effluent is not charged in Project Accounting



126

US_MSJ_00001066

Schematic of El Paso Valley Conveyance System, Including EPWU



Barroll Rebuttal, App A June 15, 2020 127

127

Bustamante Effluent Amounts and Disposition

- During Irrigation Season Bustamante discharges effluent into Riverside Canal.
- Discharge into Riverside is used by EPCWID, but there is no Project Accounting charge.
- Average annual discharge to Riverside: 22,727 AF.
- Average discharge to Riverside during Release Season: 15,556 AF.

In some winter months, Bustamante effluent is sent to a drain and is not used by Project.

EPCWID has had contracts with Hudspeth Irrigation District to sell municipal effluent to Hudspeth.

Barroll Rebuttal, App A June 15, 2020 128

128

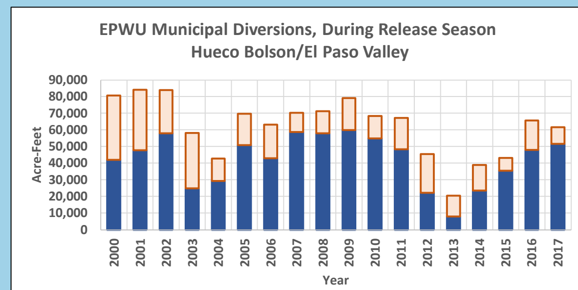
EPWU Sources of Supply in the El Paso Valley

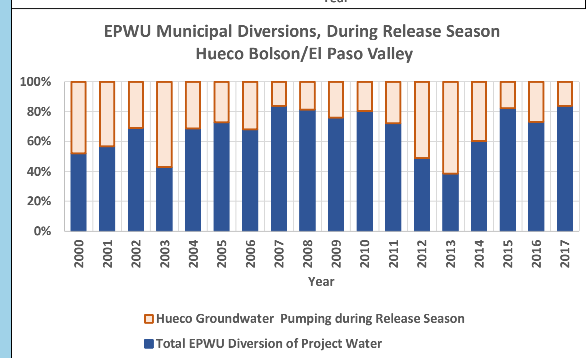
Below Courchesne, EPWU diverts Project water and pumps groundwater from the Hueco well-field)

Up to 80% of the water diverted during the Caballo release season** is Project water

Therefore most of EPWU effluent in the El Paso Valley is Project return flow

**Note that Project Accounting Charges now only include diversions made during Caballo release Season. In order to understand the composition of the uncharged Caballo release season effluent, I compare effluent discharge and EPWU Hueco pumping during that same period





Total EPWU Municipal Effluent Discharged into Project Works in El Paso Valley During Caballo Release Season

	Haskell Credit for Discharge to ACE during Release Season	Bustamante to Riverside during Release Season	Total EPWU Effluent in El Paso Valley During Release Season
1999	12,732	21,775	34,507
2000	10,700	19,583	30,283
2001	11,360	16,070	27,430
2002	10,844	5,876	16,720
2003	9,595	15,556	25,151

2015	5,461	12,027	17,488
2016	7,712	17,102	24,814
2017	7,204	14,651	21,855
Averages:	**8,741**	**15,556**	**24,298**

Impact of Effluent Accounting in El Paso Valley

- EPCWID uses Project return flow free of charge
- EPCWID's Charged Diversions are smaller as a result
- EPCWID ends up with more unused Allocation which it can then "carry over"
- Total Project Charged Diversions are smaller, which reduces Diversion Ratio
- Smaller Diversion Ratio means that EBID's D3 Allocation is smaller

131

7. Accounting Factor (c) El Paso Valley Drain Flow

- El Paso Valley drain flows comprised part of Project Supply at the time of the Compact and later.
- During the D2 period (1951 – 1978) Reclamation records indicate that an average of 8,200 AF/yr of El Paso Valley drain water was diverted into EPCWID's conveyances and this water was counted as Project Supply.
- Current Project Accounting does not include a term for El Paso Valley drain flows, and the flows of the pertinent drains have been depleted by groundwater pumping in Texas and Mexico.

132

El Paso Valley Drain Flow

Historically, El Paso Valley drain flow was used within the Project as Documented by Rio Grande Joint Investigation

100

TABLE 90.—*Estimated percentages of reservoir water, arroyo inflow, and drainage in net diversions and disposal of reservoir releases, Elephant Butte-Fort Quitman section, 1930–36*

Division or item	Mean disposal of reservoir water 1930-36 (percentage distribution)	Mean percentage content, 1930-36, in net diversions, of—			
		Unused reservoir releases [1]	Arroyo inflow	Drain flow and seepage	Total
Rincon	8.5	97.5	2.2	[2] 0.3	100.0
Mesilla	46.4	89.8	2.8	7.4	100.0

Passing Fort Quitman	3.9	17.2	14.8	68.0	100.0
Total	100.0				

[1] Distinguished from returned drainage originally from the reservoir.
[2] Invisible accretion to river.

Estimates based on detail study of all available data, 1930–36, on river flow, reservoir releases, diversions, wastes, drain flow, and arroyo inflow.

A number of drains discharged into the Rio Grande in the El Paso Valley above the last Project diversions at Tornillo

Diversion of this water at the Tornillo Canal heading for use in the lower part of EPCWID was a normal part of Project Operations

133

El Paso Valley Drains Above Fabens

Kirby (retired Project Superintendent) wrote in 1994:

It is my remembrance that this admission [of the Tornillo Division into the Project] was <u>only agreed to by EBID</u> provided that the Tornillo Division would divert and use, as part of their water supply, the drain waters that accumulated into a collection channel at Fabens. There was a pumping station at this location later changed to a gravity diversion that moved water into the Tornillo Canal. (Emphasis in the original.)

134

El Paso Valley Drain Flow Component of Project Supply

In 1938 the course of the Rio Grande was rectified in the El Paso Valley near Fabens and the Tornillo Canal Heading

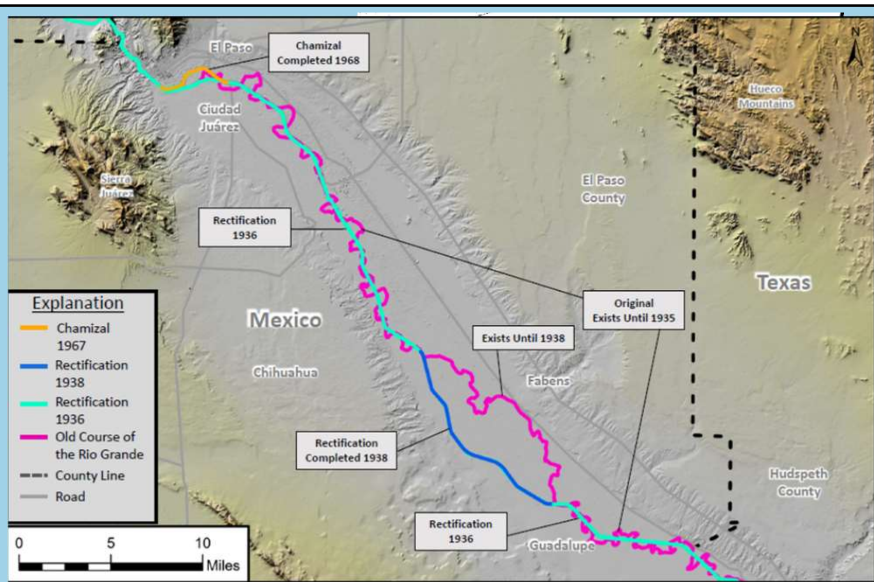

Figure 4.5a – Major changes in the position of the Rio Grande, 1903 to present.

McDonald Morrissey

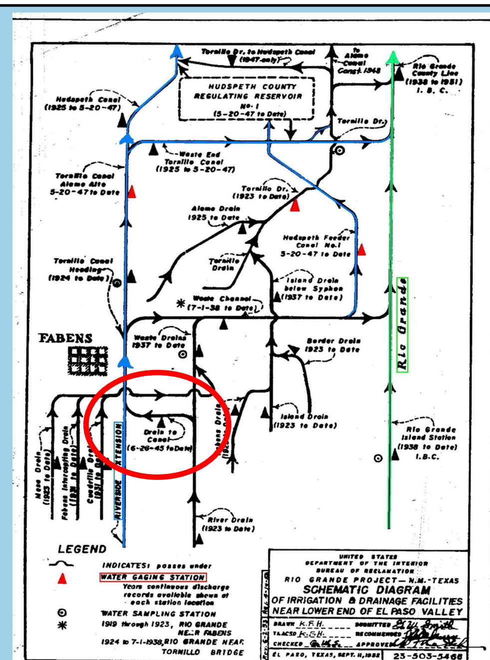
Barroll Rebuttal, App A June 15, 2020 135

135

El Paso Valley Drain Flow Component of Project Supply

After Rectification, drains were rerouted.

The River Drain was engineered to discharge into the Riverside Canal Extension for delivery to the Tornillo Canal.



Schematic of the Project conveyance system in part of the El Paso Valley, from Cortez, 2005, slide 32:

El Paso Valley Drain Flow

DRAIN RETURN FLOW - EL PASO VALLEY

SOURCE: Letters from Besch to Gregg 11/17/53 1945 - 1951 Letter from Gregg 12/18/52

DESCRIPTION: Parts of this drainage return is diverted back into the system, part is delivered to Hudspeth, and part reaches the Rio Grande.

1964	2,758		

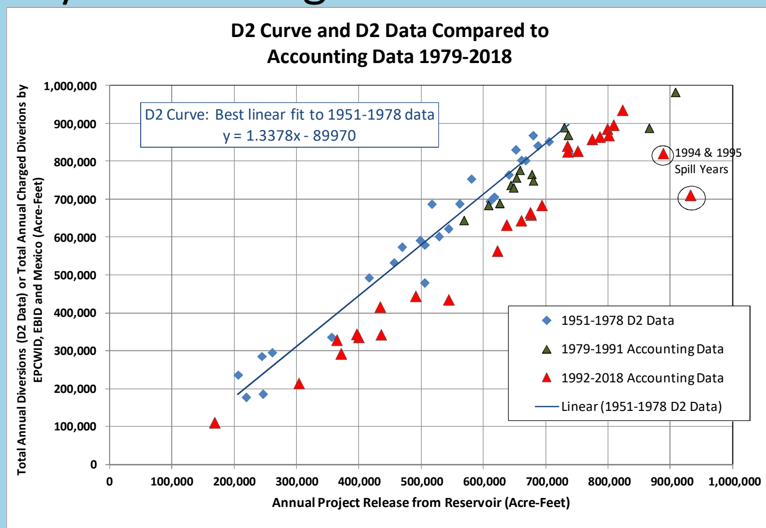
Current Status of El Paso Valley Drain Flows at Fabens

- These drain flows have likely been reduced because the amount of irrigation acreage above Fabens has decreased
- Remaining drain flows would likely have been depleted by the effects of Texas groundwater pumping
- There is no term in Project Accounting for diversion of drain flow in the El Paso Valley
- Part of the negative departure from D2 is likely related to:
  - The absence of these drain flows or
  - Failure to divert these drain flows, or
  - Failure to charge EPCWID for any diversion of these drain flows

8. How do these Accounting Factors Impact the Distribution of Project Supply?

- Off-season diversions: The D2 Curve is artificially inflated by the inclusion of flows that are no longer counted. Under D3 Allocation, EBID's Allocation is reduced for any negative departure from the D2 Curve, therefore EBID's Allocation is being artificially reduced.
- EPWU effluent: EPCWID diverts and uses the effluent it gets from EPWU in the El Paso Valley. Because this water use is not charged to EPCWID, the sum of the Charged Diversions is lower than it should be, increasing the discrepancy between Charged Diversion and the D2 Curve.
- El Paso Valley Drain Flow. Again, the D2 Curve is artificially inflated by the inclusion of drain flow diversion that either no longer exist or are no longer counted as Charged Diversions.

How Much of the Departure from D2 Could be Caused by Accounting Issues?

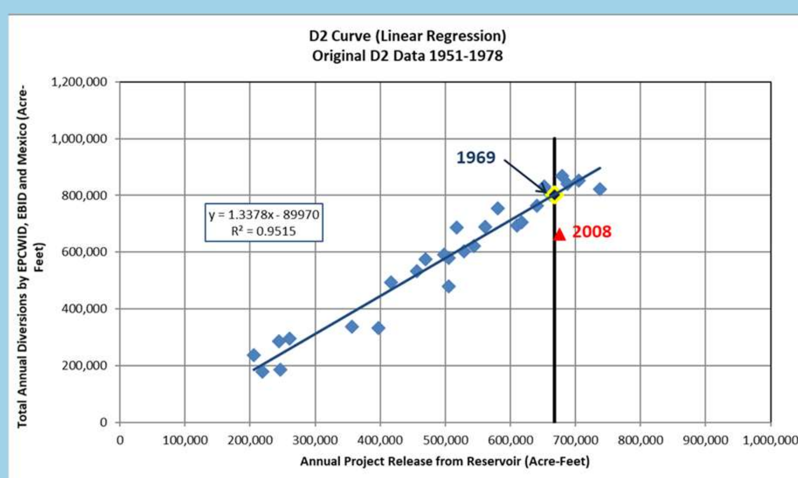


Barroll Rebuttal, App A June 15, 2020 143

143

Examine the Application of Current Accounting Rules to Historical D2 Data: 1969

- 1969 was chosen because:
- 1969 falls "on the D2 Curve"
- There is more recent year (2008) which has approx. the same Caballo Release for ready comparison



Barroll Rebuttal, App A June 15, 2020 144

144

1969 WDR Data: How much would be charged today under post-1978 Accounting rules?

Charged Diversions would be 74,292 AF less than the reported 1969 diversions

Diversion Ratio calculation: 1969 recorded diversions: 1.20

Applying Current Account Rules: 1.09

Table 2. (Modified Table 7.1 from Barroll (2019) Components reordered, Calculated Diversion Ratio added). Analysis of 1969 WDR Diversions

	WDR Values *	WDR Values broken down by Component	Estimated Charged Diversion using Post-1979 Accounting	Difference in Total Accounted Diversions: WDRs vs. Post-1979 Accounting
EBID Diversion	421,000	404,000	404,000	17,000
EPCWID Diversion	321,000	263,708	263,708	57,292
(a) Off-Season Diversions		38,000		
(b) EPV Drain to Canal		2,292		
(c) Estimated Post-1979 Credits EBID **		17,000		
(c) Estimated Post-1979 Credits EP#1**		17,000		
Mexico	60,000	60,000	60,000	
Total Accounted Diversions	802,000	802,000	727,708	74,292
Caballo Release	667,700	667,700	667,700	
Diversion Ratio	1.20		1.09	

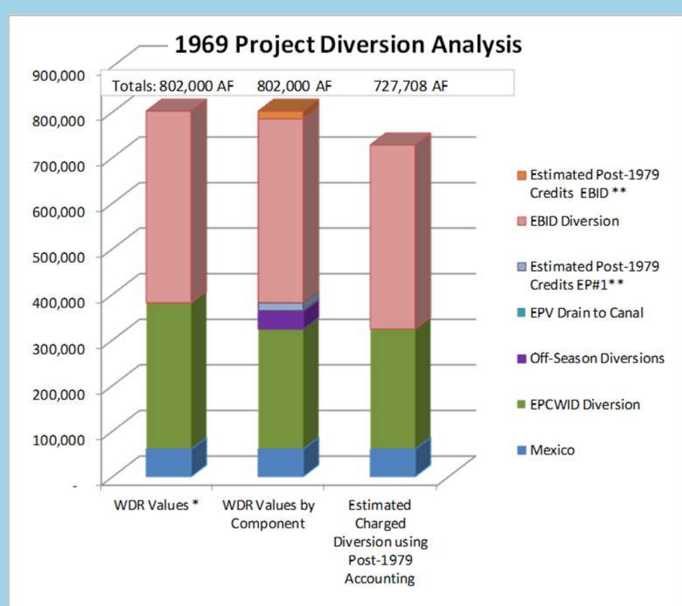
* WDR Values adjusted so that Mesilla Dam Diversions are split between the Districts Pro-Rata

** Total Estimated Post-1979 Credits calculated as the difference between total diversions and charged diversion in 2008, a year of similar water supply to 1969. This total was split 50:50 between EBID and EPCWID

Barroll Rebuttal, App A June 15, 2020 145

145

Chart of the breakdown of 1969 reported Diversions



Barroll Rebuttal, App A June 15, 2020 146

146

Effect of that Difference in the Diversion Ratio

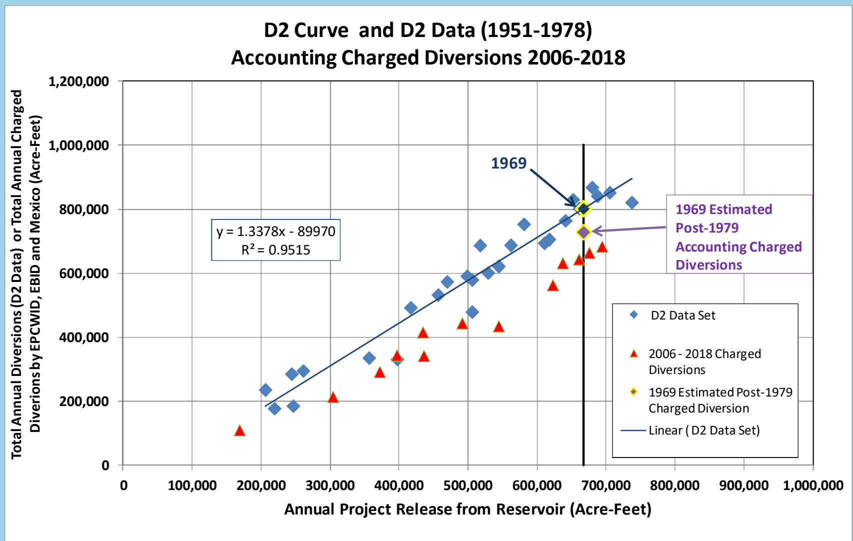
Applying that reduction in the Diversion Ratio in D3 Allocation results in a reduction to EBID's Allocation of 84,000 AF

Table D.2 Modified. Illustration of the Effect of Variation in the Diversion Ratio
Example: Project Performance during 1969
Compare D3 Allocation with Diversion Ratio Calculated Using WDR Diversions, to D3 Allocation with Diversion Ratio Calculated Using Post-1978 Accouting
(Values rounded to nearest 1000 AF)

	D3 Allocation		**Difference**
Diversion Ratio (unitless)	1.20	1.09	0.11
Usable Water (AF)*	764,000	764,000	
Mexican Allocation (AF)	60,000	60,000	
EPCWID's Allocation (AF)	377,000	377,000	0
EBID's Allocation (AF)	480,000	396,000	-84,000
[(Usable Water x Diversion Ratio) – Mexican Allocation – EPCWID Allocation]			

* 1969 was a full-supply year (final allotment = 3.0 AF/A) and so I assume the amount of Usable Water available to the Project that year is at least 764,000 AF.

1969 Data Indicates that a Significant Portion of Current Departure from D2 is Related to Accounting



Similar Analysis for Other D2 years

149

9. Effects of Pumping in the Hueco Bolson/ El Paso Valley

- As in New Mexico, groundwater pumping can
  - Reduce discharge of groundwater into drains, reducing Project Supply
  - Increase seepage from streams and canals, reducing Project Efficiency.

Barroll Rebuttal, App A June 15, 2020 150

150

Hueco Bolson Groundwater Pumping

- Texas started large groundwater withdrawals earlier than New Mexico
- Juarez has also pumped large amounts of groundwater in the Hueco Bolson

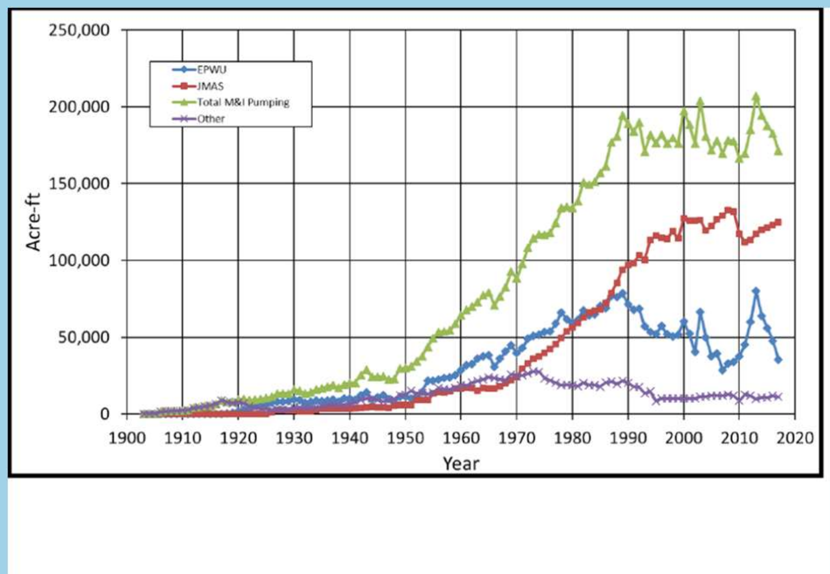

Figure 5.4 – Graph showing annual municipal and industrial pumping, 1903 to 2017.

Barroll Rebuttal, App A June 15, 2020 151

151

Drawdowns in El Paso Area Exceed 150 feet

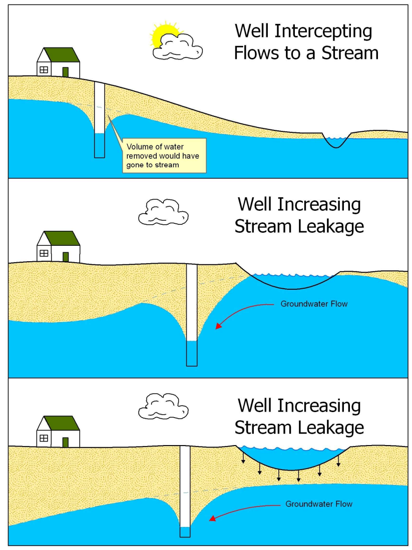
152

US_MSJ_00001079

As in New Mexico, drawdowns in Texas impact stream flow and drain flow

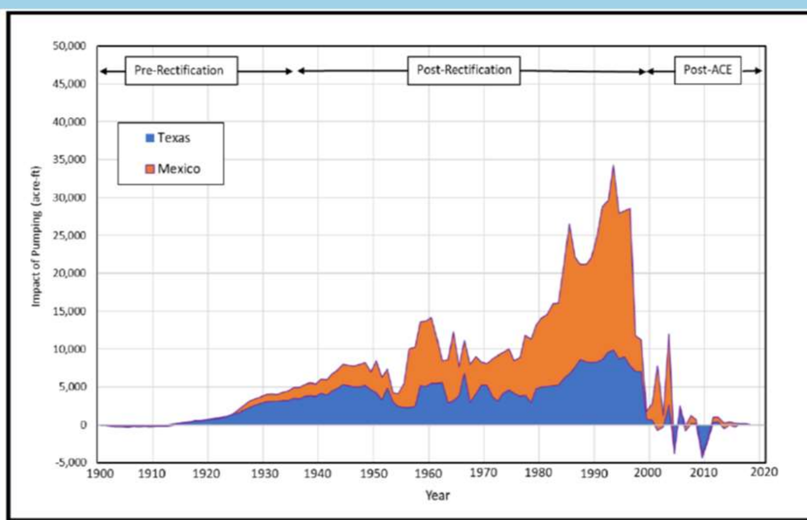


Barroll Rebuttal, App A June 15, 2020 153

153

Rio Grande Main Stem Above Riverside Dam:

Seepage losses from the bed of the Rio Grande increased due to groundwater pumping in Texas and Mexico



Note: Impact includes changes in Rio Grande evaporation, which are negligible.

Figure 9.3 – Graph showing impact of pumping by Texas and Mexico for the Rio Grande from American Dam to the Riverside Diversion for the reoperated runs, 1903 to 2017.

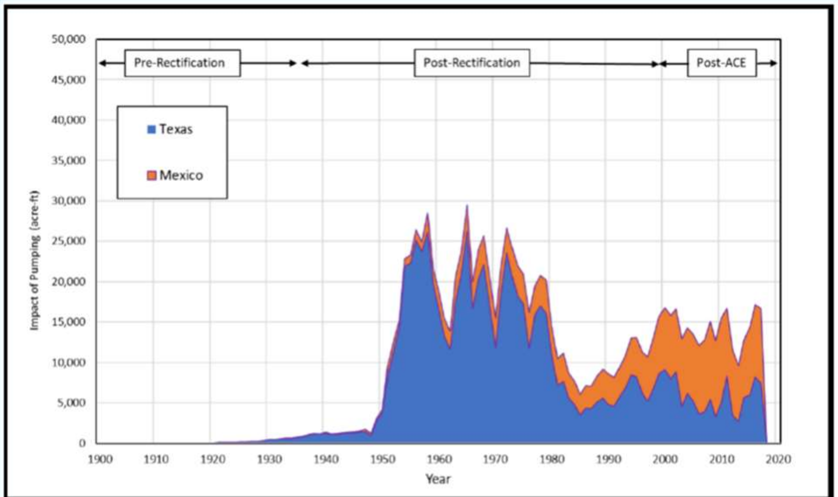
Barroll Rebuttal, App A June 15, 2020 154

154

Drain Flows in the El Paso Valley Above Fabens

Drain flows were historically diverted by EPCWID near Fabens

These drain flows have been depleted by Texas groundwater pumping



Note: For run details see Table 9.1.

Figure 9.13 – Graph showing impact of pumping on EPCWID drain flows to Fabens, Texas for the reoperated runs, 1903 to 2017.

Barroll Rebuttal, App A June 15, 2020 155

155

EPCWID's Canals and Laterals

Some parts of these are hydrologically connected to groundwater and can be depleted by groundwater pumping

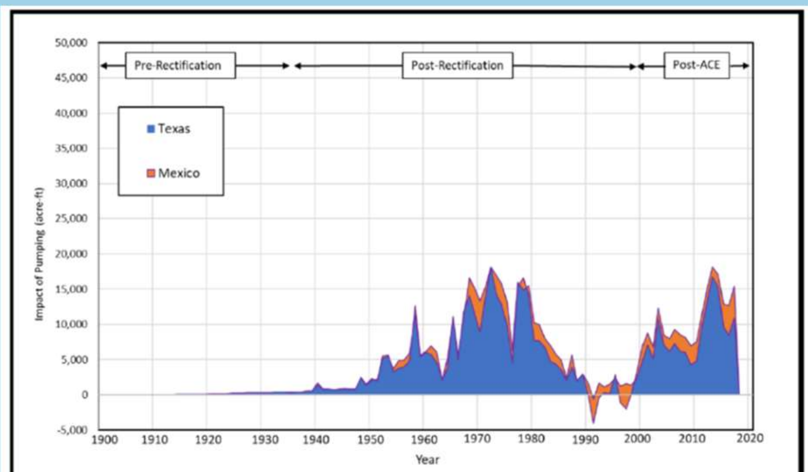


Figure 9.8 – Graph showing impact of pumping by Texas and Mexico on EPCWID canals and laterals for the reoperated runs, 1903 to 2017.

Barroll Rebuttal, App A June 15, 2020 156

156

US_MSJ_00001081

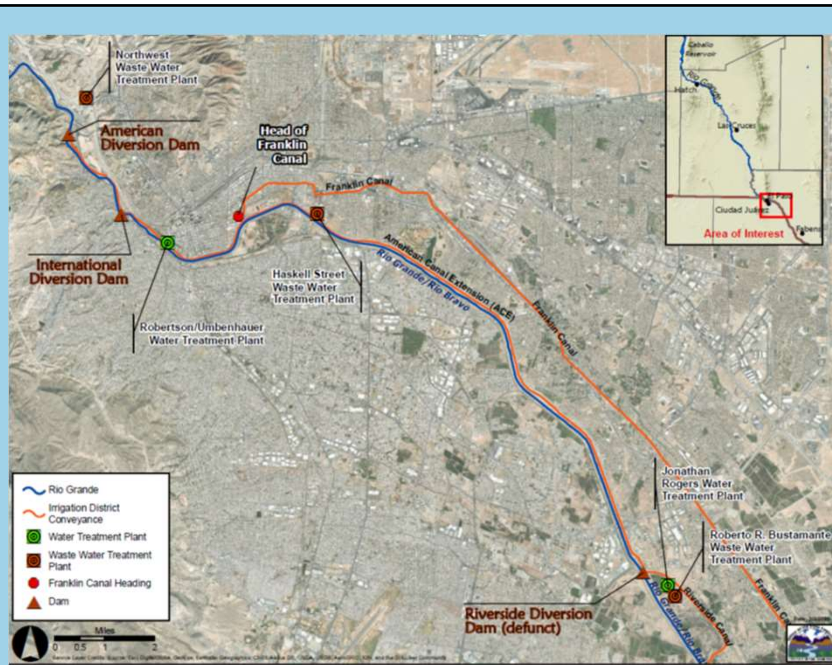
10. American Canal Extension Credit

- American Canal Extension (ACE) was built to bypass the losing reach of the Rio Grande between American Dam and Riverside Canal heading.
- Losses in this reach of the Rio Grande were caused/exacerbated by groundwater pumping in the Hueco Bolson, largely by Texas.
- ACE mitigates these losses, but then EPCWID gets a credit for having done so (up to ~20,000 AF).
- ACE Credit applied under 2008 OA reduces EBID's Allocation.
- ACE Credit gives EPCWID (and thus Texas) a credit for mitigating a problem caused by Texas.

Barroll Rebuttal, App A June 15, 2020 157

157

Map showing American Canal Extension

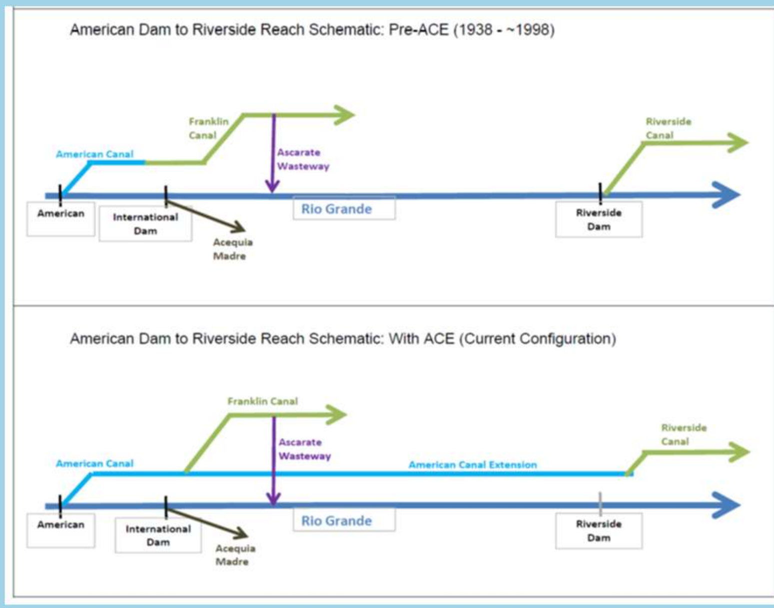


Barroll Rebuttal, App A June 15, 2020 158

158

ACE Schematic

Illustrates how ACE allows EPCWID to by-pass Rio Grande main stem to deliver water to Riverside Canal



The ACE is concrete-lined

Cortez 2003

ACE Credit

- Use of the ACE to deliver water to Riverside almost certainly avoids seepage losses from Rio Grande main stem.
- EPCWID argues that the reduction of these losses means that smaller releases from Caballo are required to meet orders at Riverside.
- EPCWID argued (successfully) that it should get a Project "allocation credit"
- EPCWID uses the ACE Credit to increase the water it sells to the City of El Paso (EPWU).
- ACE Credit reduces EBID's Allocation

Application of ACE Credit

- As 2008 OA was written, ACE Credit is applied during Allocation Process in the Allocation Spreadsheet

20	Gross D2 Diversion Allocation	942,117
21	EPCWID ACE Conservation Credit	17,998
22	Net D2 Diversion Allocation for EBID and EPCWID	888,731

- If so applied, ACE Credit increases EPCWID's Allocation and reduced EBID's Allocation by the same amount

		2008 Allocation	2008 Allocation calculated with ACE Credit set to 0	Difference (Effect of ACE)
36	Total EBID Diversion Allocation (After Transfer)	345,817	363,815	-17,998
37	Total EPCWID Allocation (After Transfer)	552,997	534,999	+17,998

ACE Credit Has Been Applied Inconsistently

- In some years it is applied in Allocation spreadsheet
- In some years it is added on to EPCWID's Allocation in the Accounting records at the end of the year

DRAFT - EPCWID Diversion Allocation Charges for September 2015

Total Allotment Diversions Charges					**106,065**	**165,872**
Diversion Allocation					188,117	188,117
Est. Annual Conservation Credit Diversion Allocation						11,651
Accrued Conservation Credit Diversion Allocation						11,651
Total Diversion Allocation						199,768
District Allotment Balance						22,245
EOY Allocation Balance						**33,896**

- In some years it has not been applied at all

Effect of ACE Credit Applied at the End of the Year

When ACE Credit is added on to EPCWID's Allocation at the end of the year:

- EPCWID cannot make use of it in current year
- It is included in EPCWID's Carryover account to following year
- It increases paper water in EPCWID's Carryover account
- It reduces the part of Useable Water available for Current-Year Allocation the following year
- It reduces EBID's Allocation the following year
- It may increase the likelihood of a Carryover Transfer to EBID, but that possibility depends on EPCWID's water use

Summary of ACE Credit Issue

- ACE Credit rewards EPCWID for mitigating a problem largely caused by Texas
- Application of the ACE Credit harms EBID

11. Effects of Carryover on EBID and New Mexico

- EBID's Allocation is now so low it can make little use of Carryover.
- EPCWID's Allocation in full-supply years is much higher than its demand, and so it can carry over large amounts of unused Allocation.
- Under the 2008 OA, Carryover plus water needed to deliver it is subtracted from Usable Water before performing Current-Year Allocation.
- Carryover accounts are never reduced for evaporation and may include paper water.
- EPCWID's large Carryover accounts have acted to reduce Current Year Supply and the amount of water allocated to EBID.

Carryover is a New Feature of Project Allocation and Accounting

- As late as 2007 Reclamation's Project Manager, Bert Cortez, declared:

"The practice for nearly 100 years of Project operations was that any unreleased storage water or unused diversion Allocation from either district went back into the Project supply to be allocated anew the next year"

And Dr. King wrote for EBID:

"Carryover of unused Allocation by individual districts from one year to the next of either delivery or diversion was never included in the management of the Rio Grande Project prior to 2006. Implementing carryover in the Allocation procedure for the Project would be a substantial change in the Allocation of Project Water, which would in turn have a substantial impact on Project operations and hydrology"

Since 2006 EBID's Allocation Has Been Too Low to Accumulate Much "Unused Allocation" to Carryover

Table A.13. EBID Allocation and Charged Delivery Summary 2006 - 2019

Year	Current-Year Allocation AF	Carryover from Previous Year AF	Transfer from EPCWID AF	Total Allocation AF	Total Charged Diversions AF	Unused Allocation AF	Mexican Adjust-ment AF	Potential Carryover to Next Year AF

EPCWID's Allocation Has Been Higher than Its Demand in Full Supply Years, Allowing Substantial Carryover

Table A.14. EPCWID Allocation and Charged Delivery Summary 2006 - 2018T

Year	Current-Year Allocation + ACE Credit	Carryover from Previous Year	Transfer to EBID	Total Allocation	Total Charged Diversions	Unused Allocation	Mexican Adjust-ment	Potential Carryover to Next Year
	AF	AF	AF	AF	AF	AF	AF	AF
2006	241,657	0		241,657	177,183	64,474	0	64,474
2007	367,291	36,200		403,491	278,252	125,239	0	125,239
2008	405,073	106,982		512,055	279,173	232,882	0	232,882
2009	402,159	232,882	-82,044	552,997	320,083	232,914	0	232,914
2010	309,515	232,914	-10,271	532,158	304,937	227,221	-2,874	224,347
2011	43,466	224,347		267,813	258,772	9,041	-1	9,040
2012	132,935	9,042		141,977	136,380	5,597	0	5,597
2013	41,446	5,597		47,043	53,530	-6,487	0	-6,487
2014	106,590	-6,487		100,103	97,418	2,685	0	2,685
2015	197,629	2,685		200,314	165,872	34,442	-1,969	32,473
2016	235,908	32,473		268,381	216,309	52,072	-1,893	50,179
2017	401,842	50,179		452,021	249,919	202,102	0	202,102
2018	143,038	202,102		345,190	280,674	64,516	0	64,516
2019	399,655	64,466	-75,333	388,787	155,872	232,915	0	232,915

Part of the reason EPCWID's Charged Diversions are as low as they have been is that EPCWID is **not charged for** its diversion and use of ~24,000 AF/yr of EPWU effluent in the El Paso Valley

In the D3 Allocation Process, Current Year Allocation is Reduced to Ensure Total Carryover Can be Delivered

- The amount of "Usable Water for Current Year Allocation" is Usable water minus "Carryover Obligation"
- "Carryover Obligation" is usually even higher than total Carryover

Rio Grande Project Diversion Allocations (Data as of Oct. 31, 2011)		
8	Total Usable Water Available for Release	426,821
9	Carryover Obligation using Estimated Diversion Ratio	281,459
10	Total Usable Water Available for Current Year Allocation	145,362
11	EBID Allocation Balance (Previous Year)	20,015
12	EPCWID Allocation Balance (Previous Year)	224,348
26	Diversion Ratio	0.868

Total Carryover equals 244,362 AF

In 2010 – 2011 the "Paper Water" Problem Became Evident

- Carryover exceeded Usable Water in Storage as of 10/15/2010
- When "Carryover Obligation" is included, 62,846 AF of winter inflows went to satisfy "Carryover" and "Carryover Obligation." These inflows were thus not available for Current Year Allocations.
- EBID's Current Year Allocation in 2011 was only 57,090 AF.

Table D.4. 2010 – 2011 Example of New Inflow to Reservoir Needed to Fulfill Existing Carryover Accounts and Obligation

2010 - 2011 Example of when Carryover Accounts Required Additional Inflows

		Storage, Carryover and Credit Conditions as of October 15 2010	Storage, Carryover and Credit Conditions as of January 1, 2011
Total Water in Reservoir Storage	(AF)	386,735	497,789
CO Compact Credit	(AF)	800	2,700
NM Compact Credit	(AF)	100,500	164,700
San Juan Chama Water	(AF)	60,796	64,250
Usable Water In Storage	(AF)	224,639	266,139
EBID 2010 Unused Allocation (Carryover from 2010 to 2011)	(AF)	20,014	
EPCWID 2010 Unused Allocation (Carryover from 2010 to 2011)	(AF)	224,348	
Total Carryover (Carryover from 2010 to 2011)	(AF)	244,362	
Diversion Ratio	(unitless)	0.98	0.85
2011 Carryover Obligation (divide total Carryover by 2011 Diversion Ratio	(AF)		287,485
Inflows after October 15 required to fulfill Carryover Obligation			62,846

171

Summary of Carryover Issue

- It is a new feature of the Project (fully implemented starting 2007)
- It largely and substantially benefits EPCWID
- EBID's Allocations are too low to accumulate much Carryover
- Carryover Accounts can contain "paper water"
- Carryover is not reduced to account for evaporation
- Carryover reduces water available for Current Year Allocation to the detriment of EBID

172

12. Net Effect of 2008 OA on EBID and New Mexico

- D3 Reduces Allocation to EBID
  - Reduces aquifer recharge from canal seepage
  - Increases need for groundwater pumping to meet demand
- Groundwater levels in Rincon and Mesilla valleys decline further
  - Drain flows decrease
  - River losses increase
- Further reduction in Project performance
- Further reduction in EBID's Allocation

Net Result: Vicious Cycle

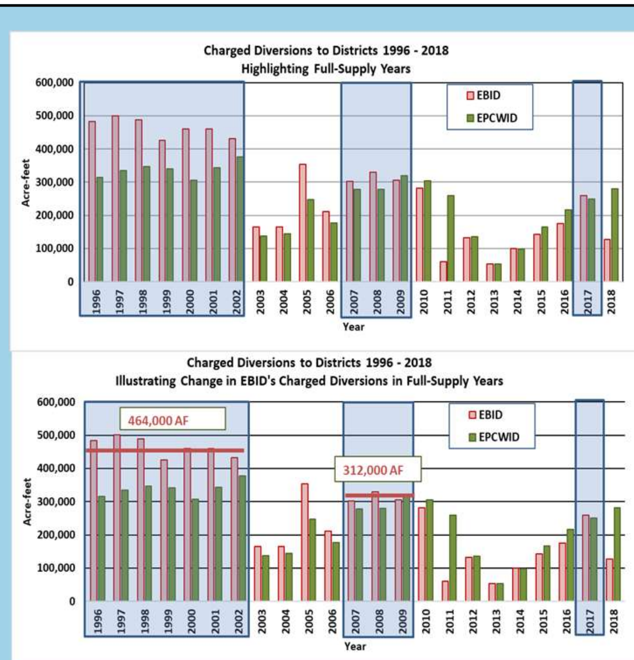
(Double Whammy/Positive Feedback Loop as stated by Dr. Phil King)

173

EBID's Full-Supply Allocation and Diversion Has Been Greatly Reduced

Reduced Project diversion causes reduction in canal seepage, historically a major source of recharge to the aquifers of the Rincon and Mesilla Valleys

With a reduced Allocation, farmers need to pump more groundwater to grow their crops



174

US_MSJ_00001090

Reduced Aquifer Recharge and Increased Pumping

Dr. Phil King calls this a "Double Whammy"

Barroll estimates the aquifer water budget in the Rincon and Mesilla valleys is worse off by at least 100,000 AF in many years

175

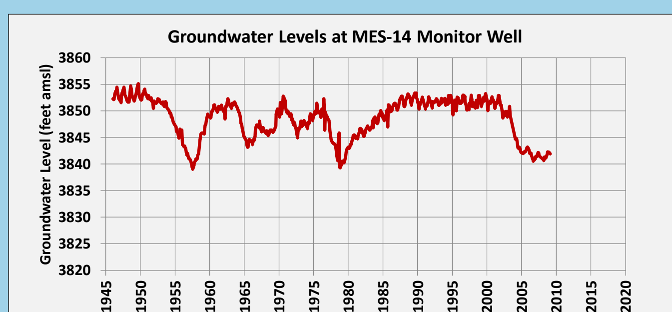
Historical Groundwater Conditions in Rincon and Mesilla Valleys

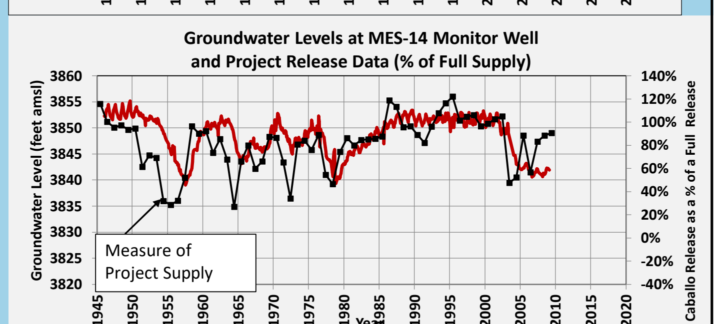
Groundwater levels fluctuated with Project Supply.

Groundwater levels

- Dropped during low-supply years
- Recovered during full-supply years

Aquifer was resilient





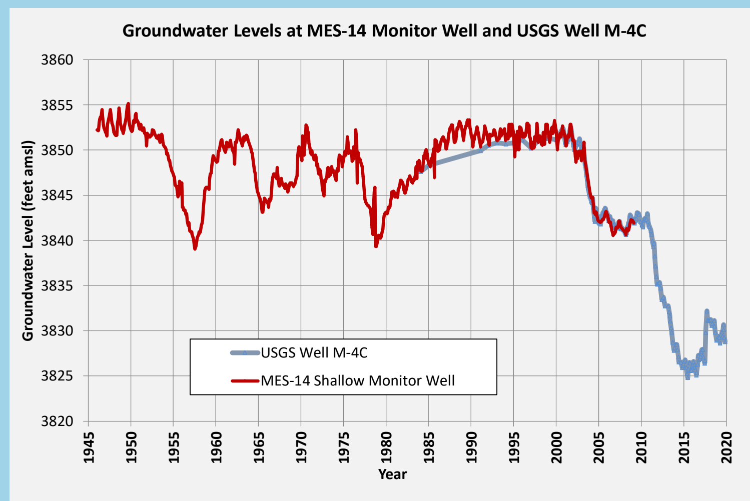
176

US_MSJ_00001091

More Recently, under D3 Allocation:

Groundwater levels

- Drop during low-supply years
- Do not recover during full-supply years

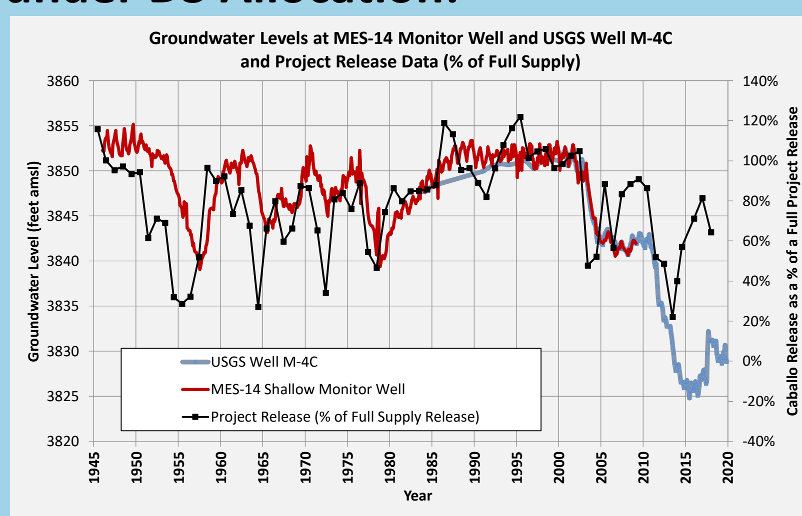


177

More Recently, under D3 Allocation:

Groundwater levels

- Drop during low-supply years
- Do not recover during full-supply years



178

Vicious Cycle (Positive Feedback Effect)

- Project performance deficit leads to reduced EBID Allocation
- Reduced EBID Allocation leads to increased aquifer stress (less recharge and more groundwater pumping)
- Increased aquifer stress leads to lower groundwater levels
- Lower groundwater levels lead to lower drain flows and increased seepage loss from Rio Grande
- Lower drain flows/increased losses make Project performance worse

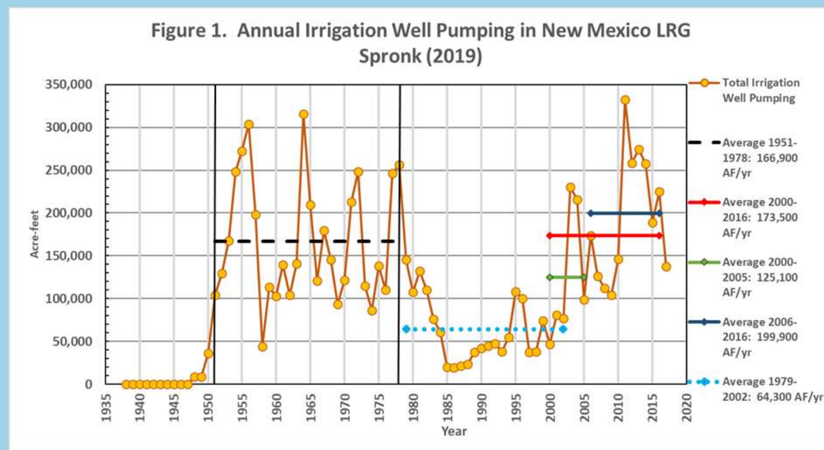
13. US Claim: D3 Reallocation is Necessary to Offset NM Pumping on EPCWID and Protect EPCWID's Project Supply Against Excessive NM Pumping

- US provides no technical analysis to quantify the effect of NM pumping on Project Supply or EPCWID deliveries
- New Mexico pumping has not greatly increased since D2 Period
- As demonstrated earlier, a significant part of the apparent discrepancy between current Project performance and historical Project performance is caused by factors other than New Mexico pumping

Irrigation Pumping in New Mexico

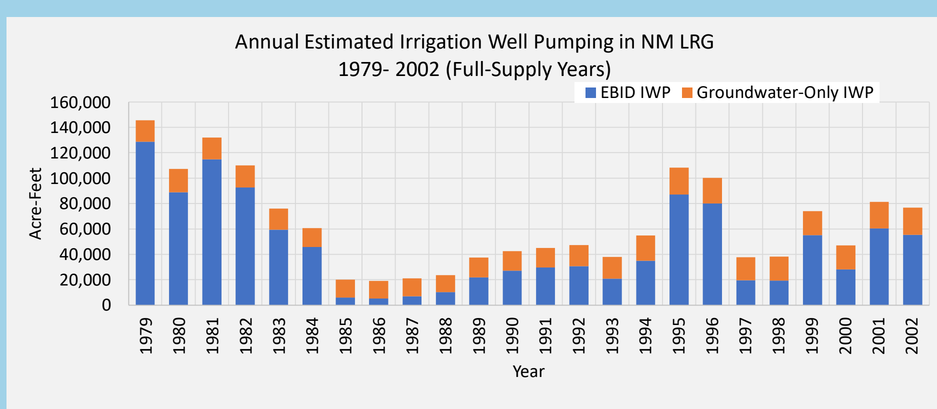
New Mexico irrigation well pumping (IWP) is high in recent years. Historically IWP was high during dry years in the D2 period.

In recent years NM IWP is aggravated by decrease in EBID's allocation under 2008 OA.



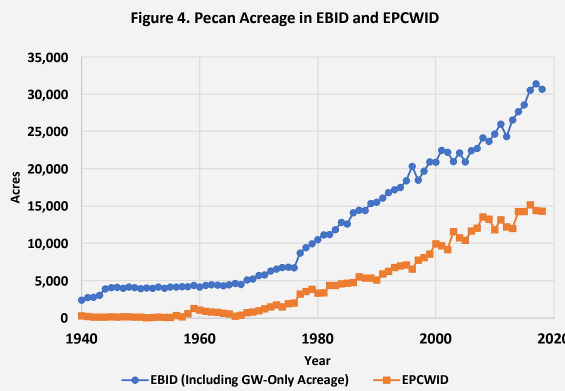
Estimated Irrigation Well Pumping in New Mexico During Project Full-Supply Years 1979 - 2002

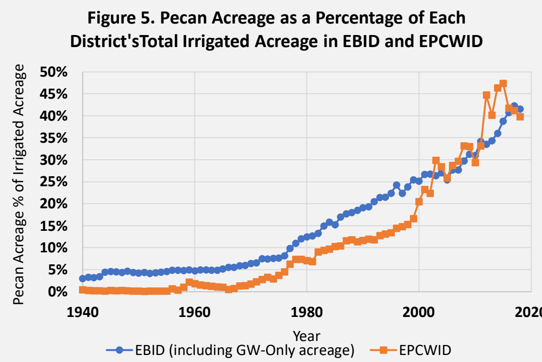
New Mexico has approximately 6,000 acres irrigated with groundwater-only (non-EBID).
There are EBID farmers who use some groundwater, regardless of surface water supply



Acreage of High-Water-Use Crops Have Increased in Both Texas and New Mexico

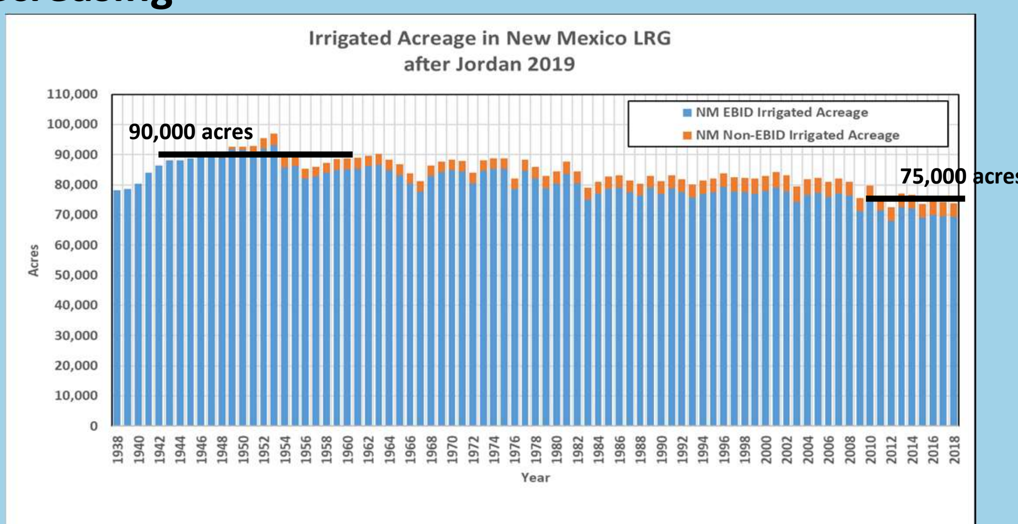
In both Districts, pecans are now about 40% of irrigated acres





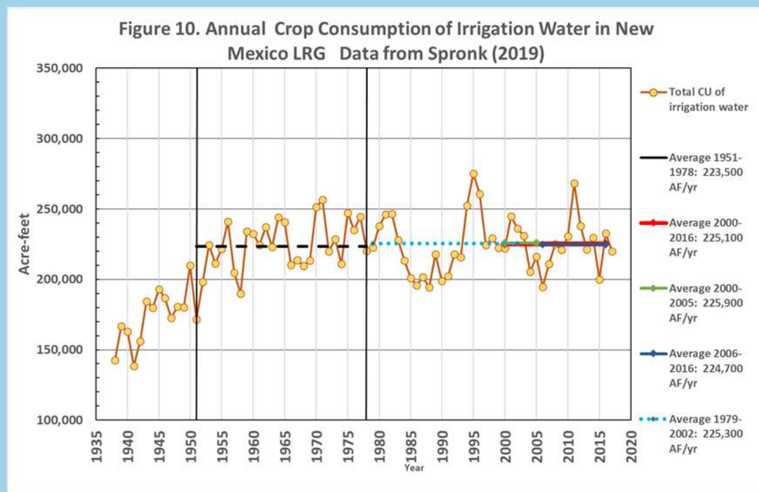
183

Total Irrigated Acreage in NM LRG Has Been Decreasing



184

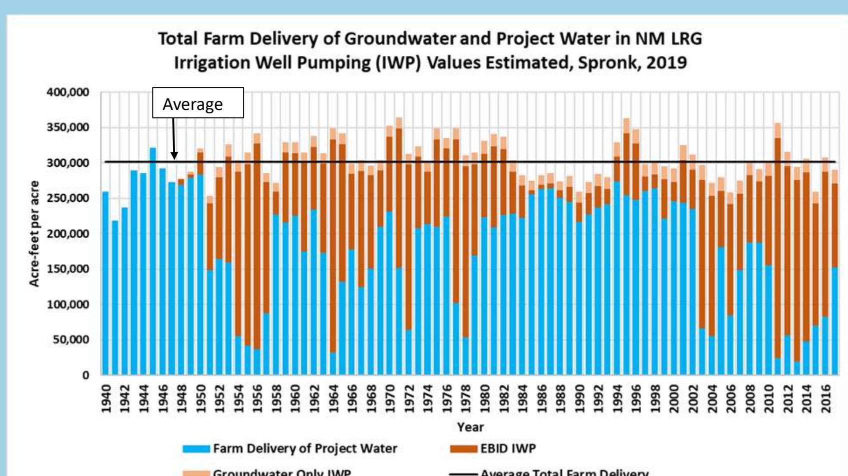
Estimated Net Irrigation Depletions in New Mexico Have Not Increased Since 1950's



Barroll Rebuttal, App A June 15, 2020 185

185

Estimated Farm Application of Irrigation Water in New Mexico (GW + SW) Has not Increased



Barroll Rebuttal, App A June 15, 2020 186

186

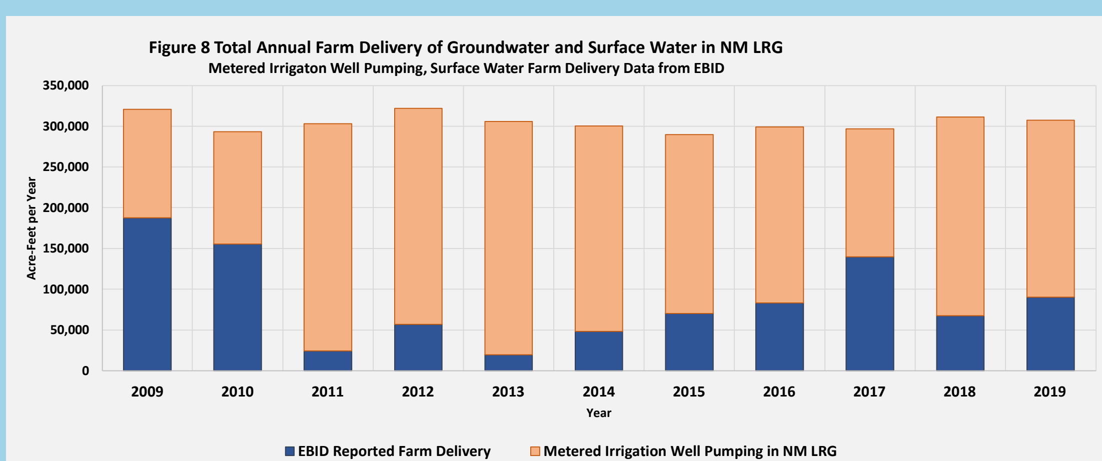
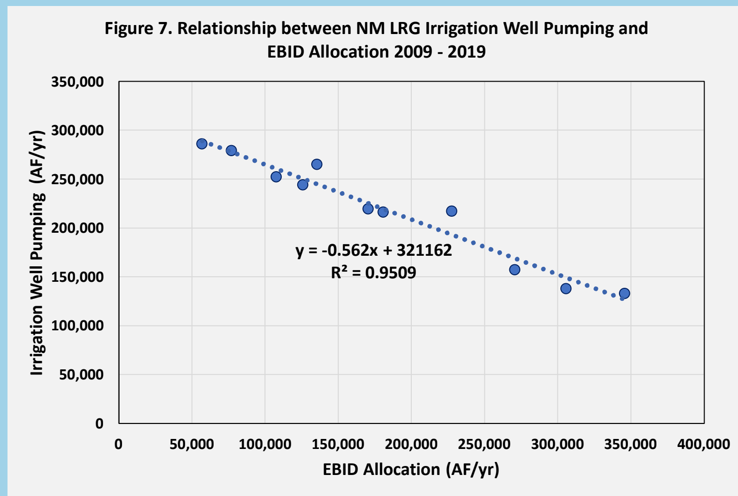
Estimated Values: 2008 Irrigation well pumping set equal to metered 2009 irrigation well pumping. 2019 Irrigated Acreage set to reflect levels in recent years.

Total Farm Delivery (SW + GW) Has Been Stable



Irrigation Well Pumping in New Mexico is Totally a Function of Surface Water Supply

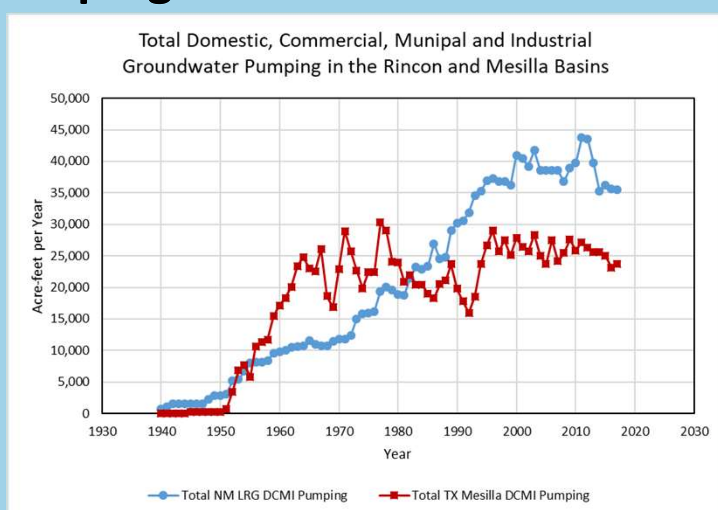
- Correlation between IWP and EBID Allocation is almost perfect.
- $R^2 = 0.95$
- NM's recent high groundwater pumping (since 2006) is almost certainly aggravated by the reduction in Allocation caused by D3 Allocation



Non-Irrigation Pumping in Rincon-Mesilla Basins

New Mexico DCMI (Domestic, Commercial, Municipal, Industrial) pumping leveled off in about 2000. Total amount is about 40,000 AF/yr.

Texas DCMI pumping in the Mesilla Basin is about 25,000 AF/yr.



14. Neither TX nor US Refute Barroll Analysis Showing:

- Before 2006 EBID and EBID farmers were entitled to order 57% of US Project Supply.
- Before 2006 the actual distribution of Project Supply between the Districts was approximately 57% to EBID and 43% to EPCWID.
- Starting in 2006 there was a large reduction in the share of Project Supply allocated to EBID, and the share of water EBID received.
- The large reallocation that began in 2006 is due to the new D3 Allocation method plus Carryover
  - D3 Allocation reduces EBID's Allocation for all negative departures in Project performance from historical levels defined by the D2 Curve.
- A significant part of the negative departure from D2 is caused by changes in Project Accounting and other factors not related to New Mexico.

Barroll Rebuttal, App A June 15, 2020 191

191

15. Neither TX nor US Refute Barroll Analysis Showing:

- EBID's Allocation is now so low that it is impossible for EBID to take advantage of Carryover.
- EPCWID has been able to create large Carryover accounts from its unused Allocation in full-supply years. Part of the reason EPWID can accumulate large amounts of unused Allocation is because it can now use El Paso municipal effluent in the El Paso Valley free of charge.
- Carryover is never reduced for evaporation and can include paper water. EPCWID's large Carryover account can reduce the amount of water available for Current Year Allocation, and thus the amount of water allocated to EBID.

Summary Opinions and Conclusions

In this Supplemental Report, I summarize results of certain runs of the revised Integrated Lower Rio Grande Model ("ILRGM") to further support the opinions I express in my 2019 Expert Report and 2020 Expert Rebuttal.

The questions that I use the ILRGM model results to address are:

1) What are the impacts of New Mexico's groundwater pumping on the amount of water allocated and delivered to Texas through the Rio Grande Project?

2) What are the impacts of D3 Allocation and the 2008 OA on the amount of water allocated and delivered to New Mexico by the Project?

3) How do the impacts of New Mexico's groundwater pumping on Texas compare with the amount of water re-allocated away from EBID and New Mexico under the 2008 OA?

4) What has been the impact of changes in Project operations and accounting in the El Paso Valley on the amount of water allocated and delivered to New Mexico by the Project?

5) How would Project allocation and delivery differ if the conditions existing during the D2 period (1951 – 1978) had continued to the present day?

My analysis consists of comparisons of Project allocation between different model runs, and comparison of Project diversions between model runs. In general, a District's diversion amounts are driven by and constrained by the amounts it is allocated. As a result, analysis of modeled allocations and diversions usually show similar trends, with minor differences in quantity and in detail. Typically, I look at both types of results in order to understand the model results more fully.

RUN 3 SUMMARY:

The impacts of New Mexico groundwater pumping are calculated by comparing a run of the ILRGM in which **all historical New Mexico groundwater pumping was turned off (Run 3)** to the historical Base Run (Run 1)**.** The resulting impacts occurring in 1980 through 2017 are as follows:

- There is no impact on the allocation of Project Supply to EPCWID or EBID for the full-supply years 1980 – 2002.

- There are limited impacts to EPCWID in the years 2003 through 2005 when all of New Mexico's pumping is turned off in Run 3. The cumulative total impacts to the Districts occurring during 2003 – 2005 are:

- An increase of EPCWID's allocation totaling 117,000 AF over all three years 2003, 2004 and 2005
- An increase of EPCWID's net diversion for all three years totaling 80,000 AF
- An increase of EBID's allocation for all three years totaling 151,000 AF
- An increase of EBID's net diversion for all three years totaling 146,000 AF

- The impacts simulated for 2006 – 2017 are dominated by the imposition of D3 + Carryover from the 2008 Operating Agreement, which resulted in significantly increased groundwater pumping by EBID farmers. As a result, the simulated impacts are larger than those that would have occurred if the 2008 OA had never been implemented. During these years, 2006-2017, New Mexico is shorted Project surface water.

RUN 11 SUMMARY:

The impacts of 2008 Operating Agreement ("D3 + Carryover") on the amount of Project water allocated and delivered to New Mexico can be calculated both from an analysis of actual Project Allocation and Diversion data, and by the analysis of outputs from the ILRGM (Run 11 versus Run 1 comparison).

- Analysis of historical allocation and diversion data shows that EBID's Allocations and Diversions after 2006 fall short of a 57% share of Project Supply by approximately 600,000 AF over the period 2006 through 2019.

- EBID's average annual shortfall from 57% is 50,000 AF each year starting in 2006. This is a first-order analysis (i.e. a conservatively low estimate without reallocation and re-operation) that does not include the actual changes in Project performance that would occur, and supply that would result from a significant change in allocation, such as a return to 57:43 Allocation.

- The actual effects of reallocation **are** simulated by the ILRGM. Using the ILRGM, I calculate that the impacts of 57:43 (or D1/D2) Allocation during 2006 – 2017, as compared with historical/actual D3 Allocation + Carryover during that time. The ILRGM impacts are as follows:
  - EBID's simulated D1/D2 Allocations are 1,218,000 AF higher than its Allocation under D3 + Carryover.[1] This indicates that on average EBID is allocated 103,000 AF less each year because of the 2008 Operating Agreement.

[1] This is cumulative total of differences over the 2006 – 2017 period, comparing D2 Allocation with Current-Year Allocation under D3 + Carryover.

- EBID's total simulated diversions under D1/D2 Allocation are 1,238,000 AF higher than under D3 + Carryover. This indicates that on average EBID receives 103,000 AF less Project Water each year because of the 2008 Operating Agreement.

- EPCWID's D1/D2 Allocations during 2006 – 2017 are a total of 185,000 AF lower than EPCWID's Allocations under D3 + Carryover for the same period.[2] This is an average of 15,000 AF/yr additional allocation to EPCWID under the 2008 Operating Agreement.

- EPCWID's total net diversions under D1/D2 Allocation are 336,000 AF lower than under D3 + Carryover. This is an average of 28,000 AF/yr of additional Project water to EPCWID.

The large magnitude of the EBID impacts calculated when comparing D1/D2 Allocation v. D3 + Carryover primarily results from two different factors:

1) Direct reallocation of water away from EBID under 2008 Operating Agreement, including the effects of the large amounts of EPCWID Carryover, and

2) Hydrologic effects of the increases in New Mexico groundwater pumping and decreases in aquifer recharge caused by the 2008 Operating Agreement. These aquifer impacts reduce Project performance (reduce the Diversion Ratio), reduce Project Supply, and thus further reduce EBID's allocation under the D3 Allocation method (i.e. "the vicious cycle").

Comparison of the results described above shows that the reduction in EBID's allocation and diversion caused by the 2008 Operating Agreement (D3 + Carryover) is much larger than the effect of New Mexico groundwater pumping on EPCWID in the years leading up to the adoption of D3 + Carryover. This finding directly refutes contentions by United States witnesses:

- Dr. Ferguson (2019) on page 5 states that "Under the D3 Method, EBID foregoes a portion of its annual diversion allocation to **offset** the impacts of groundwater pumping in New Mexico on Project allocations and deliveries to EPCWID."

- Dr. King (2019) on page 7 states: "The intended impact of the 'D3 Allocation method' is to **offset** the impacts of groundwater pumping in New Mexico on EPCWID."

Dr. Ferguson and Dr. King claim the 2008 Operating Agreement was intended to "offset" the impacts of New Mexico's pumping on the Project deliveries, yet both have acknowledged that no quantification of potential impacts from groundwater pumping was ever done during the development of the 2008 Operating Agreement. The ILRGM Run 11 prepared by New Mexico proves that the 2008 Operating Agreement significantly reduced EBID's yearly allocation and this reduction is not an appropriate offset for impacts from groundwater pumping. In sum, the analyses I have presented demonstrate that the actual impact of New Mexico groundwater pumping on

[2] This is cumulative total of differences over the 2006 – 2017 period, comparing D2 Allocation with Current-Year Allocation under D3 + Carryover.

EPCWID is **far less** than the amount of Project Supply that has been reallocated away from EBID under the 2008 Operating Agreement (D3 + Carryover).

RUN 15 SUMMARY:

Furthermore, as described in Section 5 of this Supplement, changes in Project operations and Project accounting in the El Paso Valley since the D2 period (1951- 1978) have also had a large negative impact on EBID's Project Supply. If these changes were rolled back, there would be a considerable benefit to New Mexico (see Runs 15).

- If the relatively recent ACE Credit were eliminated, and EPCWID were again charged for its diversion and use of EPWU wastewater treatment plant discharges into the Project, the ILRGM calculates the result would be a cumulative total increase in Project diversions to EBID's of 470,000 AF over the period 2000 – 2017, and an average increase of 36,000 AF/yr from 2006 through 2017.

- Alternatively, if EPCWID were required to divert El Paso Valley drain flows, as they had done historically, and were charged for such diversions, the ILRGM calculates an increase in EBID's allocation by a cumulative total of 471,133 AF, and an cumulative increase in Project diversions to EBID of 458,000 AF over the period 2000 - 2017.

- Both sets of issues were addressed in a combination run that eliminated the ACE Credit, charged EPCWID for its diversion and use of wastewater treatment plant discharges and utilized El Paso Valley drain returns in the ILRGM (Run 15). The results of this run show a total increase of 880,000 AF to EBID Project diversions from 2000 through 2017.

RUN 16 SUMMARY:

Other analysis using the ILRGM (Run 16, described in Section 6 of this supplement) shows that if Project allocation methods and the operations and accounting within Texas after 1978 had remained consistent with the D1/D2 period (1951-1978), EBID would have been allocated and would have received more Project Supply in recent years than they have actually received.

- Specifically, if the US had required EPCWID to use drain returns as it did historically, charged EPCWID for use of wastewater discharged into the EPCWID system, and kept the historical operations at D1/D2, the result reflect the historical Project operations and eliminates the inequities the US has forced on New Mexico through improper Project accounting and improper Project allocation.

1 Introduction

This supplement incorporates and summarizes the results of certain "runs" of the New Mexico Integrated Lowe Rio Grande Model ("ILRGM") as they relate to and help quantify some of the issues raised in my earlier expert reports in this litigation: Barroll (2019) and Barroll Rebuttal (2020). These issues include the impacts of New Mexico groundwater pumping, and the impacts of D3 Allocation and the 2008 Operating Agreement ("2008 OA") which incorporates both D3 Allocation + District Carryover accounts

In this report "D3 + Carryover" will be used a shorthand to refer to the allocation method that was initially adopted in 2006, and formalized in the 2008 Operating Agreement, that includes both D3 Allocation and District Carryover accounts.

In general, this supplement addresses the following questions based on results from the latest version of the ILRGM:

1) What are the impacts of New Mexico's groundwater pumping on the amount of water allocated and delivered to Texas through the Rio Grande Project ("Project")?
2) What is the impact of D3 Allocation and the 2008 OA on the water allocated and delivered to New Mexico by the Project?
3) How do the impacts of New Mexico's groundwater pumping on Texas compare with the amount of water re-allocated away from EBID and New Mexico under the 2008 OA?
4) What has been the impact of changes in Project operations and accounting in the El Paso Valley on EBID's share of Project Supply?
5) How would Project allocation and delivery differ if the conditions existing during the D2 period (1951 – 1978) had continued to the present day?

The rebuttal report filed July 15, 2020 by Gregory K. Sullivan and Heidi M. Welsh, Spronk Water Engineers, Inc. ("Spronk (2020)") presents the New Mexico ILRGM, and documents a number of base runs and test runs made with the ILRGM over an historical time period from 1940 through 2017. The ILRGM simulates the groundwater systems of the Rincon, Mesilla and Hueco Bolson/El Paso Valley, and also actively simulates the allocation and distribution of water by the Rio Grande Project.

The irrigation system operations associated with the Project comprises the largest and most complex part of the ILRGM system. The operations part of the ILRGM calculates the allocation of Project Supply,[3] and the delivery of that Project Supply in response to irrigation demands and the Mexican delivery schedule; and the delivery of a portion of EPCWID's allocation to the City of El Paso. Irrigation well pumping is then calculated through a comparison of irrigation demands (specified irrigated acreage and per-acre-water requirements) and the delivery of Project surface water to farms. The impacts of surface water distribution and groundwater pumping on the groundwater system are simulated in the two groundwater models of the ILRGM (one for the Mesilla and Rincon basins, the other for the Hueco Bolson), and key outputs from these groundwater models are fed back into the operations model of the ILRGM. The operation rules recalculate the Project allocation if necessary, and recalculate the reservoir releases required to obtain the associated deliveries of Project deliveries.

[3] Many of the terms using in this Supplement are defined in the glossary of Barroll (2020) starting on page 80.

The advantage of this integrated modeling approach is that it allows New Mexico to build on the stream depletion calculations produced by a groundwater model, and simulate how these streamflow depletions would translate into impacts on Project allocation, Project operations, and Project deliveries during the irrigation season.

The Base Run of the ILRGM is Run 1, a historical run that simulates

- Historical hydrologic inputs (including inflows to Elephant Butte, which constitute the ultimate source of most of the water in the system),
- Historical water demands (irrigated acreages and crop demands),
- Historical groundwater pumping,
- Historical Project operations through time,
- Historical allocation methods from 1940 through 2017, including the adoption of D3 + Carryover in 2006, formalized in the 2008 Operating Agreement.

A number of hypothetical alternative runs have been performed in which modified groundwater pumping and/or alternative Project operation and accounting scenarios are simulated for the same time period, and same hydrologic inputs, as the Base Run. The impacts of these modifications on Project allocation and deliveries can be quantified by comparing the pertinent alternative run to the Base Run. All of these are fully documented in Spronk (2020). In this supplement I analyze pertinent parts of the output data from certain ILRGM runs.

2 Run 3 versus Run 1: Net Effect of All New Mexico Groundwater Pumping

Run 3 is an alternative run which is set up the same as the Base Run (Run 1) except for the fact that all groundwater pumping in New Mexico has been turned off. Comparison of Run 3 to Run 1 allows us to quantify the impacts of all New Mexico pumping on the hydrologic system and on Project allocations and deliveries.

In Run 3 all non-irrigation pumping in New Mexico is set to zero, and wastewater treatment plant returns and urban deep percolation associated with that pumping are set to zero, eliminating all associated depletions. Irrigation well pumping in New Mexico is also set to zero, and aquifer recharge associated with irrigation return flow is reduced accordingly. The net result is a lower amount of irrigation consumptive use, which each year is automatically set to the amount that could be sustained with surface water only.

The elimination of New Mexico groundwater pumping causes a reduction in loss from the Rio Grande, some reduction in canal seepage, and an increase in drain flows in the Rincon and Mesilla Valleys. The model simulates these effects and also calculates how Project performance, Project allocation, and releases from Project storage would change as a result of these changes in hydrologic conditions.

Comparison of Run 1 and Run 3 allows us to isolate the net effects of New Mexico groundwater pumping, and quantify those impacts. A summary of this comparison is documented in Spronk (2020) and the supporting documents associated with that report. In this section I present analysis of the model output from these runs, starting from the year 1980, approximately when Reclamation began allocating water to the EBID and EPCWID ("the Districts") instead of allotting water to Project farmers directly.[4] To be consistent with Spronk (2020) I provide these results in the form of graphs and tables in which the impact of pumping is calculated as Run 3 minus Run 1, and represent **the change in Project allocation and diversions that would result from turning off all New Mexico pumping.**

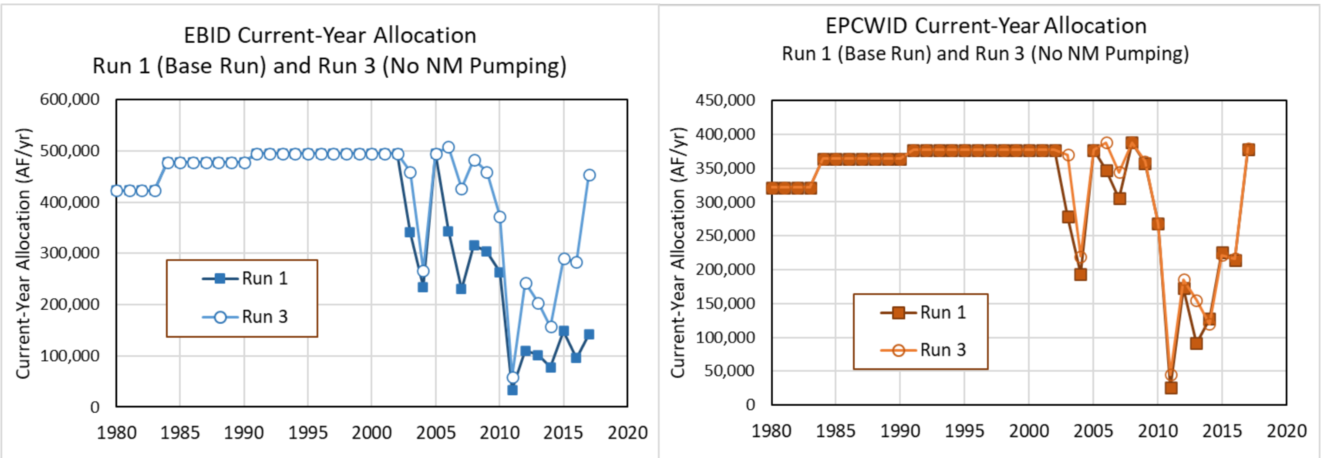
2.1 Current-Year Allocation

This Section deals with the simulated impact of New Mexico groundwater pumping on Project Allocation; that is, the impact of New Mexico pumping on the amounts of Project Supply each District was entitled to order each year under historical allocation procedures.

Figure 1 shows each Districts' Current-Year Allocation (excluding Carryover) for the years 2006 – 2017 simulated for Run 1 (historical pumping and Project operations) and Run 3 (no New Mexico pumping, and resulting Project operations).

[4] Results from earlier times, and a more complete documentation of these model runs and results can be found in Spronk (2020).

Figure 1. Simulated Current-Year Allocations to Districts, Runs 1 and 3



The Project historically enjoyed full supply conditions from 1979 – 2002, and the ILRGM simulates full-supply allocation in those years in both the Base Run and Run 3. As shown in Figure 1, New Mexico pumping has no impact on Project allocation during those years. Starting in 2003, the Project has less than a full supply in many years, and during this period New Mexico groundwater pumping has had an effect on Project Allocation. Figure 2 shows the difference between the allocations to each District in Run 1 and Run 3, and these values are tabulated in Table 1 for the years 2003 – 2017.

In general, turning off pumping during the full supply years reduces the releases from Caballo necessary to meet demands. As long as there is already sufficient water in reservoir storage, this practice has no effect on annual Project allocation. In effect, during full-supply conditions, reductions in groundwater pumping that impact Project efficiency cause "accretions" to reservoir storage.

If the reservoir spills, as it did in the mid 1980's and mid-1990's, earlier accretions to reservoir storage manifest as an increase in the amount of water spilled. Reservoir storage immediately after the spill would not reflect any of those earlier storage accretions. In effect, after a spill, the reservoir "resets."

When a series of full-supply years is ended by low-supply conditions as happened in 2003, then the storage accretions that occurred since the last spill manifest as a greater amount of water in storage at the beginning of that first low-supply year than would have occurred otherwise. (The amount of storage increase is impacted by reservoir evaporation, which is higher when reservoir levels are higher.) Under less-than-full-supply conditions, this increase in reservoir storage results in greater allocations in that first dry year. This is the effect the ILRGM Run 3 simulates in 2003 and 2004.

Figure 2. Simulated Difference in Current-Year Allocations to Districts, Runs 1 and 3: Net Impact of All New Mexico Groundwater Pumping

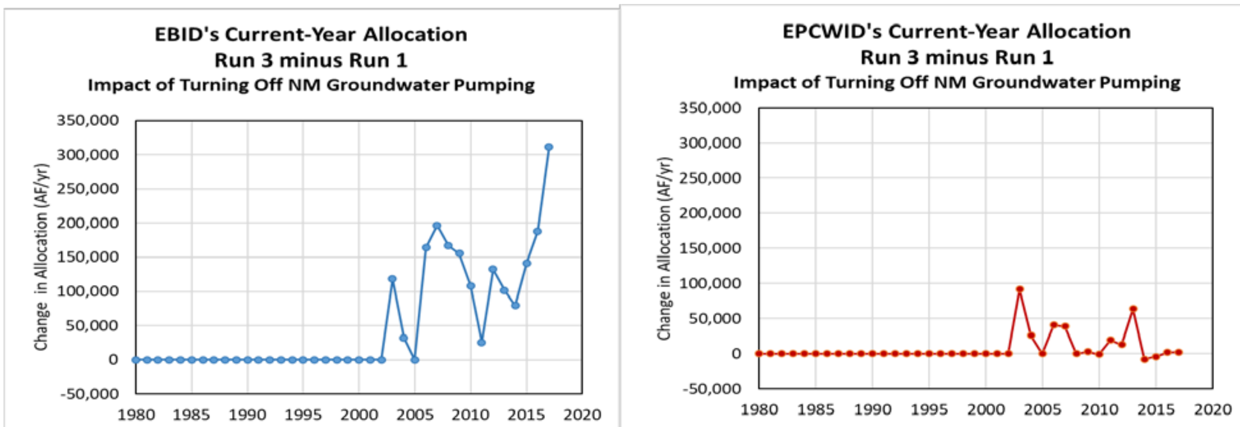


Table 1. Simulated Current-Year Allocations to Districts, Runs 1 and 3: Net Impact of Turning Off All New Mexico Groundwater Pumping

Current-Year Allocations to EBID and EPCWID Comparison of Run 3 and Run 1, Net Impact of Turning Off New Mexico Groundwater Pumping						
	EBID			EPCWID

2004	234,774	267,299	32,525	193,878	219,828	25,950
2005	494,979	494,979	0	376,862	376,862	0
2006	343,239	507,468	164,229	347,542	388,192	40,650
2007	230,031	427,069	197,039	305,167	343,917	38,749
2008	316,148	483,073	166,925	388,192	388,192	0
2009	303,662	458,928	155,266	357,470	360,138	2,668
2010	263,891	372,316	108,425	268,731	267,759	-972
2011	33,619	59,197	25,578	25,596	45,071	19,474
2012	110,596	243,258	132,662	172,242	185,207	12,965
2013	101,912	203,868	101,955	91,165	155,217	64,052
2014	77,693	156,904	79,211	127,555	119,461	-8,094
2015	148,876	290,234	141,358	225,858	221,672	-4,186
2016	95,409	283,590	188,181	214,548	216,279	1,732
2017	141,763	453,437	311,674	377,309	379,667	2,358

The data in Table 1 indicate that the cumulative impact of New Mexico's groundwater pumping on EPCWID's Current-Year Allocation in the years 2003 through 2005 (the years that led up to the adoption of D3 Allocation in 2006) totaled 117,500 AF.[5] In order to calculate the effect of New Mexico pumping on the amount of water EPCWID would actually receive, I analyze the simulated diversions in Section 2.2.

[5] 117,546 AF is the sum of 91,596 AF from 2003 plus 25,950 AF from 2004.

The later impacts shown in Figure 2 and Table 1, for the years 2006 through 2017, reflect the increase in New Mexico irrigation well pumping caused by the implementation of 2008 Operating Agreement (D3 + Carryover), and its reduction in EBID's allocation. Furthermore, these differences do not reflect the beneficial effect of D3 Allocation itself has on EPCWID's allocation compared with previous allocation methods, which would only have allocated EPCWID 43% of the Project Supply.[6] (See Section 4 for this analysis.)

Table 1 shows that turning off all New Mexico groundwater pumping also has a net positive impact on EBID's Current-Year Allocation in 2003 and 2004, the years leading up to the adoption of D3 + Carryover. The change in reservoir level simulated at the beginning of 2003 (described above) impacts EBID's Allocation as well as ECPWID's. The total impact of turning off New Mexico groundwater pumping increases EBID's allocation in the years 2003 – 2005 by a cumulative total of 151,000 AF. Starting in 2006, the net impact of New Mexico groundwater pumping on EBID's allocation grows dramatically. This reflects two related factors:

1) Irrigation well pumping by EBID farmers in the Base Run is systematically higher starting in 2006 because D3 Allocation has systematically reduced EBID's Project share of surface water Supply to account for all negative departures from the D2 Curve (Barroll (2019) and (2020)).
2) Negative departures from D2 and reductions in EBID's allocation in the Base Run are further aggravated by the increased EBID farm pumping required to grow crops under low D3 Allocations.

2.2 Net River Headgate (RHG) Diversions

This Section presents the simulated effects of New Mexico groundwater pumping on the Districts' Net River Headgate (RHG) Diversions of Project Water[7]. The Net RHG Diversions shown here are the net amount that each District is simulated to have diverted over each calendar year, and these values are calculated as the total canal heading diversions (including EPWU diversions for municipal supply), less any by-pass water (El Paso Valley Carriage in New Mexico, and Ascarate wasteway flow in the El Paso Valley), with an adjustment to assign part of the diversions at Mesilla Dam to EPCWID[8]. In general, RGH Diversions are greater than the Districts' Charged Diversions, in part due to the diversions occurring outside of the Caballo Release season (which are not included in Charged Diversions), diversion of water spilled from reservoir storage, and due the effect of to Project Accounting credits. In this section I analyze RHG diversions instead of Charged Diversions in order to ensure that all potential impacts to EPCWID's irrigation supply caused by New Mexico pumping are considered.

---

[6] In this report, when I refer to each District's allocated or diverted percentages of Project Supply, I am referring to the Project Supply that is allocated to, or diverted by the Districts, exclusive of the Mexican delivery.

[7] Some Project Diversions accounted for in both the Charged Diversions and RHG diversions are not actually made from the "River", that is from the bed of the Rio Grande. EPCWID now diverts water from the American Canal and American Canal Extension, and it is those diversion amounts which are used in Project Accounting and in Spronk's (2020) calculation of FHG diversions.

[8] Neither EPCWID's Charged Diversions or the RHG diversions analyzed here include the diversion and use of EPWU wastewater discharged directly into the ACE and Riverside Canal, which Dr. Blair refers to as "District Water" but not "Project Water" (Blair, A.W., 2001, "Sources and Quantity of Rio Grande Project Water Available for Conversion to Uses Other than Irrigation under the Proposed Third-Party Implementing Contract among EPCWID, the City of El Paso, and the United States", Exhibit D of Contract No. 01-Wc-40-6760.)

Figure 3 shows the simulated Net RHG diversions for both Run 1 and Run 3 for each District. Figure 4 shows the difference between the two runs for each District, which represents the simulated impact of New Mexico pumping on each District's RHG Diversion. These data are tabulated in Table 2.

Figure 3. Simulated Net RHG Diversions, Runs 1 and 3

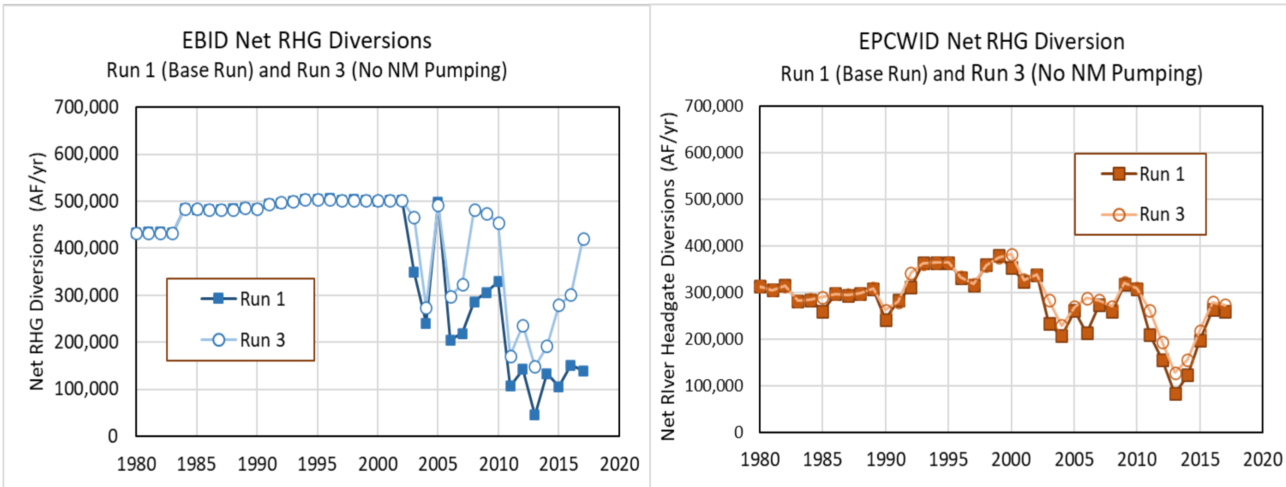

Figure 4. Simulated Differences in Net RHG Diversions, Runs 1 and 3: Net Impact of Turning Off All New Mexico Groundwater Pumping

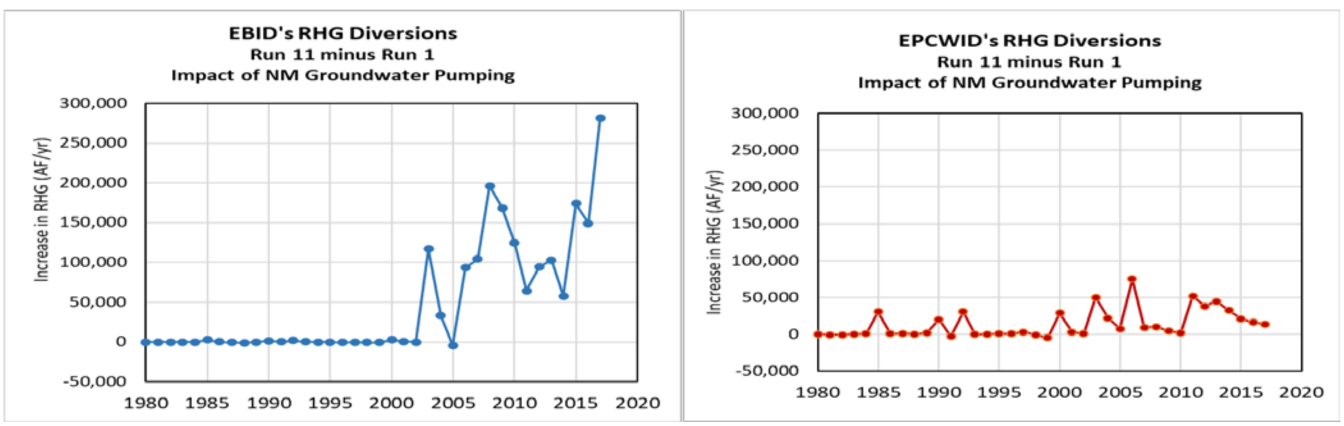

The results tabulated in Table 2 show that the simulated increase in EBID diversions associated with turning off New Mexico groundwater pumping totals 146,000 AF for the years 2003 through 2005, the years leading up to the 2006 adoption of D3 + Carryover (then formalized as the 2008 Operating Agreement). The corresponding increase in EPCWID diversions for the years 2003 through 2005 totals 80,000 AF.

As before (Section 2.1), the net large impacts of New Mexico groundwater pumping on EBID's diversions that are simulated starting in 2006 represent the larger amounts of groundwater EBID farmers must pump to supply their crops due to decreased surface water Supply under D3 +

Carryover. Similarly, the changes simulated in EPCWID's diversions from 2006 forward in also reflect the effects of New Mexico's increased groundwater pumping under D3 Allocation.

Table 2. Simulated Net RHG Diversions, Runs 1 and 3: All NM GW Pumping

2.3 Summary and Conclusions

The ILRGM results show that impacts of **turning off all New Mexico groundwater pumping** on the Districts' allocation and diversion for the years 1980 through 2017 are as follows:

- There is no impact on the allocation of Project Supply to EPCWID or EBID for the full-supply years 1980 – 2002.
- There are limited impacts to EPCWID in the years 2003 through 2005 when all of New Mexico's pumping is turned off in Run 3. The cumulative total impacts to the Districts occurring during 2003 – 2005 are:
  - An increase of EPCWID's allocation totaling 117,000 AF over these three years 2003, 2004 and 2005
  - An increase of EPCWID's net diversion over these three years totaling 80,000 AF
  - An increase of EBID's allocation over these three years totaling 151,000 AF
  - An increase of EBID's net diversion over these three years totaling 146,000 AF
- The impacts simulated for 2006 – 2017 are dominated by the imposition of D3 + Carryover from the 2008 Operating Agreement, which resulted in significantly increased groundwater pumping by EBID farmers. As a result, the simulated impacts are larger than those that would have occurred if the 2008 OA had never been implemented. During these years, 2006-2017, New Mexico is shorted Project surface water.

3 Historical District Allocations and Deliveries: Departure from 57:43

In Barroll Rebuttal (2020) I performed analysis of the reported Current-Year Allocations to, and Diversions by, the Districts from 2006 through 2019, to calculate the amount by which EPCWID Current-Year Allocation exceeds 43% of the total Current-Year Allocation to the Districts. Essentially, this analysis is a conservatively low, first-order estimate of the effects of D3 Allocation and the 2008 Operating Agreement on EBID.

This Allocation calculation is shown below as Table 3. The departure from 57:43 allocation is here calculated by taking the total amount allocated to the Districts each year and reallocating that amount 57% to EBID and 43% to EPCWID.

In the first columns of Table 3, reported Current-Year District Allocations (from Reclamation records) are tabulated and summed. 43% of that total is calculated. The final column represents the amount by which EPCWID's actual Current-Year Allocation exceeded 43% of the whole. The total amount by which EPCWID's Current-Year Allocation has exceeded 43% over the period 2006 through 2019 is approximately 693,000 AF. This calculation is a "zero-sum game" in that any increase to EPCWID's allocation above 43% is equal to the amount by which EBID's allocation falls short of 57%. Therefore, this analysis provides a first order estimate that EBID's Allocation has been reduced by a total 693,000 AF in period 2006 – 2019.

Table 3. Reported Current-Year Allocation Data: Departure from 57:43, 2006-2017

(Rebuttal Table 9) EPCWID Current-Year Reported Allocation in Excess of 43% of the Total Current-Year Allocation to Districts

Total					**531,389**

The data in Table 4 do not include the amounts of EPWU wastewater discharged into EPCWID's conveyances and used by EPCWID farmers without any Project accounting charge. (EPWU operates the City of El Paso's municipal water system.)[9]

Table 5 is a re-analysis of the diversion data so as to include this uncharged EPWU wastewater. The amount included is the reported discharge of EPWU wastewater into EPCWID conveyances in the El Paso Valley during the Caballo release season (the time period for which Project Charges are now computed).

[9] EPWU is El Paso Water Utilities. For more detail on the issue of EPWU wastewater in the El Paso Valley, see Barroll Rebuttal (2020) Section R7.

As shown in Table 5, EPCWID's total diversions (including wastewater) are 708,000 AF greater than 43% of the total District diversions. Conversely, EBID's total diversions are 708,000 AF less than 57% of the total District diversions (including all wastewater).

Table 5. Reported Diversion Data including EPWU Wastewater in the El Paso Valley: Departure from 57:43, 2006-2017

Total						**708,377**
Estimated Values						

As described in Barroll Rebuttal (2020, page 47), this is a first order analysis. This analysis does not incorporate the effects of the improvement in hydrologic conditions that would result from the increase in EBID's allocation and the application of additional surface water within EBID. This improvement would tend to increase drain flows and reduces seepage losses, increasing the Project Diversion Ratio and further increasing EBID's Allocation. As such, this analysis probably understates the amount by which EBID's allocation would increase if Project Supply water were divided more equitably. Furthermore, the Allocation calculation does not incorporate the likely changes in total reservoir releases and subsequent changes in Usable Supply that would result from changes in allocation. In order to calculate the effect of both of these second order factors, it is necessary to use an integrated model, such as the ILRGM. The results of that analysis are in Section 4.

3.1 Summary and Conclusions

Analysis of reported Project allocation and diversion data provides a conservative estimate of how much water has been reallocated away from EBID as a result of D3 + Carryover, compared to EBID's historical 57% share of Project Supply.

This analysis shows for the period 2006 through 2019:

- EBID's Current-Year Allocations under D3 + Carryover fall short of 57% of the Current-Year Allocation to the Districts by a total of 693,000 AF. On average EBID's Current-Year Allocation falls short of 57% by 50,000 AF each year.

- EBID's Charged Diversions under D3 + Carryover fall short of 57% of District Charged Diversions by a total of 531,000 AF, or an average of 38,000 AF each year.

- If EPCWID's uncharged diversion and use of EPWU wastewater in the El Paso Valley is included in the diversion calculation, then EBID's share of diversions falls short of 57% by a total of 708,000 AF, or an average of 50,000 AF each year.

4 Run 11 versus Run 1: Net Effect of D3 Allocation Compared with D1/D2 (57:43) Allocation

Run 11 is an alternative run, which is set up the same as the Base Run (Run 1) except for the fact that the Project allocation method is not changed to D3 + Carryover in 2006[10]. Instead, Run 11 continues to apply D1/D2 Allocation throughout the 2006 to 2017 period. Comparison of Run 11 to Run 1 allows us to quantify the impacts of D3 Allocation and the 2008 OA on Project operations and deliveries relative to a 57:43 allocation split of Project Supply implemented through D1/D2 Allocation[11]. This analysis with the ILRGM not only calculates the immediate reallocation of water on Project allocation and distribution, but also calculates the resulting impacts on the hydrologic system, how those impacts change Project performance, and then how those changes in Project performance further change Project allocation and distribution.

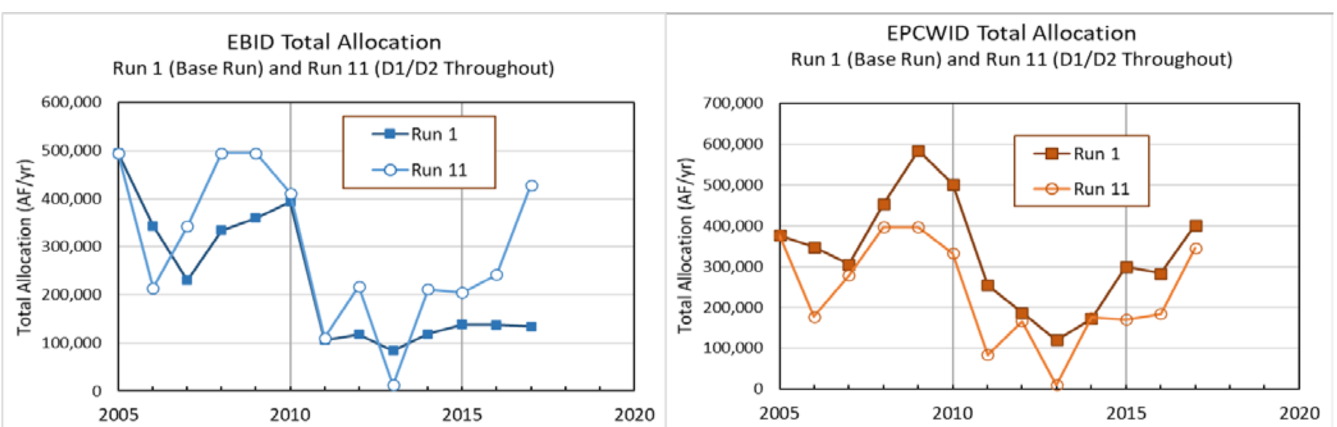
In this section I present analysis of the model output from these runs starting from the year 2005, just before the two model runs diverge. To be consistent with Spronk (2020), these results are presented in the form of graphs and tables showing Run 11 minus Run 1. These results represent the change in allocation or diversion caused by **returning to D1/D2 (57:43) Allocation.**

4.1 Total Allocation

Figure 5 shows the Total Allocation (including Carryover) to each District, for the time period 2005 – 2017, for Run 1 (the Base Run) and for Run 11. I show these graphs to illustrate the effects of Carryover, especially for EPCWID in low-supply years.

In general, EBID's Total Allocation is higher in Run 11 (the D1/D2 run) than in Run 1, as would be anticipated in a return to 57:43 Allocation. Conversely, EPCWID's Total Allocation is lower in Run 11 than in Run 1, as would be anticipated both because of EBID's increased Run 11 allocation, and subsequent greater water use; and also because in Run 11 EPCWID is not able to accumulate Carryover for use in low-supply years.

Figure 5. Total Allocation to Districts, Runs 1 and 11



[10] The Base Run implements D3 Allocation in 2006 and Carryover in 2008.
[11] A description of the D1/D2 Allocation method, the D3 Allocation method, and Carryover under the 2008 OA can be found in Barroll (2019).

4.2 Current-Year Allocation

Current-Year Allocation results for each District from Runs 1 and 11 are plotted in Figure 6.

Figure 6. Current-Year Allocations to Districts, Runs 1 and 11

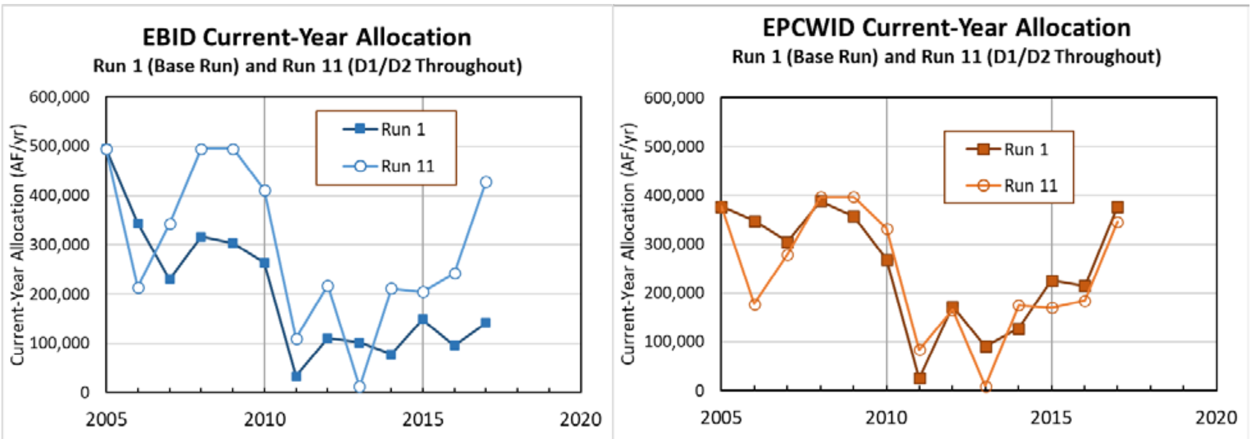


Figure 7 shows the difference in Current-Year Allocation results for each District, and Table 6 tabulates Current-Year Allocation results for each District. As shown in Figures 6 and 7 and in Table 6, the effects of a return to D1/D2 (57:43) Allocation are predominantly positive for EBID, with a cumulative total 1.2 million AF of increased allocation. This means that the net effect of the implementation of D3 + Carryover has been a reduction in EBID's allocation by 1.2 million AF over the 12 years from 2006 through 2017.

The effect of a return to D1/D2 are predominantly negative for EPCWID, and with a total reduction in Current-Year Allocation of 0.2 million AF. This means that the net effect of the implementation of D3 + Carryover has been an increase in EPCWID's allocation by 0.2 million AF over 12 years from 2006 through 2017, 1/6th (one-sixth) of the amount by which EBID's allocation was reduced. That is to say: the large deficit to EBID caused by D3 + Carryover results in only a modest benefit to EPCWID.

Figure 7. Difference in Current-Year Allocation in Districts, Runs 1 and 11: Net Impact of Implementing D1/D2 Allocation 2006-2017 instead of D3 Allocation + Carryover

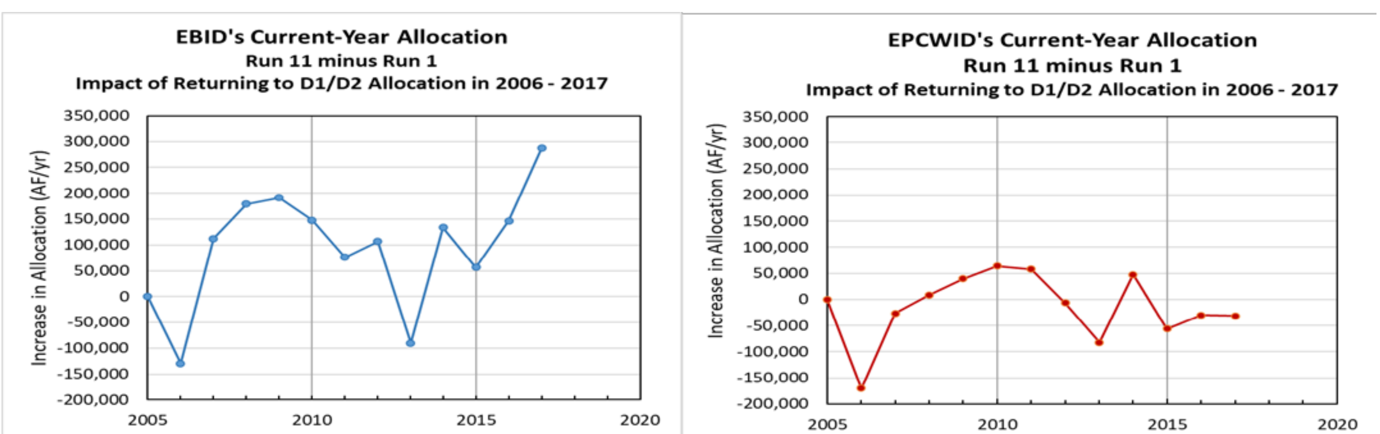

Table 6. District Current-Year Allocations, Runs 1 and 11: Net Impact of Implementing D1/D2 Allocation 2006-2017 instead of D3 + Carryover

4.3 Net RHG Diversions

In this section I quantify the impact of D3 Allocation plus Carryover on the Districts' RHG Diversions by comparing results from Runs 1 and 11.

Figure 8 plots the RHG Diversion results for each District for the period 2005 – 2017 from Runs 1 and 11. Figure 9 plots the difference in RHG Diversions between the two runs, showing the net effect of Allocation method on how much water the District are simulated to divert at their canal headings.

Figure 8. Net RHG Diversions, Runs 1 and 11

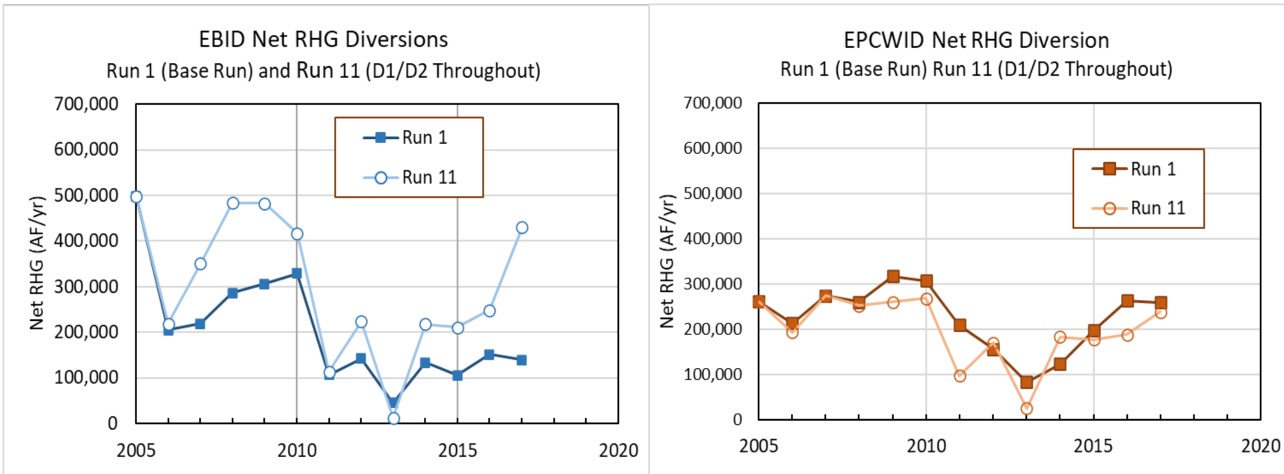

Figure 9. Difference in Net RHG Diversions: Runs 1 and 11, Net Impact of Implementing D1/D2 Allocation 2006-2017 instead of D3 Allocation + Carryover

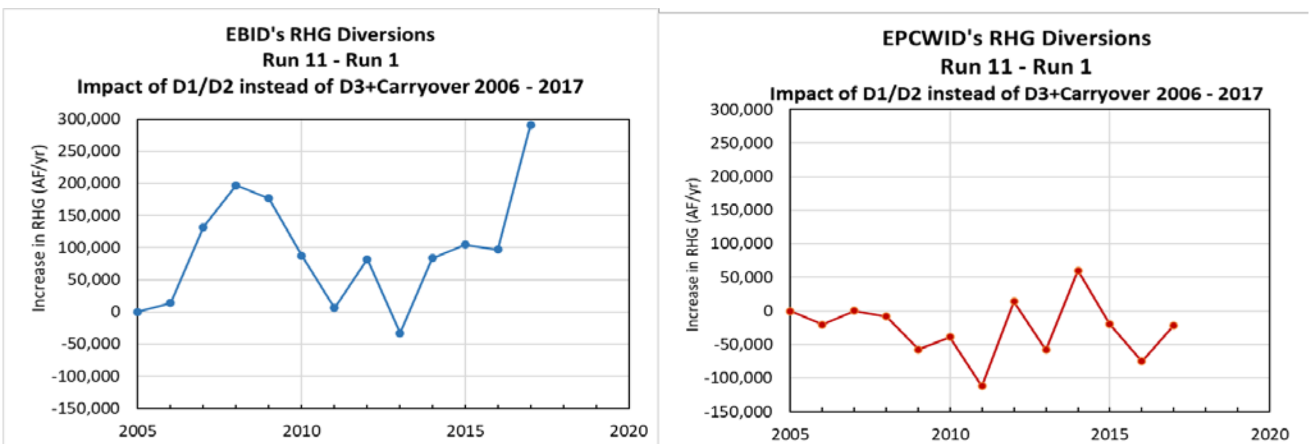

The results plotted in Figures 8 and 9 show that EBID diverts considerably more water under the D1/D2 Allocation (57:43) than under D3 + Carryover. Conversely EPCWID diverts less water under D1/D2 Allocation than under D3 + Carryover.

The RHG Diversion results from Runs 1 and 11 are tabulated in Table 7. In summary, the ILRGM calculates that under D1/D2 Allocation, EBID would have diverted approximately 1.2 million acre-feet more than under D3 + Carryover, while EPCWID would have diverted 0.3 million acre-feet less. **Again, the net effect of the 2008 OA is to reduce EBID's water supply by a large amount (approximately 103,000 AF/yr on average since 2006), in order to obtain a relatively small increase in the supply to EPCWID (approximately 30,000 AF/yr on average since 2006).**

Table 7. Simulated Net RHG Diversions, Runs 1 and 11: Net Impact of Implementing D1/D2 Allocation 2006-2017 instead of D2 Allocation + Carryover

Totals			**1,238,371**			**-335,752**

4.4 Simulated Total Project Supply Amounts

The results in Table 7 indicate that more total water is delivered to and diverted by the Districts under D1/D2 Allocation than under D3 + Carryover, even though both model runs have the same annual inflows to Elephant Butte Reservoir supplying the Project. Essentially, D1/D2 Allocation allows more water in total to be delivered to the Project canal headings downstream than the 2008 Operating Agreement does, for the same total amount of Reservoir inflow. **This result is a natural outcome from the general principal in irrigation systems that when more water is applied to lands upstream, there is more opportunity for "recycling", by which the same water is diverted 2 or 3 times as it passes to downstream diversion points as return flow.**[12]

In the Lower Rio Grande, the extra water provided to EBID also improves aquifer conditions in the upper Project by reducing groundwater pumping, reducing seepage losses from the main stem of the Rio Grande, and improving drain flows. The total reduction in seepage losses and increase in drain flows contributes to the total amount of water the Project can deliver, thereby improving the delivery performance or delivery efficiency of the Project.

[12] Other factors contribute to this difference in the total Project Supply delivered to the Districts: both total reservoir evaporation and Mexican deliveries are different between these two runs.

This is illustrated by the Project Diversion Ratios from the two model runs. (The Diversion Ratio is a measure of Project delivery performance, and is defined as the total annual Charged Diversions of Project Water divided by the annual release of Project water from Storage.) Figure 10 is a plot of the simulated Diversion Ratios simulated for Runs 1 and 11, and Table 8 provides a tabulation of these values. Figure 10 shows that Run 11, in which D1/D2 Allocation is applied from 2006 – 2017, typically has a higher Diversion Ratio, which is consistent with a higher total Project diversion per quantity of Reservoir release.

Figure 10. Simulated Diversion Ratios in Run 1 and Run 11

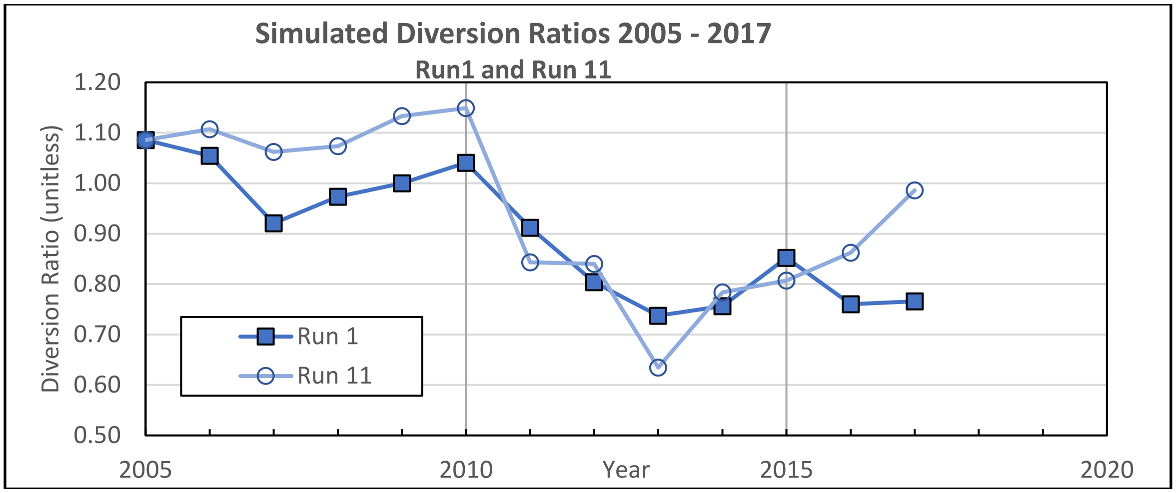

Table 8. Simulated Diversion Ratios, Run 1 and Run 11, 2005-2017

Simulated Diversion Ratios, Run 1 and Run 11					
Year	Run 1	Run 11	Year	Run 1	Run 11

2010	1.04	1.15	2017	0.77	0.99
2011	0.91	0.84			

4.5 Summary and Conclusions

In 2006, the Rio Grande Project made a substantial change in its allocation procedure, adopting D3 Allocation and District carryover accounts. The effects of this re-allocation are calculated by comparing Run 11, which implements D1/D2 (57:43) Allocation in 2006 through 2017, to Run 1, in which D3 + Carryover Allocation is implemented in those years.

The impacts during the years 2006 – 2017 resulting from this re-allocation are as follows:

- The cumulative total of EBID's simulated D1/D2 Allocations during 2006 – 2017 are 1,218,000 AF higher than EBID's simulated Current-Year Allocations under D3 + Carryover. This indicates that on average EBID is allocated 103,000 AF less each year because of the 2008 Operating Agreement.

- The cumulative total of EBID's simulated diversions under D1/D2 Allocation during 2006 – 2017 are 1,238,000 AF greater than EBID's simulated diversions under D3 + Carryover. This indicates that on average EBID receives 103,000 AF less Project Water each year because of the 2008 Operating Agreement.

- EPCWID's D1/D2 Allocations are a cumulative total of 185,000 AF lower than EPCWID's Current-Year Allocations under D3 + Carryover. This is an average of 15,000 AF/yr additional allocation to EPCWID under the 2008 Operating Agreement.

- EPCWID's net diversions under D1/D2 Allocation are a cumulative total of 336,000 AF lower than under D3 + Carryover. This is an average of 28,000 AF/yr of additional Project water to EPCWID.

These results show that the adoption of the 2008 Operating Agreement (D3 Allocation + Carryover) had significant negative impacts on the amount of Project Water EBID was allocated and diverted. The large magnitude of the EBID impacts primarily results from two different factors:

1) Direct reallocation of water away from EBID under 2008 Operating Agreement, including the effects of the large amounts of EPCWID Carryover, and

2) Hydrologic effects of the increases in New Mexico groundwater pumping and decreases in aquifer recharge caused by the 2008 Operating Agreement. These aquifer impacts reduce Project performance (reduce the Diversion Ratio), reduce Project Supply, and thus further reduce EBID's allocation under the D3 Allocation method (i.e. "the vicious cycle").

5 Runs 15, 15a, 15b, and 15c (Run 15 et al.): Early EPCWID Operations

Run 15 et al. are hypothetical runs that are identical to the historical base run (Run 1) except that changes in accounting, operations and pumping are implemented in the El Paso Valley. Runs 15, 15a and 15b modify EPCWID operations and accounting in the later parts of these model runs, to more consistently reflect operations and Project Accounting in the El Paso Valley as they occurred in earlier years, prior to the 2008 OA and prior to the change in accounting that occurred in 1979.

5.1 Run 15a: Charges for All EPWU Wastewater and Elimination of ACE Credit

Run 15a changes Project Accounting so that EPCWID is charged for the diversion and use of all wastewater discharged from the City of El Paso in the El Paso Valley ("EPV Wastewater") during the Caballo release season, including wastewater discharged into EPCWID conveyances.[13] Run 15a also eliminates the relatively recent ACE Credit, which awards EPCWID extra allocation as a reward for mitigating delivery inefficiencies that were in part caused by Texas groundwater pumping.[14]

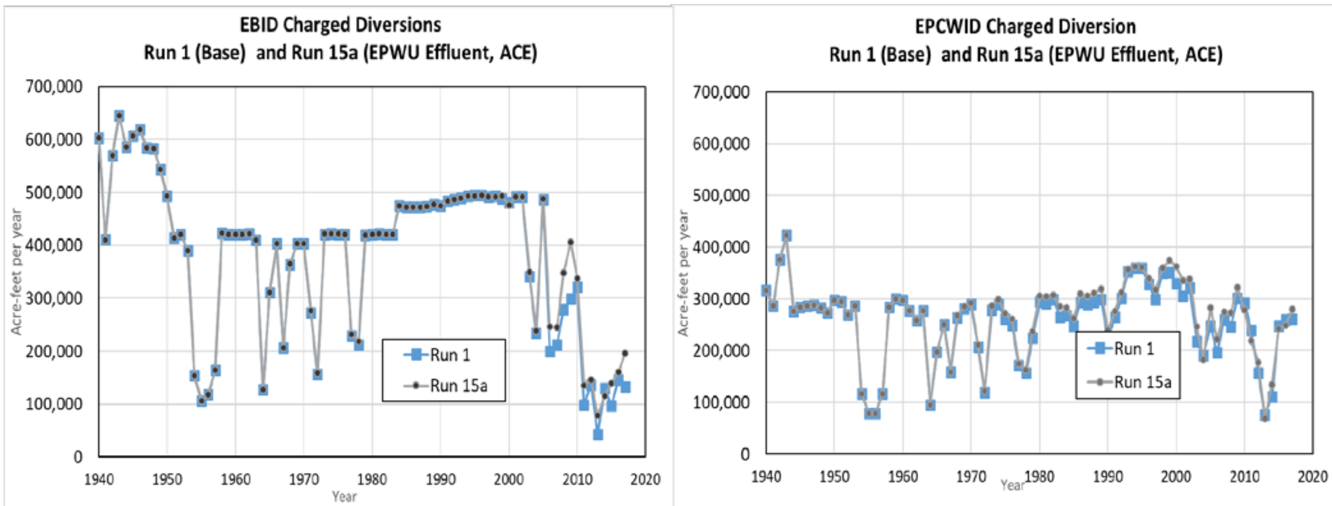
The accounting in Run 15a is more consistent with earlier Project operations and accounting. From the earliest days of the Project until 1967 all of El Paso's wastewater was discharged into the Rio Grande above Riverside Dam, and the diversion of this water at Riverside was included in the accounting of Project Supply.[15] The ACE Credit did not exist until 2003, and was instituted to reward the ACE bypass of the Rio Grande seepage that itself was largely caused by Texas and Mexican groundwater pumping. Aside from these accounting changes, Run 15a is the same as Run 1 (the historical base run) and a comparison of these runs allows us to isolate the effects of the accounting anomaly that allows EPCWID to use El Paso wastewater (which largely consists of Project return flow[16]) free of charge, and the ACE Credit.

The simulated Charged Diversions from Run 1 (the Base Run) and Run 15a are plotted in Figure 11 for the entire simulation period, 1940 – 2017.

[13] For more complete discussion of El Paso Valley wastewater issues, see Barroll (2020), Section R7.
[14] For more complete discussion of the ACE, see Barroll (2020), Section R8.
[15] Starting in 1967, part of El Paso's wastewater was discharged into the Riverside Canal at a location below the gage at which the Riverside diversion are measured, and so this wastewater was not included in accounting of Project Supply. Starting in 1999, Haskell R Street wastewater (which previously discharged to the Rio Grande and was accounted Project Supply) was intercepted by the American Canal Extension, and from that time forward EPCWID has been allowed to divert and use that water without charge.
[16] Barroll (2020), Section R7.

Figure 11 shows that these accounting changes have little to no impact on EBID's diversions before 2006, and that starting in 2006 they tend to increase EBID's Charged Diversions. EPCWID's Charged Diversions for Run 15a show a small increase starting in approximately 1980, reflecting the fact that in Run 15a EPCWID is being charged for the diversion and use of EPWU wastewater, which in Run 1 it is using free of charge.

Figure 11. Simulated Charged Diversions, Runs 1 and 15a, 1940-2017



Simulated Charged Diversions for the period 2000 through 2017 are plotted in Figure 12 and tabulated in Table 9. Table 9 shows that the benefits to EBID of charging EPCWID for all EPWU wastewater and eliminating the ACE Credit are substantial, as EBID's diversions from Run 15a are considerably higher than Run 1. EBID's Charged Diversions in Run 15a are greater in every year, and the total increase in EBID's Charged Diversions in this period is 470,000 AF. EPCWID's Run 15a Charged Diversions are also somewhat higher but this is largely because in Run 15a EPCWID is charged for the diversion and use of EPWU wastewater, while in Run 1 EPCWID still diverts and uses the wastewater but is not charged for it.

Figure 12. Charged Diversions, Runs 1 and 15a, 2000-2017

Review of these results (and the more complete set of results in Spronk (2020)) indicates that these accounting factors (ACE Credit and EPWU wastewater charges) have little impact on EBID until the advent of D3 Allocation + Carryover. This is because D3 Allocation reduces EBID's allocation for any reduction in the Diversion Ratio, and the Diversion Ratio is calculated using Charged Diversions. As a result, any reduction in Charged Diversions (including those due to accounting credits) automatically reduces EBID's D3 Allocation (Barroll (2020), Table 3).

Furthermore, Carryover causes these factors to have additional negative impacts on EBID. Prior to the implementation of Carryover, the effect of Allocation Credits and uncharged diversions on EPCWID's Allocation would disappear at the end of each year when all unused allocation returned to the common supply of water available for the next year's allocation. Under Carryover, EPCWID's unused allocation is carried over into the following year, and converted into Carryover Obligation that is sequestered out of the Usable Supply before any allocation to EBID can occur (Barroll (2020), Sections R6 and R9). **In recent years, part of EPCWID's unused allocation results from not being charged for the use of EPWU wastewater in the El Paso Valley and from the ACE Credit.**

5.2 Run 15b: EPCWID Utilization of El Paso Valley (EPV) Drain Flows

Run 15b is identical to Run 1, except that it changes EPCWID operations and Project Accounting so that 1) EPCWID diverts and uses drain flow from the River Drain system[17] when available, adjusting its reservoir demand accordingly, and 2) EPCWID is charged in Project Accounting for the diversion and use of this drain flow.

This diversion of EPV drain flows and Project charges associated with those diversion are consistent with earlier Project operations and accounting. Prior to 1938, the River Drain (and other drains as well) discharged into the Rio Grande above the Tornillo heading,[18] which was at that time the last diversion heading in the Rio Grande Project. This drain flow is here referred to collectively as "EPV drain flow". This drain water was diverted at the Tornillo Canal heading, and it was accounted as Project Supply.

Following the Rectification of the Rio Grande in the Fabens area in 1938, the drain system near Fabens was re-routed so that water from the River Drain (and its tributary, the Middle Drain) could be diverted into the Riverside Canal Extension, which now supplied the Tornillo Canal heading. Any drain flow not diverted was routed to the Fabens Waste Drain. Reclamation records from 1945 until about 1980 show diversions of up to 30,000 AF/yr from the River Canal into the Riverside Canal Extension, and Project Records indicate that these diversions are included in the Reclamation Water Distribution Reports that form the basis of the D2 Curve.[19] That is, such diversions were accounted as part of Project Supply. Other drains in this area were routed directly into the Fabens Waste Drain.

Post-1978 Project Accounting does not include any term for the diversion of El Paso Valley drain flows, and there is no evidence that EPCWID has diverted drain flow in the Fabens area for many years. Nevertheless, these drain flows were a historical source of Project Supply, both in the years leading up to the Rio Grande Compact and during the D2 period. Run 15b provides an estimate of how much drain flow could have been diverted by ECPWID near Fabens throughout the model run. Comparison of Run 15b and Run 1 provides an estimate of the effect of El Paso drain flow on the distribution of Project Supply if diverted and charged to EPCWID.

The ILRGM simulates all of the drains above Fabens as one, so in order to simulate diversion of only the flows from the River Drain system the simulated diversion amount diverted is capped at 70% of the total simulated drain flow above Fabens.

---

[17] The Middle Drain discharges into the River Drain below the River Drain's gaging point, and so the gaged flows of both drains are available for diversion into the Riverside Canal Extension at Fabens.

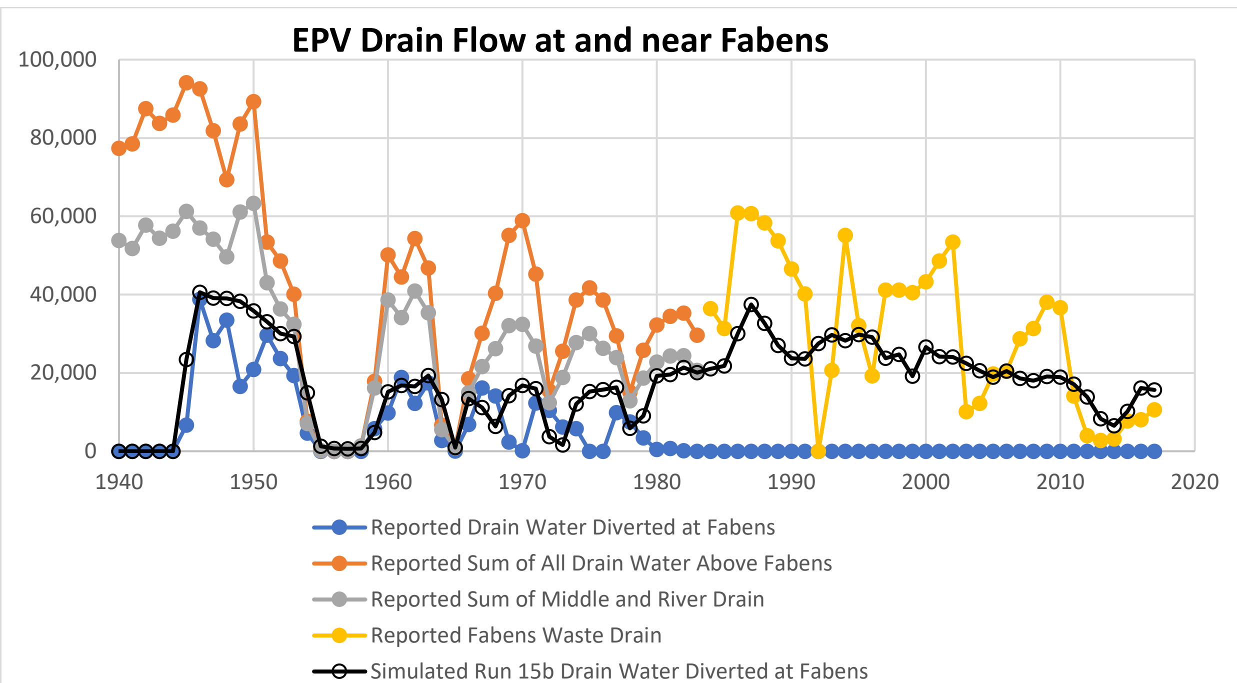
[18] The Tornillo heading was built in 1923 for the stated purpose of capturing Project return flows. "[T]he site of this heading [Tornillo] furnishes the means to collect a large amount of recovered and developed water of the project for use in the Tornillo area, and for sale to the Hudspeth Counting Irrigation District below the project limits." 1923 Project History, Chapter 1, Introductory and General, page 5.

[19] Barroll (2019), Section 5.2.2 and Appendix C.

A comparison of the historical reported drain flows near Fabens[20], historical diversions of drain flow at Fabens, and the simulated diversion of drain flow at Fabens from Run 15b, is provided in Figure 13. These data show:

1) The actual reported diversion of drain flow at Fabens during the 1940s through the 1970's is reasonably represented by Run 15b. In a number of years, the model simulates somewhat higher drain flow diversions, representing the availability of more drain flow than was actually diverted.
2) In approximately 1980, the diversion of drain flow at Fabens appears to have ceased, even though the flows measured in the Fabens Waste Drain indicates that the drains above Fabens were still flowing.
3) Run 15b of the model simulates diversion of drain flow roughly consistent with the actual availability of drain flow as measured in the Fabens Waste Drain through approximately 2011, after which the Run 15b simulates diversion of more drain flow than was likely available historically. This may either be a reflection of a less than perfect calibration of drain flow, or may be a result of better general hydrologic conditions in Run 15b compared with historical conditions due to diversion and use of EPV drain flows during the 1980's, 1990's and 2000's.

Figure 13. Drain Flows Near Fabens, Reported Diversion of Drain Flow at Fabens, and Simulated Diversion of Drain Flow Near Fabens (Run 15b)



[20] Following the Rectification of the Rio Grande all of the El Paso Valley drains above Fabens were routed into the Fabens Waste Drain, with the exception of the flow from the River Drain which was diverted into the Riverside Canal Extension. The El Paso Valley drains above Fabens were measured separately until 1984, after which the resulting flow in the Fabens Waste Drain was measured.

Differences between Runs 1 and 15b (in which EPV drain flow is utilized) become noticeable in approximately the year 2000. Current-Year Allocation results from Runs 1 and 15b for the period 2000 through 2017 are plotted in Figure 14 and Tabulated in Table 10.

These results show that in the year 2003 allocations for both EBID and EPCWID are significantly higher in Run 15b than Run 1. This happens because during full-supply years that preceded 2003 (the late 1990's and early 2000's), EPCWID's use of EPV drain flow in Run 15b resulted in EPCWID calling for less water from reservoir storage. By the end of 2002, the last full-supply year, reservoir storage in Run 15b is significantly greater than in Run 1. Greater reservoir storage allows larger 2003 allocations in the Run 15b.

Starting in 2006, EBID is also allocated substantially more water in Run 15b than in Run 1. This suggests that the improvement in Project Performance caused by the use of EPV drain flows resulted in a higher Diversion Ratio and higher consequent allocation to EBID.

Total			**471,133**			**148,398**

Charged Diversions from Runs 1 and 15b for the years 2000 through 2017 are plotted in Figure 15 and tabulated in Table 11. EPCWID's Charged Diversions in Run 15b are generally slightly larger than in Run 1, while EBID's Charged Diversions in Run 15b are significantly larger than in Run 1**. This means that the EBID would get a significant benefit if EPCWID were to divert, and be charged for diverting, EPV drain flows.** Table 11 shows that EBID's total cumulative Charged Diversions since the year 2000 might have been as much as 460,000 AF greater if EPCWID had diverted, and been charged for the diversion of, EPV drain flows since the mid-1990's. (Benefits to Project Storage accruing prior to the last reservoir spill in the mid-1990's would have been wiped out by the spill.)

5.3 Run 15: Combined EPCWID Accounting Run: EPCWID Utilization of EPV Drain Flows, Charged for Use of EPV Wastewater, and Elimination of ACE Credit

Run 15 combines both of the modifications from Run 15a and Run 15b. That is, in Run 15 the ACE Credit is eliminated, all EPWU wastewater in the El Paso Valley that is delivered to EPCWID during the Caballo release season is charged to ECPWID in Project accounting, and drain flow at Fabens is diverted by EPCWID and charged to ECPWID in Project accounting. The results of this combined run are shown for the years 2000 through 2017 in Table 12. These results show a large benefit to EBID, totaling 880,000 AF, if EPCWID's operations (diverting EPV drain flow) and accounting (Project charges for EPV drain flow and use of all EPWU wastewater) were modified so as to be more consistent with earlier – and more equitable – Project operations and accounting.

2015	96,739	148,888	52,149	246,835	233,473	-13,362
2016	145,167	168,777	23,609	259,694	256,086	-3,607
2017	132,611	230,944	98,333	261,451	282,792	21,341
Total			**880,466**			**301,164**

Table 12 also shows that EPCWID would have, on average, higher Charged Diversions if these operational and accounting changes were made. This increase in Charged Diversion probably largely reflects the fact that under the model scenario EPCWID is now being **charged** for its historical use of EPWU wastewater, thus increasing its Charged Diversion.

Note that the net impacts from Run 15a and Run 15b do not add up to the net impacts from the combined Run 15. This result occurs because the ILRGM is a non-linear model that simulates the existing non-linearities in Project allocation and operations. For example, when Project storage levels (in the reservoirs) are low, and Project allocations are relatively low, an increase in reservoir storage can increase the Project allocations. However, once a District's allocation has been increased to its full-supply amount, further increases in Project storage will not cause increases in that District's allocation. This change in response is "non-linear" (that is, the response is not directly proportion to the causal factor), and a model that simulates this correctly will also be non-linear.

5.4 Summary and Conclusions

If the relatively recent ACE Credit were eliminated, and EPCWID were again charged for its diversion and use of EPWU wastewater treatment plan discharges into the Project, the ILRGM calculates the result would be a cumulative total increase in EBID's Project diversions of 470,000 AF over the period 2000 – 2017. The annual impacts become larger starting in 2006, the year D3 Allocation + Carryover is implemented in the Base Run. Impacts average 36,000 AF/yr from 2006 through 2017. Increases in EPCWID's Charged Diversions are also simulated, a total of 230,000 AF from 2000 to 2017, but this increase is largely a result of EPCWID being charged for the EPCWID wastewater it has recently been using without charge.

If EPCWID were required to divert El Paso Valley drain flows, as they had done historically, and were charged for such diversions, the ILRGM calculates an increase in EBID's allocation by a cumulative total of 471,133 AF, and an increase in EBID Project diversions by a cumulative total of 458,000 AF over the period 2000 - 2017. EPCWID's simulated allocations and Charged Diversions would also have been larger. Current-Year Allocations would have been larger by a cumulative total of 148,000 AF and Charged Diversions by a cumulative total of 92,000 AF. These increases are simulated because the diversion and use of El Paso Valley drain flows would constitute an increase of Project Supply above current levels.

Both sets of issues were addressed in a combination run that eliminated the ACE Credit, charged EPCWID for its diversion and use of wastewater treatment plant discharges and utilized El Paso Valley drain returns in the ILRGM (Run 15). The results of this run show a total increase of 880,000 AF to EBID Project diversions from 2000 through 2017.

6 Runs 16 and 16a: Conjunctive Management at D1/D2 Period Levels

At the direction of New Mexico's legal counsel, I have worked with New Mexico expert Greg Sullivan to describe two scenarios that are consistent with my Opinions related to the D1/D2 Allocation and the Project operations and accounting procedures in place during the D1/D2 time period (1951 – 1978). Mr. Sullivan then coordinated with other New Mexico experts to simulate those scenarios using New Mexico's ILRGM for the historic period from 1940 to 2017. The Spronk Rebuttal Report (2020) provides a description of the scenario specifications and the results of the modeling analyses along with high-level observations of the results. In this Supplemental Report, I describe the basis for the scenarios (Run 16 and Run 16a) and offer some observations of the results.

6.1 Model Results

Runs 16 and 16a are hypothetical runs that simulate the hydrologic history of the Project area through 2017, in which

- Project Supply is allocated 57:43 using the D1/D2 Allocation method through 2017,
- The operational and accounting principles described in Run 15 are implemented through 2017, and
- Groundwater use to the levels occurring during the D2 Period (1951-1978) is incorporated.

In essence Runs 16 and 16a are simulations that extend earlier Rio Grande Project operations (including diversion of El Paso Valley drain flows), earlier Project accounting (including charges for the diversion of EPWU wastewater and El Paso Valley drain flows), and 57:43 Project allocation, until the present time. In addition, pumping limitations are imposed so that irrigation pumping levels cannot exceed the level occurring during the D2 time period (Run 16 and 16a) and non-irrigation well pumping is limited to the maximum amount occurring during the D2 time period (Run 16a). The only difference between Runs 16 and 16a is that in Run 16a non-irrigation well pumping (municipal, industrial, etc.) is also limited, with the limit set equal to the maximum amount diverted for those uses during the D2 Period.

Table13 provides a summary of how key model parameters are set for Run 1 and Runs 16 and 16a.

Table 13. Summary Description of Settings for Runs 1, 16, and 16a

Summary of Runs 1, 16, and 16a			
	Run 1	Run 16	Run 16a
NM Irrigation Well Pumping	Historical, calculated based on crop demand and SW shortage	10-year average limited to 166,866 AF/yr, calculated as in Run 1	10-year average limited to 166,866 AF/yr, calculated as in Run 1
TX Irrigation Well Pumping	Historical, calculated based on crop demand and SW shortage	10-year average limited to 70,783 AF/yr	10-year average limited to 70,783 AF/yr
NM Non-Irrigation Well Pumping	Same as occurred historically	Same as occurred historically	Limited to maximum of D2 period: 20,993 AF/yr
TX Non-Irrigation Well Pumping	Same as occurred historically	Same as occurred historically	Limited to maximum of D2 period: 30,264 AF/yr in Mesilla basin, 89,979 AF/yr in Hueco bolson
Irrigated Acreage and Irrigation Water Requirements	Same as occurred historically	Same as occurred historically	Same as occurred historically
Project Allocation Method	57:43 through 2005, D3 in 2006 & 2007, D3+Carrover 2008-2017	57:43 using D1/D2 Method	57:43 using D1/D2 Method
EPWU Wastewater	Diversion and use EPWU wastewater discharged in El Paso Valley not charged to EPCWID	EPCWID charged for diversion and use of EPWU wastewater during Caballo Release Season	EPCWID charged for diversion and use of EPWU wastewater during Caballo Release Season
EPV Drain Flow	No charge for use of El Paso Valley drain flow after 1978	EPCWID diverts and is charged for diverting available drain flow in El Paso Valley	EPCWID diverts and is charged for diverting available drain flow in El Paso Valley
ACE Credit	ACE Credit implemented starting 2003, historical values	ACE Credit eliminated	ACE Credit eliminated

Because both Run 16 and 16a simulate 57:43 Allocation through 2017, EBID's allocation does not suffer the dramatic reduction in 2006 caused by D3 Allocation (as actually occurred, see Barroll (2019), Section 8), and New Mexico irrigation well pumping is not artificially inflated as a result. Also, in both runs EPCWID is charged in Project Accounting for all diversion and use of drain flow in the El Paso Valley during the Caballo release season, the ACE Credit is eliminated, and EPCWID diverts and is charged for use of El Paso Valley drain flow. These changes improve EBID's allocation and diversion of Project Supply in many years, especially (as shown in Section 5 of this report) since the year 2003. This improvement of EBID's Project Supply further reduces the need for irrigation well pumping in New Mexico. As a result, in Runs 16 and 16a, New Mexico irrigation well pumping never reaches the limits described in Table 13. EPCWID does not reach those limits either, because of the large reduction in EPCWID's irrigation water demand since the D2 Period (1951 – 1978).

Figure 16 is a plot of the annual Current-Year Allocations for EBID and EPCWID for the years 2000 through 2017 for Run 16 and 16a. Figure 17 is a plot of the Charged Diversions for EBID and EPCWID for the years 2000 through 2017 for Run 16 and 16a.

Figure 16. Simulated Current-Year Allocations, Runs 1, 16 and 16a

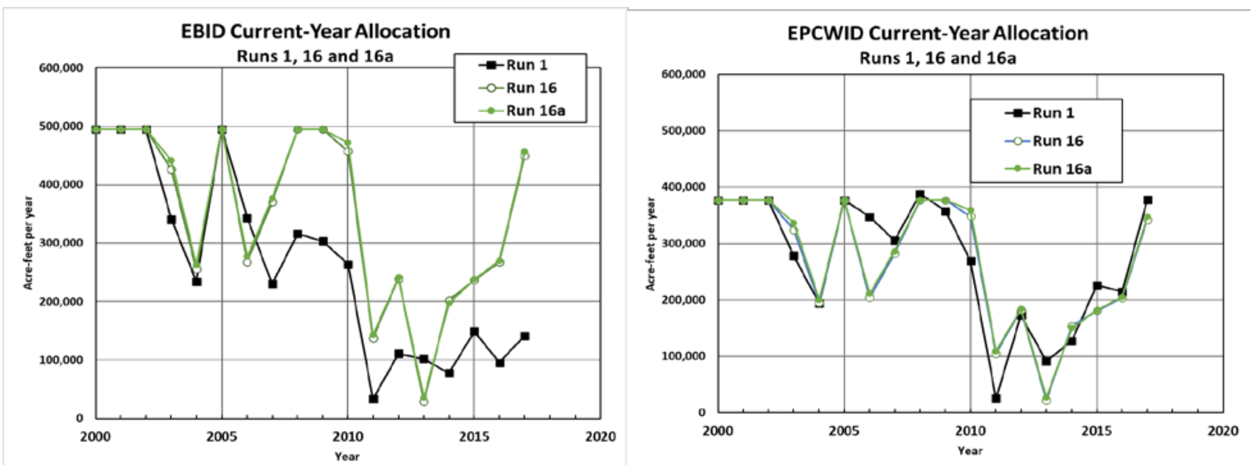

Figure 17. Simulated Charged Diversions, Runs 1, 16 and 16a

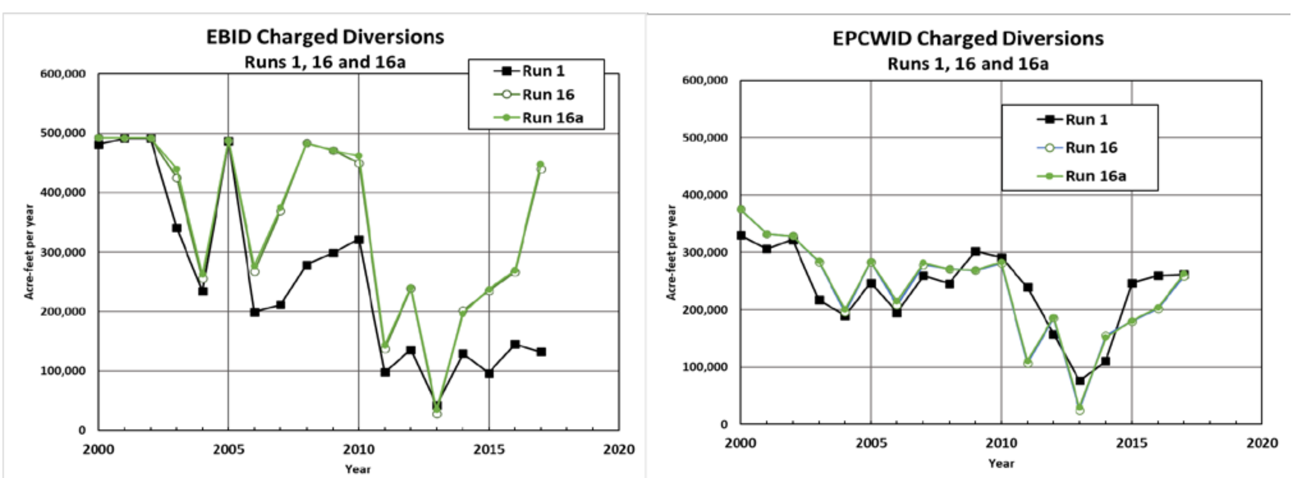

Figures 16 and 17 show almost no difference between the results from Runs 16 and 16a. This indicates that the factors that differ between the runs (that is: New Mexico non-irrigation well pumping reaching approximately 40,000 in Run 16 and remaining at 20,000 AF/yr in Run 16a) have little impact on the model results. In part this is likely caused by the fact that **much of New**

Mexico's non-irrigation well pumping is effectively offset by wastewater returns to the Rio Grande which are accounted as Project Supply when diverted downstream (see Barth Rebuttal, 2020). This small impact is also probably related to the fact that non-irrigation well pumping in the New Mexico part of the LRG is quite small compared with other stresses, such as irrigation well pumping.

Figure 16 also shows that EBID's allocations and Charged Diversion are considerably higher in Run 16 (and 16a) than they are for Run 1, while EPCWID's allocation and diversions in Run 16 are sometimes higher, and sometimes lower, but generally not greatly different that those in Run 1. These differences in diversion are quantified in Table 14. Over the 18-year period from 2000 through 2017, EBID diverts a total 1,620,000 AF more in Run 16 than it did in the Base Run (Run 1). Conversely, EPCWID diverts 39,000 less in Run 16 than it did in the Base Run. This shows that the reallocation involved in the 2008 OA does not greatly benefit EPCWID compared to what it would have diverted if D1/D2 conditions still applied (including the Run 15 EPCWID operational and accounting changes). EBID, on the other hand would have benefitted greatly if 57:43 allocation had been maintained and EPCWID had been operated and its diversions accounted for, as had been the case during the D1/D2 Period.

Table 14. Simulated Charged Diversions, Runs 1 and 16, 2000-2017

Charged Diversions to Districts, Runs 1 and 16 (D1/D2 Condition Runs)						
	EBID Charged Diversions			EPCWID Charged Diversions		
	Run 1	Run 16	Run 16 - Run 1	Run 1	Run 16	Run 16 - Run 1
2000	481,143	492,739	11,596	329,682	375,090	45,408
2001	491,744	492,324	580	306,054	332,195	26,141
2002	491,796	491,891	95	321,794	328,814	7,020
2003	340,912	425,454	84,542	217,108	283,336	66,228
2004	234,605	255,608	21,003	190,306	195,609	5,304
2005	486,958	487,885	927	246,933	283,691	36,759
2006	199,360	267,685	68,325	195,503	207,908	12,405
2007	211,626	369,990	158,364	259,806	278,182	18,376
2008	278,630	483,791	205,161	246,057	271,102	25,044
2009	298,781	471,418	172,636	302,148	268,942	-33,206
2010	321,683	450,155	128,473	291,560	280,760	-10,800
2011	98,467	137,620	39,152	239,594	106,967	-132,627

2013	42,538	28,416	-14,122	76,014	25,001	-51,013
2014	129,599	202,114	72,514	110,806	155,354	44,549
2015	96,739	235,254	138,515	246,835	180,242	-66,593
2016	145,167	266,750	121,583	259,694	201,779	-57,915
2017	132,611	440,497	307,886	261,451	258,450	-3,002
Sum			**1,620,743**			**-39,722**

6.2 Summary and Conclusions

Runs 16 and 16a simulate a continuation of the conditions existing during the D2 Period (1951 – 1978) into the present day. The model modifications that were implemented to simulate Project allocation, accounting, and operations during the D2 period are:

1) D1/D2 Allocation applied through 2017
2) Post-1978 irrigation well pumping limited, on average, to the average levels occurring during the D2 Period
3) (Post-1978 Non-irrigation well pumping limited to the maximum level occurring during the D2 Period: Run 16a only.)
4) ACE Credit eliminated
5) EPCWID charged for its diversion and use of EPWU wastewater in the El Paso Valley throughout the Run
6) Continued diversion and use of El Paso Valley drain flows by EPCWID throughout the Run

In fact, the pumping constraints did not impact the simulated irrigation well pumping in Runs 16 or 16a for either New Mexico or Texas. Texas's irrigation demands have decreased substantially since the D2 period, and the Project modifications made for Runs 16 and 16 did not change that. For New Mexico, the allocation, accounting, and operational modifications applied in these runs, such as D1/D2 Allocation, increased EBID's share of Project Water enough to reduce New Mexico's total need for irrigation well pumping below average D2 levels.

The non-irrigation well pumping limitation in Run 16a had no impact on Texas' non-irrigation well pumping after 1978, but that constraint did limit New Mexico non-irrigation well pumping to approximately 20,000 AF/yr.

Figures 16 and 17 show almost no difference between the results from Run 16 and Run 16a, suggesting that the impact of post-1978 non-irrigation pumping increases have small impact on Project allocation and diversions.

Comparison of Run 1 and Run 16 shows that under Run 16 (D1/D2 conditions through present) EBID is allocated and diverts more water than under actual historical conditions. EPCWID's allocation and diversion under D1/D2 conditions are sometimes higher and sometimes lower than under actual historical conditions.

In summary, if Project allocation methods and the operations and accounting within Texas had remained consistent with the D2 Period (1951-1978), EBID would be have been allocated and received more Project Supply in recent years than they have received, New Mexico farmers would have pumped less groundwater, and EPCWID's allocation and delivery of Project Supply would have been little different than under D3 + Carryover.

Consumptive Use of Applied Water in the Rincon, Mesilla, El Paso and Juarez Valleys in the Rio Grande Basin

Assignment

Pursuant to direction of legal counsel representing the State of New Mexico in the United States Supreme Court Case *Texas v. New Mexico and Colorado*, No. 141, Original, I was asked to compile and review applicable documentation and data necessary to perform the technical analyses described in this expert report. Professional staff and employees of Davids Engineering, under my direct supervision and direction, provided assistance in this work. I served as the primary author of the report and am responsible for the documentation, data, methodology, results and opinions contained herein. My curriculum vitae is provided in Appendix 11.

Dr. Richard Allen reviewed and endorses the data, documentation, analyses, results and opinions contained in this report. Dr. Allen also performed his review and work under the direction of legal counsel representing the State of New Mexico in this case. Dr. Allen's curriculum vitae is provided in Appendix 12.

Summary of Qualifications for Bryan P. Thoreson

1. My name is Bryan P. Thoreson. I am a registered Civil Engineer in California and Washington and principal engineer at Davids Engineering, Inc. in Davis, CA, where I have been employed since 1997. I have 25 years of professional experience as a civil engineer specializing in agricultural water consumptive use and water balance analyses.
2. My education includes Bachelor of Science and Master of Science degrees in Agricultural Engineering from South Dakota State University, and a Doctoral degree in Agricultural and Biosystems Engineering from the University of Arizona.
3. Prior to working at Davids Engineering, Inc., I worked for Imperial Irrigation District initially as an assistant engineer and then as an engineer from 1994 through 1997.
4. In December 2003, I became a shareholder at Davids Engineering, Inc.
5. I have completed more than 20 consumptive use and water balance analyses for irrigation and water districts.
6. Davids Engineering is being compensated for my work on this assignment at a rate of $196 per hour.
7. My professional resume, including publications authored in the previous 20 years, is included in Appendix 11.

Summary of Qualifications for Richard Glen Allen

1. My name is Richard Glen Allen. I am a registered Civil Engineer in Idaho. I am a full professor of water resources engineering in the Department of Soil and Water Science at the University of Idaho, where I have been employed since 1998. I am also the owner and principal of Evapotranspiration Plus, LLC and Allen Engineering companies. I have 42 years of professional experience as an irrigation engineer and civil engineer specializing in irrigation systems design and management, agricultural water consumptive use and water balance analyses and in satellite-based remote sensing of water consumptive use.
2. My education includes a Bachelor of Science degree in Agricultural Engineering from Iowa State University, a Master of Science degree in Agricultural Engineering from the University of Idaho, and a Ph.D. in Civil Engineering from the University of Idaho.
3. Prior to employment at the University of Idaho, I was an assistant professor, associate professor and full professor in the Department of Biological and Irrigation Engineering at Utah State

University from 1985 to 1998. Prior to that, I was an assistant professor in the Department of Civil Engineering at Iowa State University from 1983 to 1985. Prior to that, I was a research associate at the University of Idaho Research and Extension Center at Kimberly, Idaho from 1977 to 1983.

4. I was lead author on the United Nations Food and Agriculture Organization Irrigation and Drainage Paper 56: "Crop Evapotranspiration – Guidelines for computing crop water requirements" that serves as an international practice's standard
5. I was coauthor of the 1990 and 2016 American Society of Civil Engineers Manual no. 70: "Evaporation, Evapotranspiration and Irrigation Requirements" that serves as a national practice's standard
6. I have been lead author on 29 technical research completion reports related to consumptive use, evapotranspiration and irrigation water management.
7. I have authored or coauthored more than 160 papers in refereed journals and book chapters related to evapotranspiration, irrigation water requirements, irrigation system design, and remote sensing of evapotranspiration.
8. My company Evapotranspiration Plus, LLC is being compensated for my work on this assignment at a rate of $188 per hour.
9. My professional resume, including publications authored, is included in Appendix 12.

I. Consumptive Use Determination Overview

Purpose

In the context of agriculture, consumptive use is defined as "the part of water withdrawn that is evaporated, transpired, incorporated into products or crops, consumed by humans or livestock, or otherwise removed from the immediate water environment" (ASCE, 2016). Consumptive use primarily encompasses all water that is evaporated from soil and crop surfaces and all water that is transpired by crops (i.e., carried through plant tissue from the roots to stomata, or pores, in the leaves). Most field crops dry to a very low moisture content approaching harvest, so the volume of water incorporated into crop biomass is small and therefore typically neglected. As such, consumptive use is often considered approximately equal to crop evapotranspiration (ET_c). ET_c rates vary between individual crops, soil surface coverage conditions, and surrounding weather and climate conditions.

Consumptive use includes the use of water from precipitation and from irrigation. Consumptive use of applied water, or irrigation water, varies over time primarily due to variability in water supply conditions, weather patterns and crop types.

The purpose of this study was to accurately determine consumptive use of irrigation water in the Rincon, Mesilla, El Paso and Juarez Valley Study Area by evaluating historical crop areas, soil characteristics, weather conditions, agricultural practices, and other factors that have affected consumptive use over time.

This section provides an overview of the analyses used to estimate consumptive use of irrigation water – also referred to as evapotranspiration of applied water (ET_{aw}) – for irrigated lands in the Study Area under full water supply (full supply) conditions. ET_{aw} is estimated by first determining ET_c of crops in the Study Area under full supply conditions, and then apportioning ET_c between evapotranspiration of precipitation (ET_{pr}) and ET_{aw}. "Full supply" is generally understood to mean that available water supplies are sufficient to fully satisfy crop irrigation water demands for all irrigated lands. This report does not determine consumptive use under conditions of deficit irrigation, nor does it report consumptive use of municipal and industrial water use.

The Study Area includes the irrigated lands that extend along both banks of the Rio Grande from below Caballo Reservoir in New Mexico to Fort Quitman, Texas and that lie primarily within the boundaries of the Elephant Butte Irrigation District (EBID) in the Rincon and Mesilla Valleys in New Mexico, the El Paso County Water Improvement District #1 (EPCWID) in the lower Mesilla and El Paso Valleys in Texas, Hudspeth County Conservation & Reclamation District #1 (Hudspeth) in the El Paso Valley in Texas (collectively the US Districts) and the Juarez Valley Irrigation District (Juarez) in the Juarez Valley in Mexico. The Study Period considered in this analysis spans 1938 through 2018.

Overview of Methodology

This subsection provides a brief overview of the methodology used to estimate consumptive use of irrigation water. Additional detail regarding each step in this methodology is provided in the subsections that follow.

Introduction

As defined above, consumptive use is generally equivalent to evaporation (E) and crop transpiration (T), together referred to as crop evapotranspiration (ET_c) (**Equation 1-1**). ET_c encompasses evapotranspiration of all water available to crops from precipitation, irrigation and, in some cases, from shallow groundwater. The portion of ET_c that is satisfied by precipitation is typically referred to as ET of precipitation (ET_{pr}), or effective precipitation. The portion of ET_c that is satisfied by applied irrigation water is typically referred to as ET of applied water (ET_{aw}), or consumptive use of irrigation water. ET_{aw} is the variable of interest in this study; it is calculated by estimating ET_c and apportioning the total ET_c between ET_{pr} and ET_{aw} (**Equation 1-2**).

$$ET_c = Crop\ Transpiration + Evaporation \quad \textbf{(Eq. 1-1)}$$

$$ET_c = ET_{aw} + ET_{pr} \quad \textbf{(Eq. 1-2)}$$

Categories of ET_c

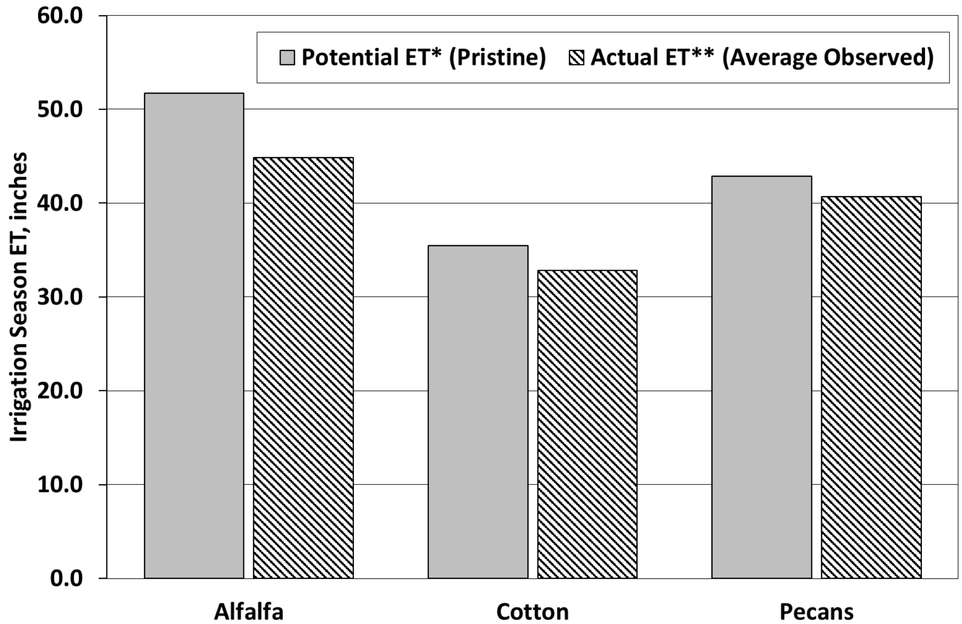
There are three categories of ET_c discussed in this report. The first is potential crop ET_c, which represents the highest potential evapotranspiration rate that could be achieved by the crop assuming ideal or "pristine" conditions with regard to water availability and crop health (ASCE, 2016).

The next is actual ET_c, which is the actual rate of evapotranspiration that occurs under actual field conditions (ASCE, 2016) in the Rincon, Mesilla, El Paso and Juarez Valleys. In years when water supplies are sufficient to fully satisfy crop irrigation water demands, actual ET_c represents consumptive use under full supply conditions. Actual ET_c cannot generally be measured directly, particularly over a large region such as the Study Area. In this report "actual ET_c" refers to ET_c computed by the METRIC (Mapping Evapotranspiration at high Resolution using Internalized Calibration) surface energy balance (described in the following section) or using crop coefficients derived from METRIC, as that is considered the most accurate method available to calculate actual ET_c over a large area. This computed value of actual ET_c represents the average ET_c across all fields containing a specific type of crop. Because of the differences between "pristine" and actual conditions, potential ET_c may be higher than actual ET_c and is generally not representative of average crop conditions (ASCE, 2016) across the Study Area (**Figures 1-1 and 1-2**).

The third and final category of ET_c discussed in this report is calculated ET_c, or ET Demands ET_c. This is the ET_c value calculated in this report following the crop coefficient – reference crop ET standard method using the ET Demands Root Zone water balance model (both described below). ET Demands ET_c is calibrated for consistency with actual ET_c determined by METRIC during key full supply years and represents an accurate estimate of consumptive use under actual crop conditions in the Study Area.

Standard Methods for Estimating ET_c

Two standard methods used to estimate ET_c in this study are the crop coefficient – reference crop ET method and the satellite-based surface energy balance method.



* Potential ET calculated based on 70th percentile Kc values (typical of pristine conditions) derived by METRIC analyses for all crop-specific areas in EBID in 2008.

** Actual ET of all crop-specific areas based on METRIC analyses for EBID in 2008.

Figure 1-1. Comparison between Potential ET (Pristine Conditions) and Actual ET (Average Observed Conditions) of Crops in New Mexico (EBID) during the 2008 Irrigation Season (March-October).

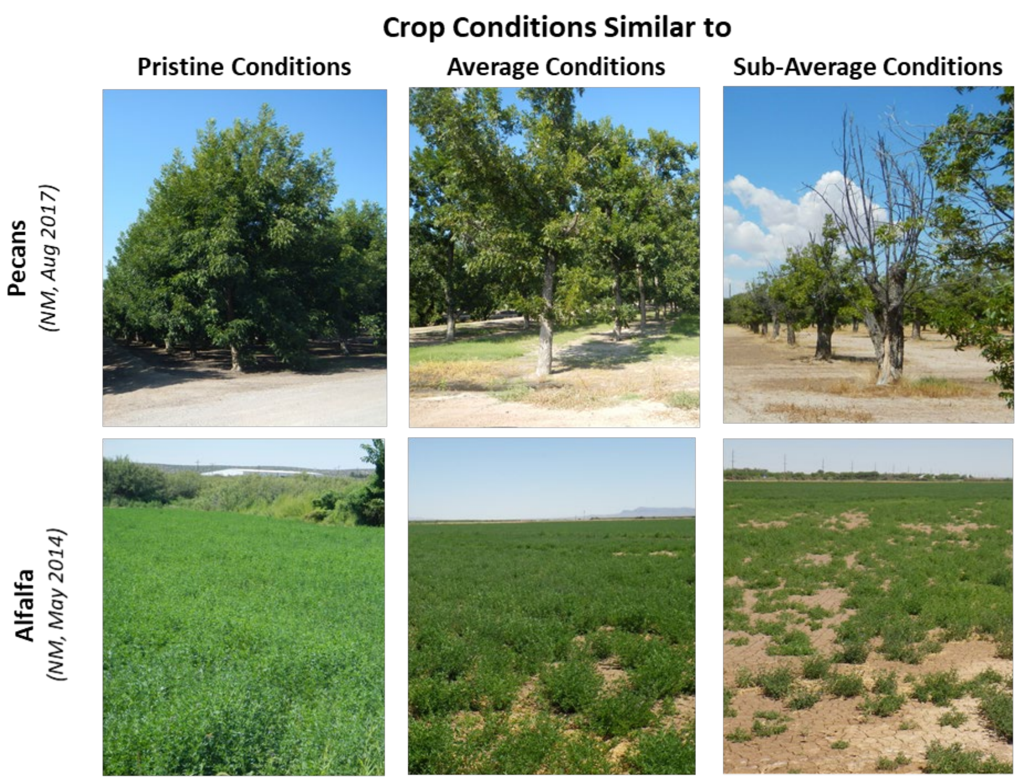


Figure 1-2. Comparison of pecan and alfalfa crops grown under conditions similar to pristine, average, and sub-average conditions, as observed in New Mexico (pecan images from August 2017, alfalfa images from May 2014).

In the crop coefficient – reference crop ET method, ET is calculated for a reference crop under local weather conditions and is then extrapolated and adjusted to other crops using local crop-specific "crop coefficients" (ASCE, 2016). A crop coefficient (K_c) is defined as "the ratio of evapotranspiration occurring with a specific crop at a specific stage of growth [ET_c] to reference crop evapotranspiration at that time [ET_{ref}]" (ASCE, 2016) and can be represented as ET_c/ET_{ref}. This method is widely accepted and used throughout the western United States and in similar arid, irrigated regions worldwide and has been extensively applied in irrigation water management and irrigation scheduling. Since the late 1990s, the method has been standardized through technical committee discussions, as reported in the Food and Agriculture Organization of the United Nations (FAO) Report Number 56 (FAO-56) (Allen, et al., 1998) and American Society of Civil Engineers Manual 70 (ASCE, 2016). The method has proven to produce accurate, robust, consistent results, and is relatively straightforward to apply (ASCE, 2016). A description of how this method is used is provided in the following paragraphs.

Another method to estimate ET_c that has been developed during the last 25 years is a surface energy balance using satellite imagery data. Surface energy balance methods can be used in tandem with the crop coefficient – reference crop method to improve accuracy of results. One widely accepted energy balance model is METRIC (Mapping Evapotranspiration at high Resolution using Internalized Calibration). The METRIC energy balance model is a widely accepted, widely applied (Serbina and Miller 2014), and accurate, ±5 to ±15% method when applied by expert users, (Allen, et al., 2011). METRIC is a surface energy balance-based group of algorithms that represents the best available science. However, executing it accurately requires an experienced expert and more time and resources than the crop coefficient – reference crop ET method, which has, traditionally, been more widely used. In this study, the two methods have been combined to achieve the benefits of both. In key years representing full supply conditions, METRIC is used to locally calibrate crop coefficients to improve local accuracy of crop consumptive use estimates. The METRIC model employs the key physical concept that transformation of liquid water to vapor via the ET process requires and consumes substantial amounts of energy (about 590 calories per cubic centimeter of water). The energy used for the ET process originates from the sun and atmosphere and provides an upper limit on expected ET rates. The METRIC model computes a balance of net radiation influx (R_n) to an area of interest and partitions that into sensible heat (H) transferred from the ground or vegetation surface to the air, heat conducted to the ground (G), and energy consumed through ET. The calculation process is driven using data from satellite imagery coupled with meteorological data from ground-based weather stations (**Figure 1-3**).

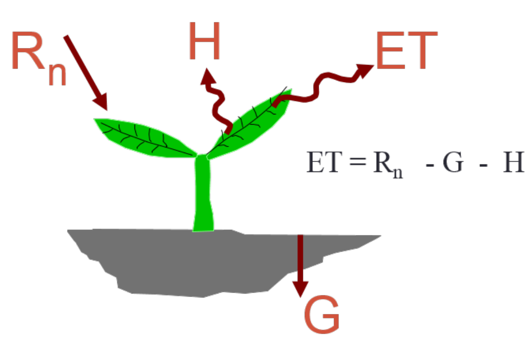

Figure 1-3. METRIC Energy Balance for Calculating ET (Allen, 2015).

The METRIC model has been in existence and under development since 2000 and has been widely applied in the states of Idaho, California, Oregon, Nevada, New Mexico, Montana, Wyoming, Colorado, Texas and Nebraska for a broad range of purposes. Those purposes include those where it is critical to estimate actual ET_c over large spatial areas, such as for water rights administration, water balances from field to regional scales, and ground-water model development. Many applications of METRIC, both in the western United States (Wyoming, Idaho, Nevada, Colorado and California) and internationally (Australia and Morocco), are summarized in Serbina and Miller (2014). General accuracy of ET_c estimated by METRIC has been estimated to be ±5 to ±15% when applied by expert users (Allen et al., 2011). The actual ET_c results from METRIC include evaporation and transpiration from ET_{aw} and ET_{pr}. The METRIC methodology has been widely vetted with more than 40 refereed journal publications.

Procedure for Estimating and Calibrating ET_c

In this study, the crop coefficient – reference crop ET method was used to estimate ET_c for the Study Area for 1938 through 2018. METRIC was used to estimate ET_c for three selected years to collect actual crop coefficient information over the entire Study Area that was then used to calibrate a local crop coefficient for each crop for use with the crop coefficient – reference crop ET method as described below.

In the crop coefficient – reference crop ET methodology, ET_c is estimated for various crops across the Study Area and for their differing growth stages over time using two locally-defined parameters: reference crop ET (ET_o here) and a crop coefficient (K_c) (**Equation 1-3**).

$$ETc = ET_O \times K_c \quad \textbf{(Eq. 1-3)}$$

First, the crop ET of a defined reference crop surface is calculated for 1938 through 2018 following accepted methods and using local, quality-controlled weather data from weather stations representative of the Study Area. In this study, the standardized Penman-Monteith (PM) methodology using the clipped cool season grass reference as described by the Food and Agricultural Organization (FAO-56 - Allen et al., 1998) and the ASCE Task Committee Report on the Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005) was used to determine daily grass reference ET (ET_o). The PM method "is recommended as the sole standard method" by FAO-56 for estimating reference crop ET, providing "strong likelihood of correctly predicting ET_o in a wide range of locations and climates [with] provision for application in data-short situations" (Allen et al., 1998). ASCE (2016) makes similar recommendations on applying the ASCE Standardized Penman-Monteith reference method in preference to all other reference ET methods.

Next, the ET_o timeseries is adapted to other crops and their differing growth conditions, water requirements, and cultivation practices using crop coefficient (K_c) curves. A dual crop coefficient approach was used in this study (ASABE, 2007 and ASCE, 2016) to distinguish evaporation from precipitation and evaporation from applied irrigation water to provide more accurate estimation of the ET_{aw} and ET_{pr} components of ET_c. In this approach, the crop coefficient is divided into a basal crop coefficient (K_{cb}) that is used to estimate the crop transpiration component of ET_c, and into an evaporation coefficient (K_e) that is used to estimate evaporation following wetting events (**Equations 1-4, 1-5 and 1-6**).

$$K_c = K_{cb} + K_e \quad \textbf{(Eq. 1-4)}$$

$$K_{cb} = \frac{Crop\ Transpiration}{ET_o} \quad \textbf{(Eq. 1-5)}$$

$$K_e = \frac{Evaporation}{ET_o} = 1.05 \quad \text{during wetting (ASCE,2016)} \qquad \textbf{(Eq. 1-6)}$$

The K_{cb} contains a small portion of residual evaporation from soil beneath crops (Wright 1982; Allen et al., 1998; ASCE 2016). In this study, K_{cb} values were developed from and calibrated using the three years of actual ET_c calculated by the METRIC satellite imagery-based energy balance analyses of actual crop water use across the Study Area. This methodology was selected as the most accurate, most consistent, and most dependable method and means to produce actual ET_c results that are spatially representative of the water use of agriculture in the Study Area.

For each crop, daily K_c values were developed for 2008 (a year representing "full supply" conditions) based on actual ET_c estimates from fields developed by the METRIC surface energy balance model using data from the Landsat satellite. The Normalized Difference Vegetation Index (NDVI), a quantitative index relating changes in crop canopy cover that serves as an indicator of crop-specific growth characteristics, was used to guide development of the time-basis for K_{cb} values from the METRIC-derived K_c values by providing information on the stage of crop canopy development.

Following the development of K_{cb} values for 2008 (a "full supply" project year), these values and other parameters were calibrated through an iterative process until they produced ET_c estimates that were within at least 10% accuracy for estimating actual ET_c calculated by METRIC for EBID in 2002 (a "full supply" year) and 2013 (a "limited supply" year). Years 2002 and 2013 were used as independent checks on the K_{cb} calibration developed using year 2008 and for error assessment.

Operation of ET Demands to Estimate ET_{aw}

Next, the crop coefficient – reference crop ET methodology was implemented in the ET Demands Root Zone water balance model using a daily calculation time step (ASCE, 2016 and ASABE, 2007) to apportion ET_c between ET_{pr} and ET_{aw}.

A daily root zone water balance is a generally accepted methodology that is widely used to estimate the portion of ET_c met by precipitation (ET_{pr}) and by irrigation (ET_{aw}) by accounting for daily inflows to and outflows from the root zone (ASCE, 2016 and ASABE, 2007). For this study, the ET Demands Root Zone model (referred to as the ET Demands model) was selected because it calculates total ET from the crop coefficient – reference crop ET method and has been widely applied to compute consumptive water use and to study the potential effects of climate change on agricultural water demands (Allen and Robison, 2009 and Allen and Huntington, 2010, Allen and Huntington, 2015, and Reclamation, 2015). Additionally, ET Demands follows the dual crop coefficient approach to more accurately account for crop transpiration and evaporation resulting from rainfall and local irrigation practices. ET Demands employs a thermal basis for estimating the rate of crop development for most crops so that effects of warmer or cooler conditions during spring and early summer that impact the rate of crop and ET development are captured (Reclamation, 2015). The daily timestep of the ET Demands model provides substantially greater accuracy than the use of monthly timesteps through its ability to follow day-to-day variation in ET extractions from soil and deep percolation fluxes through and below the root zone after (Bauer and Vaccaro, 1987; Willis et al., 1997; Allen et al., 1998; Bethune et al. 2008).

Operation of the ET Demands model (and root zone water balance models in general) requires information on weather, soils, basal crop coefficients, and other crop data as described in **Figure 1-4** below. The root zone water balance model calculates outputs including ET_c, ET_{pr}, ET_{aw}, runoff of precipitation, tailwater, and deep percolation following standardized methodologies based on known or calculated flows into and out of the root zone. The ET Demands model calculates all inflows and outflows uniquely for each different crop on a per area (per acre) basis. Total consumptive use of irrigation water can therefore be summarized across an area of interest, such as the Study Area, by multiplying the appropriate ET Demands model results (ET_{aw} volume per acre, by crop) across the historical acreage of each crop in that area.

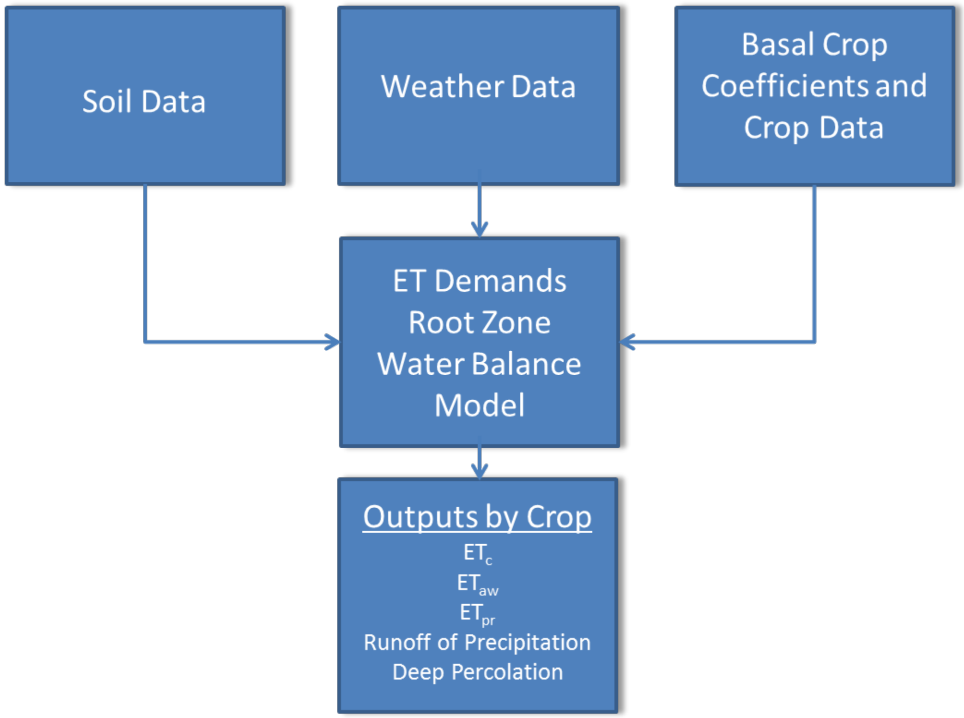

Figure 1-4. Schematic Representation of Data Inputs to and Outputs from the ET Demands Daily Root Zone Water Balance Model (ET Demands).

As described above, the basal crop coefficients used in ET Demands were developed for local conditions based on weather data and 2008 energy balance ET_c estimates (**Figure 1-5**). Crop coefficients and other crop data were calibrated to local conditions within the Study Area using remotely sensed energy balance ET_c estimates and local observations of crop plant and harvest dates and irrigation practices (**Figure 1-6**).

Finally, the ET_{aw} outputs from ET Demands (volume per acre, by crop) were multiplied by the corresponding crop acreage to estimate ET_{aw} volumes by crop (**Figure 1-7**). ET_{aw} volumes by crop were then summed to obtain the total consumptive use of irrigation water for irrigated lands.

Figure 1-8 provides an example of the process used to calculate consumptive use of irrigation water for cotton fields in EBID on one day in August 2008. A similar process was followed to calculate daily consumptive use of irrigation water for all crops in all regions of the Study Area during the entire period between 1938 and 2018.

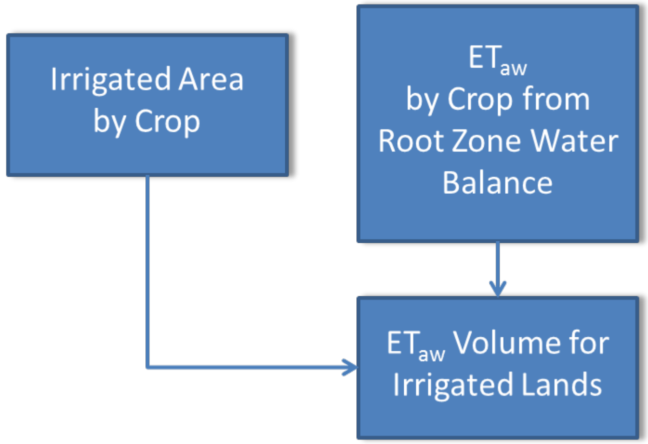

Figure 1-7. Schematic Representation of Calculation of ET_{aw} Volume for Irrigated Lands.

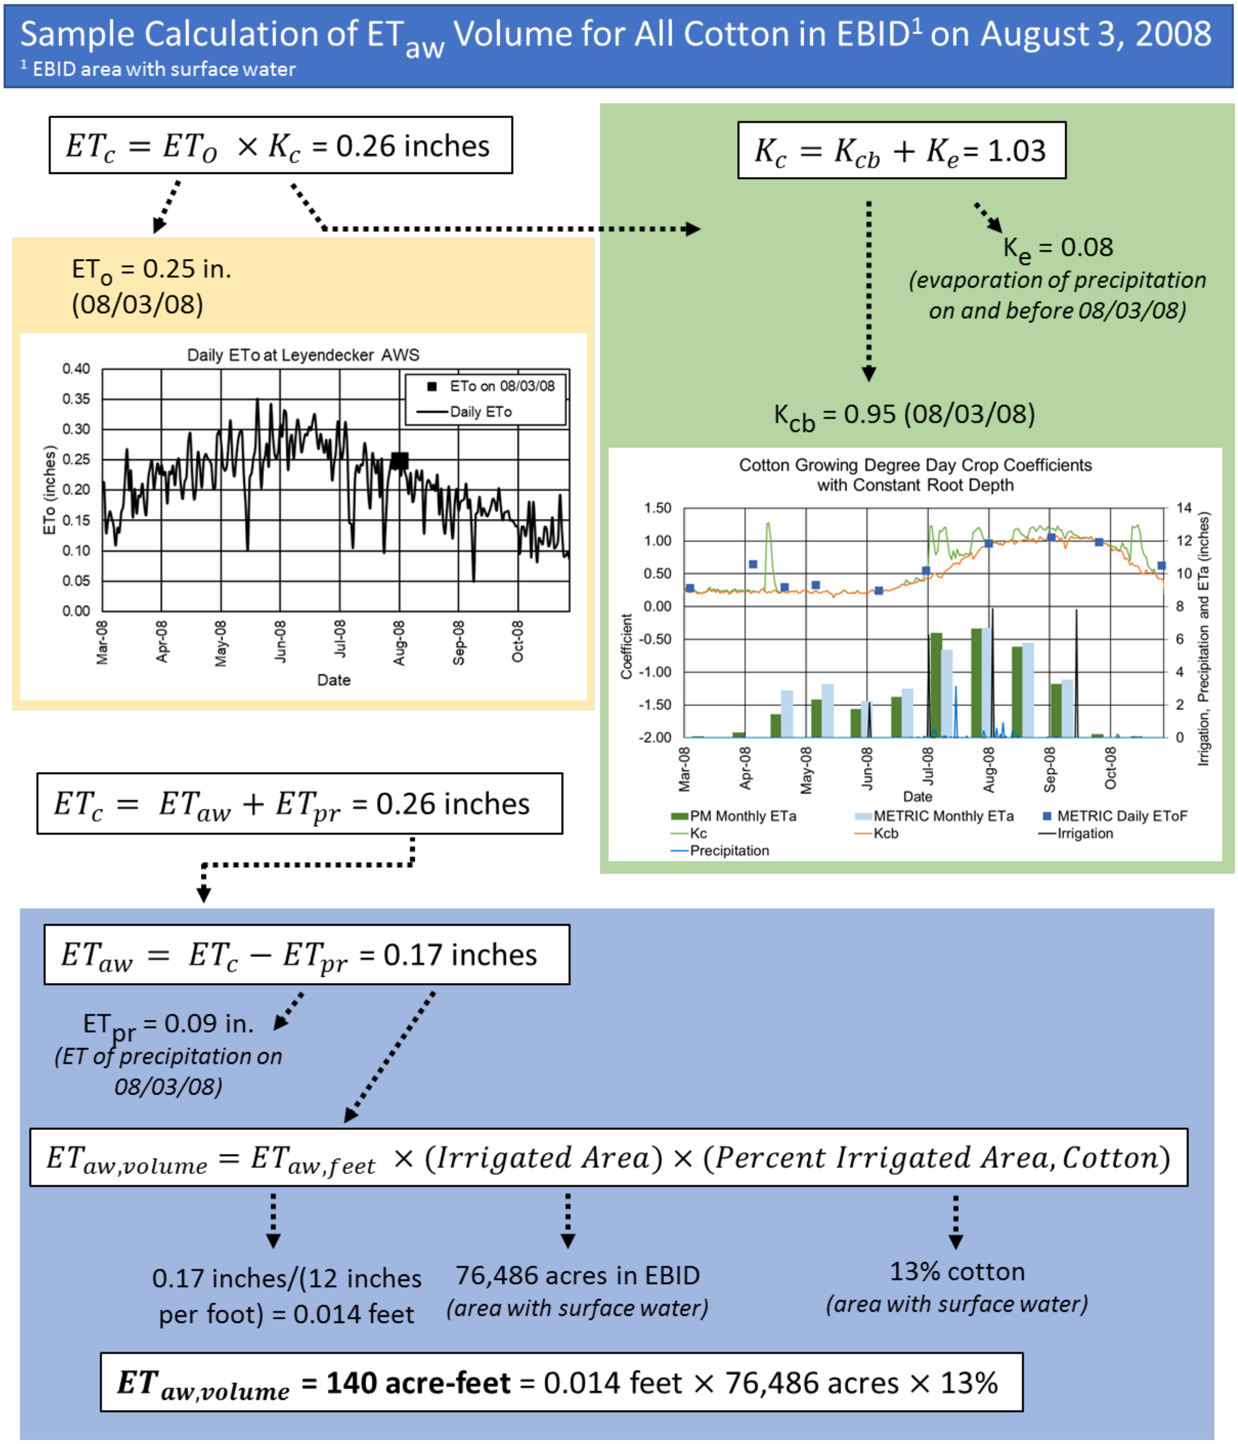

Figure 1-8. Example of Process Used to Calculate Consumptive Use of Irrigation Water for Cotton in EBID (With Surface Water) on August 3, 2008.

The following subsections briefly summarize the scientifically sound methodologies widely adopted by engineers, crop and irrigation experts that were used in our applications to develop the weather, soils, and basal crop coefficients and other crop data required by the ET Demands root zone model. Details regarding the development of METRIC ET_c estimates, operation of the ET Demands root zone model, and determination of crop irrigated areas are also briefly summarized.

The full detailed procedures and results of each step in the procedure are provided in the remaining sections of this report.

Soil Data

Soil infiltration characteristics are required in the ET Demands model to estimate surface runoff from precipitation. Additionally, soil water holding properties are required to simulate representative irrigation frequencies and applied water amounts which are used to calculate total depth of evaporation per wetting event.

Information about soil collected by the National Cooperative Soil Survey, which is published for natural resource planning and management in the Soil Survey Geographic (SSURGO) database (SSURGO, 2014), was the basis for the analysis of soil characteristics. The data are available as maps and tables. The maps outline areas called map units, which represent the most precise spatial delineation of soil characteristics publicly available. Each map unit describes soil characteristics of the components (soil series) including physical properties, interpretations, and productivity.

Soil textures throughout the Study Area were found to consist predominately of loams, which have approximately equal percentages of clay, silt, and sand, and medium intake rates and water holding capacities. The detailed methodology and results for determining the soil characteristics used in the root zone water balance model are described in Section 2.

Weather Data

Producing accurate estimates of ET_c using the crop coefficient – reference crop ET methodology requires accurate and representative weather data (ASCE, 2016). The standardized Penman-Monteith (PM) methodology as described by the Food and Agricultural Organization (Allen et al., 1998), the ASCE Task Committee Report on the Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005) and ASCE Manuals and Reports on Engineering Practice No. 70 (ASCE 2016) is a scientifically sound and widely accepted methodology for determining daily reference ET. The PM methodology requires solar radiation, air temperature, vapor pressure and wind speed data. Additionally, the ASCE Task Committee Report and ASCE (2016) recommend methodologies for estimating required inputs to the standardized equation when measured data are unavailable. The task committee report standardizes the ASCE PM methodology for application to a full-cover alfalfa reference (ET_r) and to a clipped cool season grass reference (ET_o). For this work, the clipped cool season grass reference was selected because it is commonly reported by automated weather stations (AWS) and commonly used in New Mexico and Texas.

Among all weather stations considered, the Leyendecker Automatic Weather Station (AWS) was selected to represent the Rincon and Mesilla Valleys, and the Art Ivey AWS was selected to represent the El Paso and Juarez Valleys. **(Figure 1-9)**

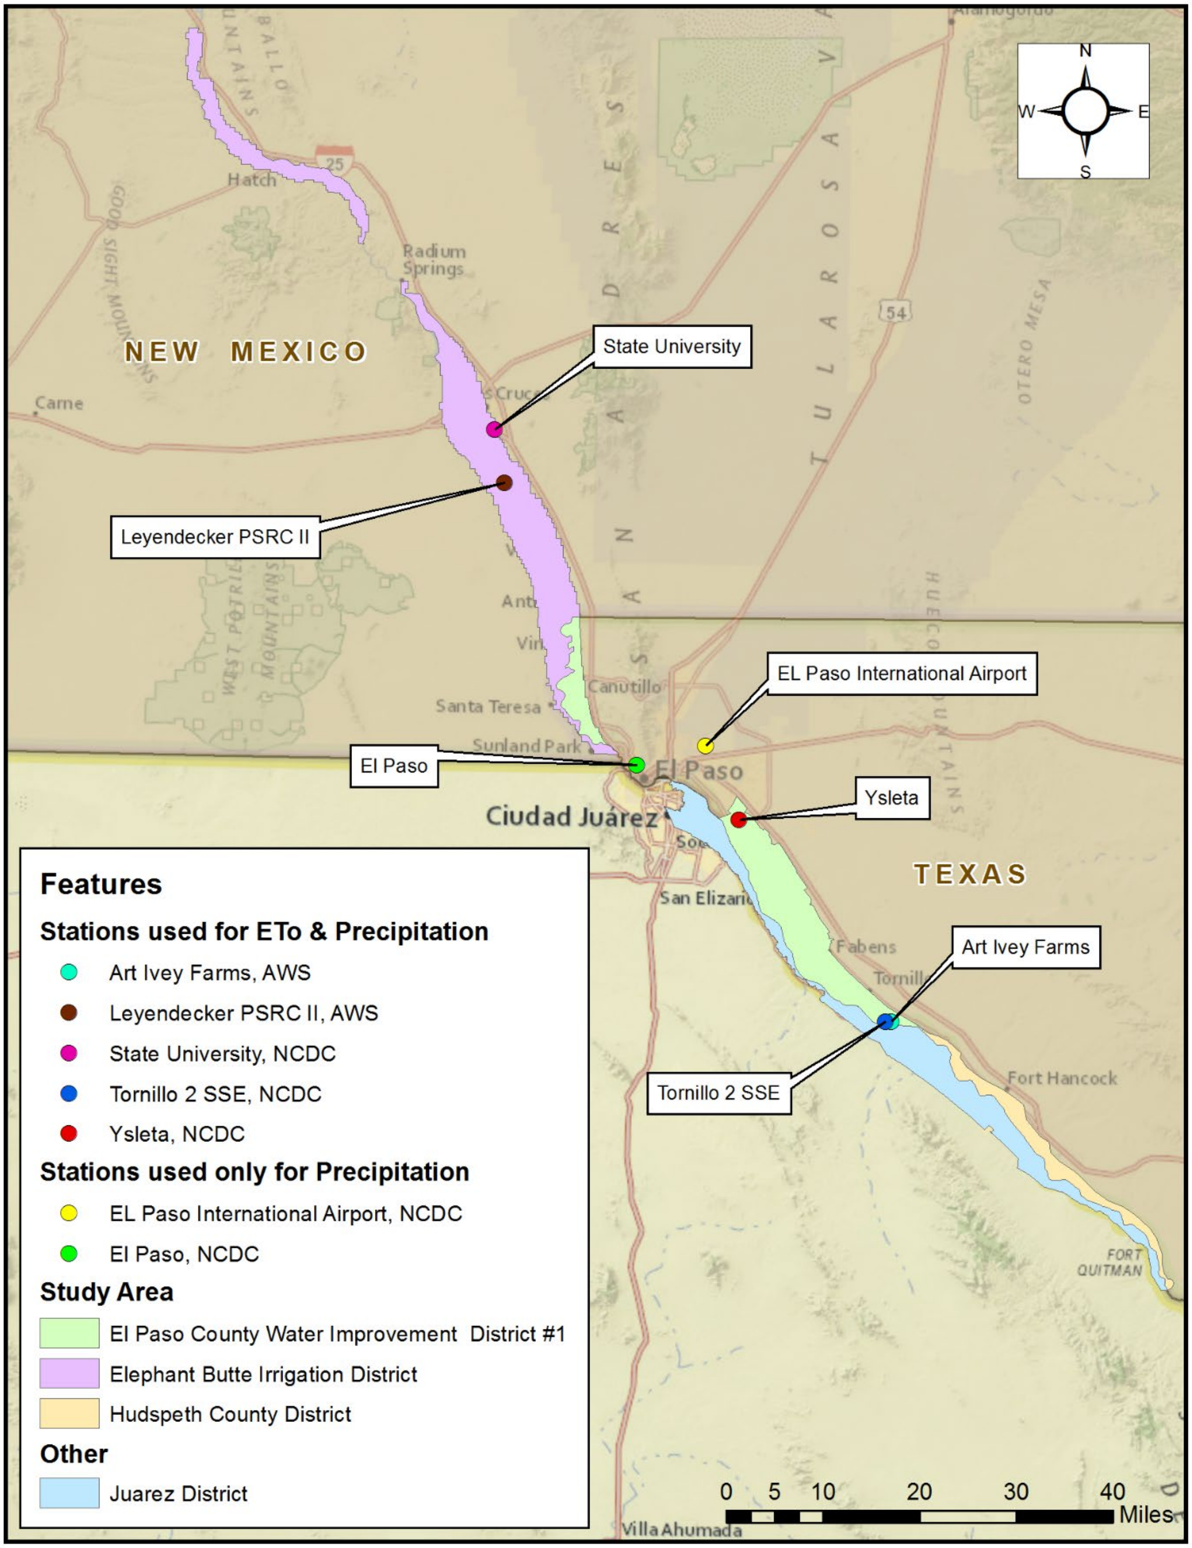

Figure 1-9. Weather Station Used in the Analysis.

The Leyendecker station is located in an agricultural area about 20 miles south of Las Cruces, and was judged to be the most representative station for irrigated areas in New Mexico due to its location interior to and surrounded by agricultural areas with more open areas of low-growing agricultural crops and fewer trees and buildings within 500 feet of the weather station as compared to other AWS stations in the Mesilla Valley. During years when data were unavailable from Leyendecker, the New Mexico State University (NMSU) weather station operated by the National Oceanic and Atmospheric Administration (NOAA) was used.

The Art Ivey station is located approximately 3.75 miles southeast of Tornillo in El Paso County, Texas, and was found to have the most complete record of weather data in the Texas region and relatively extensive areas of agriculture surrounding it. During years when data were unavailable, other stations in the Tornillo and Ysleta areas of El Paso County were used.

Weather data from the selected weather stations were reviewed for missing data, discontinuities in instrument readings (such as those resulting from dust and debris on sensors) and other problems that can affect weather data accuracy. When necessary, data were corrected with estimates of missing data or by replacing inaccurate sensor readings following accepted scientific procedures, as described in Section 3 of this report and following Allen (1996), Allen, et al, (1998), ASCE-EWRI (2005) and ASCE (2016). Hourly weather data obtained from the AWS stations were evaluated using the University of Idaho Ref-ET and QAQC program (Allen 2013). This program, developed by Dr. Richard G. Allen, provides standardized calculation of reference ET and graphical outputs of weather data parameters for analysis and applies quality control (QC) measures according to the guidelines specified in Appendix-D of the ASCE Task Committee Report on the Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005).

For the time periods when AWS weather data are not available (before 1985 and 2004, in Rincon and Mesilla, and El Paso Valleys, respectively), standardized recommended methodologies (Allen, et al, 1998; ASCE-EWRI, 2005; and ASCE, 2016) were utilized for estimating solar radiation, vapor pressure, and wind speed and the estimated parameters were used with measured temperature data from the NMSU weather station to calculate ET_o. Over the last 20 years, calculating ET_o utilizing a physically based equation and estimating missing or unmeasured data using tested standardized procedures (Allen, et al, 1998; ASCE-EWRI, 2005; Pereira et al., 2015; ASCE, 2016) has become widely accepted and a consensus has formed among ET estimation professionals that this method is reasonable and technically sound. An inventory of weather stations, quality control of weather data from the stations selected and methodology used to estimate missing parameters are described in Section 3.

Basal Crop Coefficients and Other Crop Data

Producing accurate estimates of ET_c using the crop coefficient – reference crop ET methodology requires basal crop coefficients and other crop data (ASCE, 2016). Other crop data includes crop planting and harvest dates, crop root depths and crop irrigation parameters.

Basal crop coefficients estimate crop transpiration, are used with root zone water balances to account for evaporation from precipitation and irrigation events (ASCE, 2016), and vary with crop development to relate the effects of leaf area and plant growth stage to ET_o. Changes due to increasing leaf area and growth stage are accounted for either by varying the crop coefficient with the plant's age or with other parameters indicative of the plant's growth, such as temperature. Crop coefficients are typically developed by researchers by relating ET_o to measurements of crop water use under nearly ideal growing conditions (good fertility, adequate water supply, good plant health, good management, etc.), or potential ET, which do not necessarily represent actual growing conditions in commercial agriculture. Thus, under commercial growing conditions, crop water use is typically less than estimates based on research-based crop coefficients, especially over large areas, because less than ideal growing conditions typically exist at some locations (Allen et al., 2005a; Burt et al., 2002; and Skaggs and Samani, 2005). To ensure that the crop coefficient-reference crop methodology produced actual ET_c results that are representative of commercial growing conditions in the Study Area, basal crop coefficients were developed based on actual ET_c estimates for 2008 from the satellite-based METRIC™ energy balance model. The 2008 estimates from METRIC represent hundreds of fields over all crop types and thereby quantify variation in ET_c among fields and with location in the Study Area that generally has the effect of reducing average ET_c for commercial growing conditions below pristine research conditions. Development of the local basal crop coefficients used in the ET Demands model to determine total crop water use in the Study Area is described in detail in Section 6.

Energy Balance ET_c Estimates

METRIC is a widely used (Serbina and Miller 2014) and accurate (Allen, et al., 2011) surface energy balance algorithm. A detailed description of METRIC can be found in Allen et al. (2007a, b; 2010). METRIC represents the best available science to locally calibrate crop coefficients to improve crop consumptive use estimates and is a recent advance that is gaining wide acceptance. Many applications of METRIC, both in the western United States (Wyoming, Idaho, Nevada, Colorado and California) and internationally (Australia and Morocco), are summarized in Serbina and Miller (2014). An important advantage of the energy balance methodology is that it inherently accounts for factors that cause actual ET_c under commercial growing conditions to be less than ET_c under ideal conditions (referred to earlier in this report as potential ET_c). METRIC utilizes spectral raster images from the visible, near infrared, and thermal infrared energy spectrum to compute the energy balance resulting in estimates of actual ET_c on a pixel-by-pixel[1] basis. General accuracy of ET_c estimated by METRIC has been estimated to be ±5 to ±15% when applied by expert users (Allen et al., 2011). The 2008 growing season METRIC ET_c results for EBID were used to develop crop coefficients, and results from 2002, 2008 and 2013 growing seasons were used to calibrate the ET Demands model to local conditions within the Study Area. The METRIC methodology and results are documented in four **METRIC Reports**: one each for 2002 and 2013 and one for New Mexico in 2008 and one for Texas and Mexico in 2008.

ET Demands Root Zone Water Balance Model

As described above, a daily root zone water balance is a generally accepted and widely used methodology to estimate the portion of crop water consumption met by precipitation, often referred to as effective precipitation (ASCE, 2016 and ASABE, 2007). A root zone water balance model accounts for inputs to the root zone (irrigation, rain, and capillary rise) and outputs from the root zone (evapotranspiration, runoff, and deep percolation) (**Figure 1-10**). The daily root zone water balance model assumes regular irrigation occurs when required to refill the root zone soil moisture that is depleted by estimated crop evapotranspiration. Rainfall and runoff were modeled in ET Demands based on precipitation data, irrigation frequency, and crop-soil surface characteristics, including slope, vegetation coverage, and soil type. Deep percolation (the infiltration of water into the groundwater

---

[1] A single raster element in a computer image that has a constant value across its domain. In Landsat images, a pixel has dimensions of 30 m x 30 m.

system) was modeled based on soil characteristics as well as rainfall and irrigation events at the soil surface.

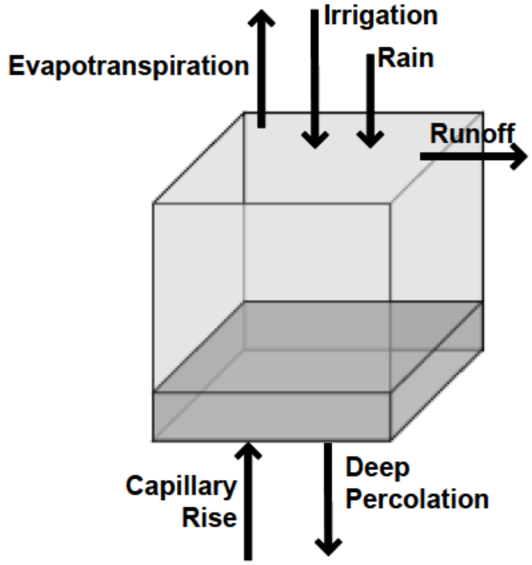

Figure 1-10. ET Demands Model Root Zone Water Balance Following FAO-56 Root Zone Water Balance. Modified from Allen et al. (1998).

The ET Demands model was chosen because it or earlier derivatives has been widely applied to compute consumptive water use (Allen and Robison, 2009 and Allen and Huntington, 2010, and Allen and Huntington, 2015) to study potential effects on agricultural water demands and use associated with climate change (Reclamation, 2015). Another important consideration was the model's use of the dual crop coefficient approach, which uses basal crop coefficients and separate soil evaporation coefficients to more accurately account for evaporation resulting from rainfall and irrigation events, the pattern of which varies from year-to-year. The simulated daily ET_{aw} values for each crop were aggregated into monthly values for each District. The monthly ET_{aw} multiplied by the irrigated area in each District represents the consumptive use of irrigation water under full supply conditions. The ET Demands model provided results for the Study Area for 1938 through 2018. The ET Demands input parameters and calibration results are described in detail in Section 7.

Irrigated Area by Crop

As previously described, the ET_{aw} per acre for each crop is multiplied by the acreage of the crop to produce the ET_{aw} volume by crop. The United States Bureau of Reclamation (Reclamation) has published an annual "Summary Statistics, Water, Land and Related Data" report based on crop census data reported by Reclamation projects (Jachens and Albertson, 1999). Districts receiving water from Reclamation projects were required to complete annual acreage reports on Reclamation Crop and Data Forms 7-316 and 7-2045 summarizing the area that receives surface water from those projects. These Reclamation reports serve as the primary basis for the historical irrigated crop area compilations. However, generally, these reports only account for cropping on lands receiving water from Reclamation projects. Thus, crops irrigated solely with groundwater are typically not included in these reports. To ensure that all irrigated crop area in the Study Area is accounted for, regardless of irrigation water source, a remote sensing application was developed and applied by INTERA. The application uses the Normalized Difference Vegetation Index (NDVI) at selected times during the irrigation season to identify irrigated lands (Intera, 2014). NDVI is a commonly used indicator of vegetation health and vigor, and establishing threshold values of NDVI and their trends during the growing season to differentiate between irrigated and non-irrigated lands in arid environments has been shown to be scientifically sound and is generally accepted (Melton, et al. 2015; Jordan and Barroll, 2013; and Clark et al., 2014). Validation of this remote sensing-based process through comparison with the results of a ground-based field survey conducted in 2016 is summarized in Section 4.

Nine crops representing about 95 percent of the area irrigated in the Study Area were selected to represent crop groups. Each crop reported in the area was assigned to one of the nine crop groups, so that 100 percent of the irrigated area in the Study Area was evaluated every year. Assignments of crops to crop groups was based on similarity of water use characteristics. The methodology used to develop total irrigated area and the area of each of the nine crop groups in each year are described in detail in Section 5.

Opinions

This section summarizes the findings of analyses supporting consumptive use determination under full supply conditions between 1938 and 2018 for the Study Area. Consumptive use of irrigation water is approximately equivalent to ET_{aw} and varies over time in the Study Area due primarily to variability in water supply conditions and crop types within the districts.

To achieve accurate ET_{aw} estimates, the ET Demands root zone model was used to compute a daily water balance tracing all inflows and outflows from the root zone. This model was selected because it accurately calculates the consumptive water use (Allen and Robison, 2009 and Allen and Huntington, 2010, and Allen and Huntington, 2015). The model has also been used to study potential effects on agricultural water demands and use associated with climate change (Reclamation, 2015).

The ET Demands model requires inputs of irrigation, precipitation, soil parameters, and ET of a reference surface (ET_o in this Study, representing a clipped cool season grass reference crop). The model then computes rainfall and runoff based on precipitation data, irrigation frequency, and crop-soil surface characteristics, including slope, vegetation coverage, and soil type; deep percolation based on soil characteristics, as well as rainfall and irrigation events at the soil surface; and ET_c for specific crops in the Study Area. To calculate ET_c and apportion it into separate ET_{pr} and ET_{aw} components, the model calculates a daily root zone water balance and uses the basal crop coefficient with the widely accepted "crop coefficient – reference crop ET" methodology (Allen, et al., 1998) (ASCE, 2016).

The ET Demands root zone model was developed and calibrated through a multi-step process involving analyses to accurately assign and determine:

- Soils and relevant soil characteristics in the Study Area (Section 2)
- Daily values of reference evapotranspiration and precipitation in the Study Area (Section 3)
- Annual irrigated crop areas in the Study Area (Sections 4 and 5)
- Locally calibrated basal crop coefficients used to estimate actual ET_c in the Study Area (Section 6)
- The ET Demands root zone model used to apportion ET_c between ET_{pr} and ET_{aw} (Section 7)
- Historical consumptive use estimates for the Study Area (monthly values between 1938 and 2018) (Section 8)

Opinions: Soils and relevant soil characteristics in the Study Area

Soil analyses conducted with information from the Soil Survey Geographic (SSURGO) database (SSURGO, 2014) found similar soil textures within the three US Districts. Loamy soils cover much of the Study Area, accounting for 87-100% of the total area in each US District. Average area-weighted soil parameters were calculated and used to characterize root zone soil in the Study Area (**Table 1-1**). Key parameters of interest include saturated hydraulic conductivity (K_{sat}); a measure of water movement through saturated soil), hydrologic soil group (alphabetical soil classification by Natural Resource Conservation Service identifying soil runoff potential, from lowest potential (A) to highest potential (D)); and available waterholding capacity (AWC; a measure of the potential water volume held in the soil that is available to crops). Although SSURGO soil data are not available for Mexico, the primary factors that determine soil type and soil characteristics – topography, soil parent material, time for soil formation, regional climate, and vegetation – were determined to be similar between Juarez and the US Districts. Thus, the average area weighted values for soil characteristics in the El Paso Valley on the east bank of the Rio Grande were used for the soils in Mexico on the west bank of the Rio Grande. Soils in all regions of the Study Area have similar AWC characteristics and generally lower runoff potential (hydrologic soil groups A and B) with correspondingly higher infiltration potential (K_{sat} greater than 1 in/hr).

Table 1-1. K_{sat}, Hydrologic Soil Group and AWC Inputs to ET Demands for Each Subarea within the Study Area.

Study Area-Subarea	Area (Acres)	K_{sat} (in/hr)	Hydrologic Soil Group	AWC (in/ft)	Area, Percent
Rincon Valley (EBID)	19,311	5.96	A	1.63	10%
Mesilla Valley (EBID and EPCWID)	74,814	4.83	B	1.72	40%
El Paso Valley (EPCWID)	39,924	1.55	B	1.76	22%
El Paso Valley (Hudspeth)	15,144	6.09	A	1.79	8%
Juarez Valley (Mexico)	36,323	2.14	B	1.77	20%
Total	185,517	NA	NA	NA	100%

Opinions: Daily values of reference evapotranspiration and precipitation in the Study Area

Daily precipitation data and reference evapotranspiration for a clipped cool season grass reference crop (ET_o) were developed from representative weather station measurements in the Study Area. Annual precipitation and ET_o data for 1938-2018 are presented in Appendix 3A.

Following visual inspection of all-weather stations in the New Mexico Study Area region, the Leyendecker Automated Weather Station (AWS) was found to be the most representative station for irrigated areas in New Mexico because of its location interior to and surrounded by irrigated agricultural areas and a greater abundance of low growing crops that permitted open flow of wind over the station. This site is located in an agricultural area about 20 miles south of Las Cruces. During years when data were unavailable from Leyendecker AWS, the New Mexico State University (NMSU) weather station data were used.

In Texas, visual inspection and data review determined the Art Ivey Farms AWS site within EPCWID to have the most complete weather data record and to be the most representative station for Texas irrigated areas, also because of its proximity to irrigated agricultural land. The Art Ivey Farms AWS site is located approximately four miles southeast of the town of Tornillo in El Paso County. During years when data were unavailable from Art Ivey Farms AWS, other stations in the Tornillo and Ysleta areas of El Paso County were used.

Quality control and quality assessment protocols were followed, and necessary adjustments were performed for hourly AWS data and daily NOAA data. Generally, some solar radiation records at both the Leyendecker and Art Ivey AWS sites were found to be artificially low and required adjustment for consistency with computed clear sky envelopes of solar radiation on cloudless days (R_{so}; the maximum R_s value that should be achieved on cloud-free days). The air temperature and humidity data at both sites were found to be consistent and did not need adjustment. Some periods of consistently low wind speed data required minor adjustment for consistency with nearby station data during short periods at both sites.

For the time periods when AWS weather data were not available, the standardized recommended methods (Allen, et al, 1998 and ASCE-EWRI, 2005) for estimating solar radiation, dewpoint temperature, and wind speed were utilized. These estimates resulted in ET_o values that were not significantly different from ET_o calculated from measured parameters (within 3 percent).

Following quality control and quality assessment of all-weather data, daily precipitation and ET_o timeseries were developed as inputs for the ET Demands model. The average annual ET_o for 1938 through 2018 was 63.2 (1,604 mm) and 63.5 inches (1,614 mm) in New Mexico and Texas, respectively. The 81-year average annual precipitation from 1938 to 2018 was 8.88 (226 mm) and 8.67 inches (220 mm) in New Mexico and Texas, respectively.

Opinions: Validation of Remote Sensing Based Processes Used to Classify Irrigation Status and Crop Type

The 2016 NMOSE survey found 21,196 acres out of 24,295 acres surveyed, or about 87.2 percent, to be irrigated in 2016. In comparison, the NDVI methodology to identify irrigated fields found 20,705 acres out of 24,295 acres observed, or 85.2 percent, to be irrigated. The NDVI methodology under estimated the irrigated area by two percent. This is well within the expected confidence range of the respective methodologies (generally plus or minus 5 percent). Therefore, no adjustment was made to these estimates based on the 2016 verification study.

The CDL methodology to identify irrigated fields underestimated the irrigated area by 2.3 percent, finding 20,590 acres out of 24,295 acres, surveyed, or 84.7 percent, to be irrigated and is also within the expected confidence range of these methodologies.

The overall accuracy of the 2016 CDL methodology to identify the nine crop groups adjusted based on the best estimate of the proportion of crop areas in the Study Area was 85.5 percent with a 95 percent confidence interval of plus or minus one percent.

Opinions: Development of Annual Irrigated Crop Areas for 1938 through 2018

Over time, there has been an overall decline in irrigated acreage in the Study Area with some variability among the Districts, as summarized below.

For example, EBID irrigated area with access to surface water averaged about 72,800 acres from 2004 through 2018 and has been generally declining since the early 1950s, when it averaged 93,100 acres.

Irrigated area within and in the vicinity of EBID with access to groundwater only (no access to surface water) averaged about 4,700 acres from 2004 through 2018 and in recent years has been generally declining after a peak at about 5,500 acres in 2000.

EPCWID irrigated area averaged about 36,400 acres from 2004 through 2018 and has been generally declining since the early 1950s, when it averaged 66,700 acres.

Hudspeth irrigated area averaged about 9,500 acres from 2004 through 2016 compared to irrigated areas between about 14,000 and 16,000 acres in the 80's and 90's.

Juarez irrigated area averaged about 33,800 acres from 2004 through 2018 and has been generally declining in recent years since its peak of 54,000 in 1986.

Since the early 1950s, the predominant crop has generally shifted from cotton to pecans in both EBID and EPCWID.

In EBID, the alfalfa crop acreage has remained about the same while it has decreased in EPCWID.

In Hudspeth, the main crop has remained cotton with some decrease in alfalfa since the early 1950s.

The main crop in Juarez remains cotton with an increase in alfalfa acreage from the early 1950s to the 1980s. Pecan area has been increasing in recent years, but still is considerably less than cotton and alfalfa.

Opinions: Development and Local Calibration of Basal Crop Coefficients

The K_{cb} curves are parameterized to represent average local conditions and stress levels across the entire population of fields in the Study Area. While these K_{cb} curves have the same general shape as published "book", or potential, K_{cb} curves for "pristine" crops, it is important to note that many individual fields have ET rates that vary from the "book" K_{cb}. These K_{cb} curves reflect influences of incidental water stress, wetness of exposed soil, and the resulting transpiration and evaporation rates. These curves better represent local conditions than "book" K_{cb} curves.

Basal crop coefficients can be developed from METRIC-derived crop coefficients and NDVI values that are based on standard procedures and that are reflective of the level of ET of applied water obtained through local irrigation and crop management practices. These basal crop coefficients can be used with a calibrated ET Demands root zone model to estimate ET of applied water. These basal crop coefficients used together with a calibrated ET Demands model and climate data result in reliable full supply ET_c and ET_{aw} estimates for all year types including years with less than full supply, ever though, the actual ET_c and ET_{aw} may be less than the full supply ET_c and ET_{aw} for years with less than a full water supply. That reduction is made in the farm water budget model.

Opinions: Local Calibration and Results of ET Demands

When used in the ET Demands root zone water balance model, locally calibrated basal crop coefficients based on 2008 METRIC actual ET for EBID yield and expected estimates of Study Area ET_c and ET_{aw} under "full supply" conditions.

Over the entire Study Area, ET Demands ET_c estimates are one, four and eight percent higher than the METRIC ET_c results in 2002, 2008 and 2013, respectively. All years are within the 10 percent calibration objective with the limited supply year of 2013 having the greatest difference.

Five of the six subareas had ET Demands total ET_c estimates within plus or minus three percent of the METRIC total ET_c estimates in 2002, the 24th consecutive full supply year. The one area (irrigated lands in New Mexico with access to groundwater only) that was not within three percent had higher ET Demands total ET_c compared to METRIC ET_c, which was found to be related to less intensive agricultural management practiced in this area. Overall, the ET Demands total ET_c estimates (representing ET_c under full supply) are higher than the METRIC total ET_c estimates (representing actual ET_c) in all areas in 2013 (a limited supply year), reflecting the expected changes in consumptive use with changes in water supply. ET Demands ET_c estimates are slightly higher in all but one area in 2008 and in all but two areas in 2002, which were full supply years. The ET Demands estimates were within three percent of the METRIC ET estimates in all areas and years having ET Demands total ET_c estimates were lower than the METRIC total ET_c estimates.

In New Mexico, the actual ET_c estimated for full supply conditions varied in its comparison to METRIC-derived estimates of actual ET_c, depending on the water sources available. ET Demands estimated total ET_c for EBID irrigated lands having access to surface water and groundwater to average 3.3 percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013. For the irrigated lands in New Mexico having access to groundwater only, the ET Demands total ET_c averaged 33 percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013. Reasons for the departure between ET Demands ET_c and METRIC actual ET_c are apparently due to suboptimal agricultural and irrigation practices in the groundwater only area.

The ET Demands total ET_c for the EPCWID irrigated lands in the Mesilla Valley averaged nine percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013. The ET Demands total ET_c for the EPCWID irrigated lands in the El Paso Valley averaged 1.7 percent more than the METRIC total actual ET_c estimates for 2002, 2008, and 2013.

In Hudspeth, the ET Demands total ET_c for the irrigated lands averaged 18.3 percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013.

In Juarez, the ET Demands total ET_c for irrigated lands averaged 3.7 percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013.

The crop coefficients used to calculate ET_c in the ET Demands model have been developed based on best practices using locally-derived calibration to the 2008 METRIC results. When the crop coefficients are used to estimate ET_c representing full water supply for 2002 and 2013, the differences between the ET Demands results and METRIC results are slightly greater than those found in 2008, but are well within generally accepted ET modeling results. Thus, the comparisons with METRIC results demonstrate that the full supply ET_c estimates developed using ET Demands and locally calibrated crop coefficients are reproducible and can be relied upon for conducting water balance and consumptive use analyses.

Opinions: Historical Consumptive Use Estimates

A reduction of five percent applied to the alfalfa and cotton ET_{aw} for the 1938 to 1953 period, reducing linearly from 1954 to zero reduction in 1970 is reasonable to accurately account for historical improvements in agricultural practices that include plant density and yield, and that have impacted ET_{aw}. ET_{aw} from 1970 through 2018 does not require adjustment.

Opinions: Irrigation Consumptive Use Coefficient

The ICUC estimates developed here and listed in **Table 1-2** and **Table 9A-1** are district-wide, annual values expressing consumption of irrigation water given irrigation performance when surface water supply is limiting. These average values reflect a large variability across the many fields of the Study Area. Notably, under conditions of limited surface water supply, growers apply additional management actions that may increase on-farm efficiencies that are reflected in increased ICUC values. Thus, in years having sufficient water supplies, the actual district-wide ICUC is less than the ICUC estimates described in this report. In addition, ICUC has changed over time with changes in on-farm practices. The main changes noted in the Study Area have been improved land leveling technologies and lining of head ditches. These on-farm improvements are reflected in the adjustments to ICUC estimates for earlier years.

Table 1-2. ICUC Values for Each Irrigation Unit for 1938 through 2018.

Years	EBID, EPCWID and Hudspeth	Comment
1984 to 2018	76%	Calculation of ICUC is based on METRIC and ET Demands results and reported farm deliveries and groundwater pumping in EBID
1983	75%	One percent per year increase in ICUC as fields are laser leveled over a five-year period
1982	74%	
1981	73%	
1980	72%	
1955 to 1979	71%	Calculated ICUC minus five percent (laser leveling improvement has not occurred during this period, leveling has been improved and farm ditches lined compared to 1938 through 1950)
1954	70%	One percent per year increase in ICUC due to improved leveling and farm ditch lining over a five-year period
1953	69%	
1952	68%	
1951	67%	
1938 to 1950	66%	Calculated ICUC minus ten percent (five percent for improved leveling and farm ditch lining from 1951 through 1954 and five percent for laser leveling from 1980 through 1983))

Opinions: Bare Ground Evaporation from Groundwater

Bare ground evaporation from groundwater is an important outflow from the groundwater system and depends primarily on climatic demand and depth to groundwater. Evaporation flux curves have been developed to estimate bare ground evaporation from groundwater for groundwater modeling. These curves have a maximum evaporative flux, termed the potential bare ground evaporation from groundwater, that represents the maximum potential bare ground evaporation from groundwater that can occur when groundwater levels are close to the ground surface. The rate and depth to groundwater at which this occurs varies based on climatic demand, precipitation, and soil texture. When the depth to groundwater is below this level, the bare ground evaporation is limited by the rate of capillary rise from the groundwater table to the evaporative layer.

II. Soils and Relevant Soil Characteristics

Purpose

The purpose of this section is to describe the soils and relevant soil characteristics found within the irrigated lands in the Rio Grande Valley from below Caballo Reservoir, New Mexico to Fort Quitman, Texas. Soil infiltration characteristics and available waterholding capacities (AWC) both affect crop consumptive use and are needed in the ET Demands root zone model to estimate evapotranspiration of applied water (ET_{aw}). The standard accepted practice for including soil effects on consumptive use in root zone water balance modeling is to develop crop-soil groups comprised of combinations of the most common crops and soil textures in an irrigated area. This section describes soil characteristics and other related information from published sources available in the public domain for soils in the Study Area and the methods used to determine soil infiltration and AWC for use in the ET Demands root zone model.

Methodology

The soils information assembled and methods for determining soil parameters are described in the following sections.

ET Demands

The primary objective of the ET Demands root zone water balance model is to estimate the ET_{aw} and ET_{pr} components of ET_c. Soil infiltration characteristics and AWC values are used to quantify water availability to crops in the model. Key parameters of interest include saturated hydraulic conductivity (K_{sat}; a measure of water movement through saturated soil) and available waterholding capacity (AWC); a measure of the potential water volume held in the soil that is available to crops).

Specifically, saturated hydraulic conductivity is used to determine a soil's hydrologic soil group – an alphabetical soil classification by the Natural Resource Conservation Service that identifies a group of soils having similar runoff potential under similar precipitation and land cover conditions, from lowest potential (A) to highest potential (D). Based on the hydrologic soil group, a curve number is selected for use with the USDA-NRCS curve number method for estimating precipitation runoff. Soil AWC values are used by the ET Demands model to estimate irrigation schedules, which are then used to estimate evaporation losses from the soil and deep percolation from the root zone (Allen and Robison 2009).

Soil Data

The Soil Survey Geographic Database (SSURGO) contains information about soil in the United States collected by the National Cooperative Soil Survey (NCSS). The NCSS is a nationwide partnership of federal, regional, state, and local agencies and private entities and institutions that cooperatively investigates, inventories, documents, classifies, interprets, disseminates, and publishes information about soils. The United States Department of Agriculture-Natural Resources Conservation Service (USDA-NRCS), formerly known as the Soil Conservation Service (SCS), organizes the NCSS and publishes scientifically sound and accepted standards for conducting soil surveys and classifying soils.

The database is available on the internet (SSURGO, 2014). Soils information is available for most areas in the United States including New Mexico and Texas. The information in the database was gathered by physical land and soil observance and collecting and analyzing soil samples (SSURGO, 2014). The database contains information on soil characteristics that was initially provided in bound hard copy soil survey publications. The soil maps are used in natural resource planning and management activities. Information available from the database includes soil infiltration characteristics, AWC, and other data necessary for plant consumptive use analyses and other water resource engineering applications.

The SSURGO database contains scientifically accepted and technically sound information on soils within the Study Area in New Mexico and Texas. The information is available as tables or as maps. Areas of soils with similar characteristics are displayed on the maps and are called map units. Each map unit is an area comprised of similar classes of soils present at the surface and within specific depth layers. The soil bulk density and the percentage of sand, clay and organic matter were obtained from the SSURGO database for each soil map unit within the Study Area. Based on the percentage of sand and clay, USDA textural classes were assigned to each soil map unit. Soils data for the Study Area in Mexico are not available in the SSURGO database.

The saturated hydraulic conductivity (K_{sat}) and AWC values obtained from the SSURGO database for each layer of each map unit were used to develop soil infiltration and AWC parameters, respectively, for each soil texture class. The procedures used to estimate these soil parameters are described in the next section.

Soil Infiltration and AWC Estimates

The distribution of soil particle size in the soil is an important factor governing soil infiltration and AWC (Soil Survey, 1993). Infiltration is defined as "the downward entry of water through the soil surface into the soil" (ASABE, 2007). Soil texture, a parameter that affects the soil infiltration rate, is defined by the weighted proportion of particles less than two millimeters in diameter. Ranging in size from largest to smallest, the three classes of particles are called "sand", "silt" and "clay". Additionally, soils are often grouped into broader classes of texture referred to generally as "sandy", "loamy" and "clayey" soils (Soil Survey, 1993). Sandy and clayey soils have sand and clay, respectively, as the predominant particles. Loamy soils have a relatively even mixture of sand, silt and clay or predominantly silt particles. Sandy, loamy and clayey soils are also commonly called coarse, medium and fine soils, respectively. Generally, sandy soils have the lowest AWC and highest K_{sat} because the coarse grains cannot be packed closely together leaving relatively large, well connected spaces that do not retain water, allowing water to flow through and drain under the force of gravity to the water table. Loamy soils have the highest AWC and lower K_{sat} because the medium size grains contain spaces for water, but these spaces are not as well connected as they are in the coarse soils. Thus, water cannot drain as quickly through the spaces. Compared to sandy and loamy soils, clayey soils have smaller spaces between particles and the spaces are the least connected. Therefore, the fine soils have the slowest water movement. Because the smaller spaces hold on to the water more tightly than loamy soils, clayey soils have a slightly lower AWC than many loamy soils.

To determine ET_{aw}, it is necessary to estimate the amount of precipitation that contributes to evapotranspiration (ET). This requires estimates of the total amount of precipitation, the amount that runs off the land and is not captured within the soil moisture profile, and the amount that is stored in the root zone and used to satisfy crop ET. To estimate the amount of precipitation that runs off, information about the soil's infiltration characteristic is used to determine the hydrologic soil group. To estimate the amount of precipitation that is stored in the soil, the soil's AWC is needed. The following paragraphs describe how these soil parameters are developed from the SSURGO database.

Determine Area-weighted Ksat

The hydrologic soil group is determined by the infiltration rate of the surface layer of the soil (NEH, 2009). SSURGO provides information on infiltration rates as low and high values of K_{sat} for each soil layer comprising a map unit. The low and high values of K_{sat} for the surface soil layer were averaged together to obtain a midpoint K_{sat} estimate of infiltration in inches per hour for each map unit. Following the methodology of Allen and Robison (2009), the average K_{sat} values for each map unit were multiplied by 0.85 to adjust for the logarithmic nature of the NRCS permeability ranges. The resulting K_{sat} values for the surface layer of each map unit were averaged, weighted by the areal extent of each map unit, for each of the three general soil textures (sandy, loamy, and clayey), for four subareas of the Study Area (the Rincon and Mesilla Valleys, the area of EPCWID in the El Paso Valley and the area of Hudspeth).

Determine Area-weighted AWC

For the AWC, a depth-weighted average is calculated for each map unit. First, the published minimum and maximum AWC for each soil layer comprising a map unit from SSURGO are averaged. Next, using the average AWC for each layer of a map unit, a weighted average was calculated based on each reported layer thickness down to 48 inches. A depth of 48 inches was selected as a reasonable maximum depth to use for the determination of AWC because it is near the midpoint of range of maximum effective root depths for the crops in the Study Area, which range from 31 to 71 inches. Additionally, the SSURGO AWC information was often not available for layers deeper than 48 inches for this area. So, if a layer extended below 48 inches, only the thickness above 48 inches was used in the calculations. For map units having depths less than 48 inches, the maximum published soil depth was used. The result is a weighted average AWC for each map unit. The resulting AWC values for each map unit were averaged, weighted by the areal extent of each map unit, for each of the three general soil textures, for four subareas of the Study Area (the Rincon and Mesilla Valleys, the area of EPCWID in the El Paso Valley and the area of Hudspeth). The resulting area averaged AWC values for the top 48 inches are used together with the maximum effective root depth for the crop to calculate the available water that can be stored in the root zone for each crop regardless of the crop's root zone depth.

Results

Soil Textures by Crop

Tables 2-1, 2-2 and 2-3 summarize the general soil texture groupings (loamy, sandy and clayey soils) of USDA soil texture classes by crop in EBID, EPCWID and Hudspeth, respectively. Loamy, sandy and clayey soils comprise 88, nine and three percent of the irrigated area in EBID, respectively (**Table 2-1**). In EPCWID, loamy, clayey and sandy underlie 88, 11 and one percent of the irrigated area, respectively (**Table 2-2**). In Hudspeth, with the exception of a few small areas of sandy soils that represent statistically negligible acreage, the irrigated area is comprised of loamy soils (**Table 2-3**). Soil textures in all three districts are predominately loamy, containing relatively equal percentages of clay, silt and sand. Detailed soil texture data were not available for the area in Mexico. Approximately 88 percent of all crops are on loamy soils with the remaining crop areas dispersed between sandy and clayey in the same general proportion that the soils are found in the Study Area. In other words, no crop is primarily grown on a single soil texture. Given the distributed nature of crops across soil textures and the predominance of loamy soils, it is reasonable to calculate and to use weighted averages of K_{sat} (infiltration rate) and AWC with all crops within geographically defined sub areas of the Study Area.

Table 2-1. General Soil Texture Areas by Crop* in Elephant Butte Irrigation District Areas with Access to Surface Water.

General Soil Texture	Cotton	Pecans	Alfalfa Hay	Chile (Peppers)	Corn, Sweet Corn, and Silage	Onions	Wheat and Small Grains	Miscellaneous Vegetables	Irrigated Pasture	Total, acres	Total, Percent
Loamy	10,487	23,823	14,483	3,503	5,735	793	752	486	5,527	65,589	88%
Sandy	651	2,653	1,804	412	448	58	19	49	668	6,762	9%
Clayey	459	748	140	95	225	0	19	24	243	1,953	3%
Total	11,596	27,224	16,427	4,011	6,407	851	789	559	6,439	74,303	100%

*The crop in each field with access to surface water for 2008 was determined from a ground-based crop survey for EBID (NMOSE, 2011).

Table 2-2. General Soil Texture Areas by Crop* in El Paso County Water Improvement District #1.

General Soil Texture	Cotton	Pecans	Alfalfa Hay	Chile (Peppers)	Corn, Sweet Corn, and Silage	Onions	Wheat and Small Grains	Miscellaneous Vegetables	Irrigated Pasture	Total, acres	Total, Percent
Loamy	12,988	9,137	2,621	0	93	99	4,630	42	2,173	31,783	88%
Clayey	1,832	570	116	0	47	38	1,076	0	202	3,881	11%
Sandy	73	88	25	0	0	0	20	0	48	253	1%
Total	14,893	9,795	2,763	0	140	137	5,725	42	2,422	35,918	100%

*The crop in each field for 2008 was determined from the geospatial crop data layer (CDL) from the United States Department of Agriculture National Agricultural Statistics Service (USDA NASS, 2014) for EPCWID.

Table 2-3. General Soil Texture Areas by Crop* in Hudspeth County Conservation & Reclamation District #1.

General Soil Texture	Cotton	Pecans	Alfalfa Hay	Chile (Peppers)	Corn, Sweet Corn, and Silage	Onions	Wheat and Small Grains	Miscellaneous Vegetables	Irrigated Pasture	Total, acres	Total, Percent
Loamy	9,726	73	1,014	0	332	0	835	0	440	12,420	100%
Sandy	14	0	0	0	1	0	0	0	2	17	0%
Clayey	0	0	0	0	0	0	0	0	0	0	0%
Total	9,739	73	1,014	0	334	0	835	0	442	12,436	100%

*The crop in each field for 2008 was determined from the geospatial crop data layer (CDL) from the United States Department of Agriculture National Agricultural Statistics Service (USDA NASS, 2014) for Hudspeth.

Soil Parameters by Subarea

The soil parameters reported by SSURGO for each soil layer in each map unit and averaged as described in the methodology section are reported by general soil texture for four subareas of the Study Area in **Tables 2-4, 2-5, 2-6, and 2-7**. The weighted average Ksat and AWC values in these tables were computed using specific soil textures (for example, clay loam) based on spatial and depth distributions. The irrigated area underlain by loamy soils varied from 87 percent in the Rincon Valley to 99 percent in Hudspeth. The area weighted average of K_{sat} ranged from 1.55 inches per hour in EPCWID in the El Paso Valley to 6.09 inches per hour in Hudspeth in the El Paso Valley. The AWC area weighted average value varied from 1.63 inches per foot in the Rincon to 1.79 inches per foot in Hudspeth.

Table 2-4. SSURGO Soil Characteristics and Parameters by General Soil Texture in the Rincon Valley area (Elephant Butte Irrigation District).

General Soil Texture	Area (Acres)	K_{sat} (in/hr)	AWC (in/ft)	Area, Percent
Loamy	16,870	4.61	1.72	87%
Sandy	2,136	17.40	0.98	11%
Clayey	305	0.22	1.62	2%
Total/weighted average	19,311	5.96	1.63	100%

Table 2-5. SSURGO Soil Characteristics and Parameters by General Soil Texture in the Mesilla Valley (Elephant Butte Irrigation District and El Paso County Water Improvement District).

General Soil Texture	Area (Acres)	K_{sat} (in/hr)	AWC (in/ft)	Area, Percent
Loamy	66,036	3.51	1.79	88%
Sandy	5,997	21.52	0.93	8%
Clayey	2,782	0.19	1.63	4%
Total/weighted average	74,814	4.83	1.72	100%

Table 2-6. SSURGO Soil Characteristics and Parameters by General Soil Texture in the El Paso Valley (El Paso County Water Improvement District).

General Soil Texture	Area (Acres)	K_{sat} (in/hr)	AWC (in/ft)	Area, Percent
Loamy*	35,433	1.54	1.77	89%
Sandy	321	22.05	0.94	1%
Clayey	4,171	0.08	1.68	10%
Total/weighted average	39,924	1.55	1.76	100%

*For loamy soil, Ksat typically varies from 0.40 in/hr to 4.00 in/hr (USDA-NRCS).

Table 2-7. SSURGO Soil Characteristics and Parameters by General Soil Texture in the El Paso Valley (Hudspeth County Water Improvement District).

General Soil Texture	Area (Acres)	K_{sat} (in/hr)	AWC (in/ft)	Area, Percent
Loamy	15,044	5.96	1.80	99%
Sandy	100	26.30	0.54	1%
Clayey	0	NA	NA	0%
Total/weighted average	15,144	6.09	1.79	100%

The National Engineering Handbook (NEH), Chapter 7, (2009) provides a table for selecting a hydrologic soil group for use with the USDA-NRCS curve number method based on soil depths to a water impermeable layer and K_{sat} values. With soil depths to a water impermeable layer greater than 40 inches and an area weighted average K_{sat} greater than 1.42 inches per hour and less than 5.67 inches per hour in the Mesilla Valley and the area of EPCWID in the El Paso Valley, hydrologic soil group B was selected as the input to ET Demands for these areas. For the Rincon Valley and the area of Hudspeth in the El Paso Valley, with an area-weighted average Ksat greater than 5.67 inches per hour, hydrologic soil group A was selected.

Soil Parameters in Mexico

As previously stated, SSURGO soil data are not available for Mexico. Topography, soil parent material, time for soil formation, regional climate and vegetation are the primary factors that determine the type and characteristics of soils in an area (Soil Survey Staff, 1993). In Mexico, these factors are similar to the factors in the US Districts. Additionally, the average area-weighted K_{sat} and AWC values for soils on the east and west sides of the Rio Grande in the Mesilla Valley south of Las Cruces were compared and found to be similar (**Tables 2-8 and 2-9**). Thus, the average area weighted values for the soils in the El Paso Valley on the east bank of the Rio Grande (**Table 2-10**) will be used to represent the soils in Mexico on the west bank of the Rio Grande.

Table 2-8. SSURGO Soil Characteristics and Parameters by General Soil Texture in the US Districts in the Mesilla Valley South of Las Cruces on the East Side of the Rio Grande.

General Soil Texture	Area (Acres)	K_{sat} (in/hr)	AWC (in/ft)	Area, Percent
Loamy	13,376	3.96	1.81	88%
Sandy	1,466	18.84	0.91	10%
Clayey	312	0.19	1.63	2%
Total/weighted average	15,154	5.32	1.78	100%

Table 2-9. SSURGO Soil Characteristics and Parameters by General Soil Texture in the US Districts in the Mesilla Valley South of Las Cruces on the West Side of the Rio Grande.

General Soil Texture	Area (Acres)	K_{sat} (in/hr)	AWC (in/ft)	Area, Percent
Loamy	29,781	2.81	1.78	90%
Sandy	1,708	28.81	0.94	5%
Clayey	1,699	0.17	1.64	5%
Total/weighted average	33,188	4.01	1.73	100%

Table 2-10. SSURGO Soil Characteristics and Parameters by General Soil Texture in the El Paso Valley area of El Paso County Water Improvement District and Hudspeth County Water Improvement District for use on the West Bank of the Rio Grande in Juarez Valley in Mexico.

General Soil Texture	Area (Acres)	K_{sat} (in/hr)	AWC (in/ft)	Area, Percent
Loamy	50,477	2.15	1.78	92%
Sandy	421	21.70	0.92	1%
Clayey	4,171	0.08	1.68	8%
Total/weighted average	55,069	2.14	1.77	100%

Opinions

Soil analyses conducted with information from the Soil Survey Geographic (SSURGO) database (SSURGO, 2014) found similar soil textures within the three US Districts. Loamy soils cover much of the Study Area accounting for 87-100% of the total area in each US District. Based on these soil textures, average area-weighted soil parameters were calculated and used to characterize root zone soil in the Study Area (**Table 2-11**). Key parameters of interest include saturated hydraulic conductivity (K_{sat}); (a measure of water movement through saturated soil), hydrologic soil group (alphabetical soil classification by the Natural Resource conservation service identifying soil runoff potential, from lowest potential (A) to highest potential (D)), and available waterholding capacity (AWC, a measure of the potential water volume held in the soil that is available to crops). Although SSURGO soil data are not available for Mexico, the primary factors that determine soil type and soil characteristics—topography, soil parent material, time for soil formation, regional climate, and vegetation – were determined to be similar between Juarez and the US Districts. Thus, the average area weighted values for soil characteristics in the El Paso Valley on the east bank of the Rio Grande were used for the soils in Mexico on the west bank of the Rio Grande. Soils in all regions of the Study Area have similar AWC characteristics and generally lower runoff potential (hydrologic soil groups A and B) with correspondingly higher infiltration potential (K_{sat} greater than 1 in/hr).

Table 2-11. K_{sat}, Hydrologic Soil Group and AWC Inputs to ET Demands for Each Subarea within the Study Area.

Study Area-Subarea	Area (Acres)	K_{sat} (in/hr)	Hydrologic Soil Group	AWC (in/ft)	Area, Percent
Rincon Valley (EBID)	19,311	5.96	A	1.63	10%
Mesilla Valley (EBID and EPCWID)	74,814	4.83	B	1.72	40%
El Paso Valley (EPCWID)	39,924	1.55	B	1.76	22%
El Paso Valley (Hudspeth)	15,144	6.09	A	1.79	8%
Juarez Valley (Mexico)	36,323	2.14	B	1.77	20%
Total	185,517	NA	NA	NA	100%

III. Daily Reference Evapotranspiration and Precipitation

Purpose

The purpose of this section is to describe the development of daily reference evapotranspiration (ET_{ref}) and precipitation values for 1938 through 2018 for use to determine consumptive use of irrigation water in the Study Area. Estimating water depletions resulting from irrigated agriculture requires information on weather and crop areas irrigated.

This section describes the methodology for developing ET_{ref} and precipitation records, the results and the findings.

Methodology

Scientifically sound and widely accepted methods for determining consumptive use of irrigation water utilize daily ET_{ref} determined using the standardized ASCE Penman-Monteith (PM) method as described by the ASCE Task Committee Report on the Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005). The PM method requires measurements or best estimates of incoming solar radiation (R_s), air temperature (T_a), relative humidity (RH) and wind speed (W_s) at hourly or daily time steps. The Task Committee Report standardizes the ASCE PM method for application to a full-cover alfalfa reference (ET_r) and to a clipped cool season grass reference (ET_o). The clipped cool season grass reference is widely used throughout the western United States and was selected for this application. Additionally, the Task Committee Report provides recommended methods for estimating required inputs to the standardized equation when measured data are unavailable. The remainder of this section describes an inventory of weather stations and available data, weather data quality control, and the methods used to estimate ET_o.

Weather Data Inventory

Weather data from irrigated areas are needed to develop estimates of consumptive use of irrigation water. Automatic Weather Stations (AWS) provide measurements of R_s, T_a, RH and W_s over hourly or shorter periods that are used to compute ET_o. AWS data are often available from state extension services and weather station networks. Prior to the advent of the AWS, National Oceanic and Atmospheric Administration (NOAA) stations recorded daily minimum and maximum air temperatures and daily precipitation. Data from these NOAA stations are available from the National Centers for Environmental Information (NCEI), formerly the National Climatic Data Center (NCDC).

In recent years, several gridded climate data sets have become available for public use. Daymet and PRISM (Parameter-elevation Relationships on Independent Slopes Model) are two of the more well-known data sets. The gridded estimates are developed by a collection of algorithms that interpolate and extrapolate from daily meteorological observations at available weather stations. Generally, the gridded estimates do not include all necessary parameters to calculate ET_o. PRISM[2] provides estimates for precipitation, daily maximum air temperature, daily minimum air temperature and daily average dewpoint temperature determined by interpolating between weather stations based on the physiographic similarity of the station to the grid cell.

[2] http://www.prism.oregonstate.edu/ accessed on May 18, 2014.

For developing ET_o values to use in determining crop water depletions, it is important that the weather local environment in which the data are collected represents that of irrigated agriculture. This is because calculated potential ET from irrigated areas in arid regions is generally lower than that calculated using weather data collected from surrounding non-irrigated areas (example: weather stations at airports). The evaporation process tends to both cool and humidify the near-surface boundary layer over irrigated fields. This cooling and humidifying effect tends to reduce estimated ET rates, including the reference ET estimate, and should be considered when selecting weather stations and data for calculating reference ET. Weather stations used to develop the gridded data are from both irrigated and non-irrigated areas. For narrow corridors of agriculture like the Rio Grande study area, this is especially true. For this reason, AWS inside the irrigated area are the preferred source for weather data to calculate ET_o for use in determining consumptive use of irrigation water rather than a hybrid type of gridded data set.

A complete inventory of weather stations both inside and near irrigated areas was conducted to select the most appropriate weather station, or stations, for the historical crop water consumptive use analysis. Selected stations were visited and site conditions assessed for additional data quality assurance.

Weather Data Quality Control

Accurate estimation of consumptive use of irrigation water requires accurate and representative weather data. Weather data from each station were reviewed and corrected when necessary, following vetted and accepted, scientific procedures (Allen, et al 1996, Allen, et al, 1998, ASCE-EWRI, 2005 and ASCE, 2016). Hourly data obtained for the AWS stations were quality checked using the University of Idaho Ref-ET and quality analysis and quality control (QAQC) program[3] (Allen 2013). This program provides graphical outputs of weather data parameters for analysis and application of quality control methods according to the guidelines specified in Appendix-D of the ASCE Task Committee Report on the Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005). Quality control procedures applied to R_s, T_a, RH and W_s are briefly described in the following sections.

Solar Radiation

Solar radiation data were quality controlled by plotting measured R_s and computed clear sky envelopes of solar radiation on cloudless days (R_{so}) for hourly or daily time steps (Allen, et al 1996, Allen, et al, 1998, ASCE-EWRI, 2005 and ASCE, 2016). Recommended equations for R_{so} that include the influence of sun angle, turbidity, atmospheric thickness, and precipitable water were used (Allen, et al 1996 and ASCE, 2016). The measured R_s is expected to reach the clear sky envelope on cloud-free days. On cloudy or hazy days, the measured R_s will not reach the clear sky envelope. Measured R_s values that consistently fall substantially above or substantially below the curve on what appear to be cloudless days indicate improper calibration or other problems, such as the presence of dust, bird droppings or something else on the sensor. When values for R_s were found to be consistently more than 3% above or below R_{so} on clear days, all values for R_s were adjusted by dividing R_s by the average value of R_s/R_{so} for clear days. Adjustment ratios were calculated at intervals of 60-day groupings for daily data and 30 day periods for hourly data. The values resulting from these adjustments were carefully reviewed to confirm reasonableness of the adjustments.

[3] REF-ET for Windows ver. 3.1.15 downloaded on May 15, 2013 from http://extension.uidaho.edu/kimberly/2013/04/ref-et-reference-evapotranspiration-calculator/

Air Temperature

Air temperature is the simplest weather parameter to measure and the parameter most likely to be of high quality (Allen, et al 1996, Allen, et al, 1998, ASCE-EWRI, 2005 and ASCE, 2016). Nevertheless, daily maximum and minimum air temperatures were plotted together vs. time, and extreme values were compared against historical extremes. Temperatures that consistently exceed the recorded extremes for a region may indicate a problem with the sensor.

Relative Humidity

Daily maximum and minimum relative humidity values were plotted and examined for values chronically lower than five to ten percent and values that were consistently over 100 percent (Allen, et al 1996, Allen, et al, 1998, ASCE-EWRI, 2005 and ASCE, 2016). Additionally, relative humidity was checked on days having recorded rainfall to confirm that the measured maximum RH values approached 90 to 100 percent. Where necessary, reasonable adjustments such as setting all values above 100 percent equal to 100 percent were made.

Wind Speed

Wind speed records were plotted and visually inspected for consistently low wind speed values (Allen, et al 1996, Allen, et al, 1998, ASCE-EWRI, 2005 and ASCE, 2016). Low wind speeds can indicate dirty or worn anemometer bearings that precede total failure of the anemometer. Any period of more than thirty days having wind speeds below 1.0 meters per second was compared to available nearby stations and, if the wind speed at the nearby station did not indicate a similar period of unusually low wind speeds, wind speed data were adjusted using ratios that were based on the nearby station.

ET_o Estimates

Over the last 20 years, it has become widely accepted, and has become a consensus within the ET estimation community, that utilizing a physically based equation with estimation of missing or unmeasured data using tested standardized procedures (Allen, et al, 1998 and ASCE-EWRI, 2005) is technically sound. For the time periods when AWS weather data were not available, including the historical periods back to year 1938, the standardized recommended methods (Allen, et al, 1998 and ASCE-EWRI, 2005) for estimating solar radiation, dewpoint temperature, and wind speed were utilized as described below.

Solar Radiation

The standardized procedures recommended by FAO-56 (Allen et al, 1998) and ASCE-EWRI (2005) estimate solar radiation from daily minimum and maximum air temperatures using an equation such as the Hargreaves-Samani (1982) equation:

$$R_s=0.16*(T_{max}-T_{min})^{0.5}\ R_a \qquad \textbf{(Eq. 3-1)}$$

Where R_s is estimated daily solar radiation, MJ m^{-2} d^{-1}, R_a is exoatmospheric radiation (also known as extraterrestrial radiation), MJ m^{-2} d^{-1}, T_{max} is the daily maximum air temperature, ^oC, T_{min} is the daily minimum air temperature, ^oC. R_s estimated by **Equation 3-1** must be limited to less than or equal to the value of R_s that is expected to occur under clear sky conditions.

ASCE (2016) also recommends the solar radiation estimation procedure developed by Thornton and Running (1999) for estimating daily solar radiation across the United States.

$$R_s= R_{so} *\{1-0.9*exp[-B*(T_{max}-T_{min})^{1.5}]\} \qquad \textbf{(Eq. 3-2)}$$

where R_{so} is theoretical solar radiation on a clear day, MJ m^{-2} d^{-1}, B is an empirical fitting coefficient, T_{max} is the daily maximum air temperature, ^oC, T_{min} is the daily minimum air temperature, ^oC. The Thornton-Running method uses a $T_{max} – T_{min}$ technique similar to the Hargreaves-Samani method, but with a differently shaped function of T_{max} and T_{min} that is automatically asymptotic to the R_{so} curve so that no post-clipping of R_s is required. Thornton-Running (1999) presented a "universal" function for B for use across the U.S.:

$$B_{T\text{-}R}= 0.031 + 0.201*exp[-0.185*(\Delta T_{month})$$ (**Eq. 3-3**)

where the subscript "T-R" indicates the use of the "universal" function for B for use across the U.S and ΔT_{month} is the difference in long term average values for T_{max} and T_{min} on a monthly basis. One value of ΔT_{month} is required for each month for each location of application.

Root mean square error (RMSE) is often used to evaluate how closely estimates compare with measured data. For this study, the RMSE was used to select the method for estimating solar radiation when measured solar radiation data were not available. The RMSE of the Thornton-Running method and the Hargreaves-Samani equation were calculated for the monthly and daily time periods that Ysleta and Tornillo temperature data overlaps with Art Ivey measured solar radiation. The equation with the lowest RMSE (i.e. providing estimates that are closest to measured data) was selected to estimate the solar radiation during the time period when measurements were not available.

Dewpoint Temperature

The dewpoint temperature, T_{dew}, is defined as the temperature at which air, when cooled, becomes saturated with water vapor, and condensation occurs, forming dew. When the air temperature is at the dewpoint, the relative humidity (RH) is, by definition, 100 percent. Because the Ysleta and the Tornillo NCEI weather stations measure only T_{max}, T_{min} and precipitation, the dewpoint temperature for these stations was estimated according to the FAO 56 (Allen et al, 1998), ASCE-EWRI (2005) and ASCE (2016) standard procedures by applying monthly offsets between daily minimum air temperature and dewpoint temperature developed from analysis of local AWS weather data sets.

The Texas ET network provided hourly relative humidity for the Art Ivey AWS for years 2004 and 2006 to 2012. To determine the offset, K_o, for calculating dewpoint temperature from the minimum temperature (**Equation 3-4**), the dewpoint temperature was computed based on daily maximum relative humidity using equations 37, 41 and D.7 from ASCE-EWRI (2005) (**Equations 3-5, 3-6 and 3-7** below).

$$T_{dew}=T_{min} - K_o$$ (**Eq.3-4**)

with K_o determined on a monthly basis during the period of weather data overlap as:

$$e_s=0.6108exp((17.27*T_{min})/(T_{min}+237.7))$$ (**Eq. 3-5**)

$$e_a=(RH_{max}/100)*e_s$$ (**Eq. 3-6**)

$$T_{dew} =((116.91+237.3*ln(e_a))/(16.78-ln(e_a))$$ (**Eq. 3-7**)

$$K_o= T_{min} - T_{dew}$$ (**Eq. 3-8**)

where e_s is the saturation vapor pressure in kPa, T is the temperature in ^oC, e_a is the actual vapor pressure in kPa and RH_{max} is the daily maximum relative humidity in percent. Daily values for K_o were averaged over each month to develop a table of twelve-monthly values as recommended by ASCE (2016). The use of the RH_{max} and T_{min} pairing in **Equations 3-5 and 3-6** is recommended by ASCE-EWRI (2005) and ASCE (2016). Because the Ysleta NOAA station was surrounded by urban areas during the time of the overlap period, 2004 to 2009, with the Art Ivey AWS station, the Tornillo NOAA station was used to determine the K_o offset.

Wind Speed

Wind speed was estimated for each NOAA station by using the mean monthly values for wind speed developed from nearby AWS stations in Texas and New Mexico, respectively as recommended by the standardized methods (Allen et al., 1998, ASCE-EWRI, 2005 and ASCE, 2016).

ET_o Variance with Estimated Weather Parameters

When ET_o is calculated with some weather parameters estimated, the variance of the resulting population may be less than that of the true underlying population. For example, wind speeds vary from day to day, but the wind speed estimates used here are mean monthly values, as previously described. This may result in reduced variation in the ET_o estimates (Allen et al., 1998).

To assess the impact of estimating solar radiation, dewpoint temperature and wind speed, the ET_o calculated from these estimated weather data were compared to the ET_o calculated using the full suite of measured weather parameters from the nearby AWS station.

Results

This section describes the results of an inventory of weather stations and available data, weather data quality control, and ET_o estimates.

Weather Station Inventory

In New Mexico, an evaluation of weather stations by Allen (2009) determined the Leyendecker station, located in an agricultural area south of Las Cruces, to be the most representative station for the New Mexico irrigated areas. In large irrigated agricultural areas, weather data from within the irrigated area is the preferred data source as temperature and humidity are both influenced by evapotranspiration (Allen et al., 1998, and ASCE, 2016). Following visual inspection and comparison with other weather stations, Leyendecker was judged to be most acceptable for calculating ET_o rates that are representative of agricultural consumptive use of irrigation water due to its location interior to and surrounded by agricultural areas and with more areas of open fetch in the weather station vicinity than AWS stations nearer to Las Cruces, for better air flow.

The Leyendecker AWS is located about 20 miles south of Las Cruces and started collecting data on January 1, 1985. Before this, the State University, NCDC, (or NMSU) station provided the most suitable record. That station began collecting temperature and precipitation data in 1896 (as the Agricultural College Station) and was moved to its present location on the NMSU campus on the edge of Las Cruces in 1959. The NMSU station was used for the years before the Leyendecker station was operating and for two years (1991 and 1992) that Leyendecker data were not available. **Figure 3-1** shows the location of the weather stations selected in the Study Area. **Table 3-1** lists the stations and time periods used for the New Mexico weather data.

Table 3-1. New Mexico Weather Data Time Series Summary for the period 1936 – 2018.

Weather Station	Start Date	End Date	Comment
NMSU	Jan. 1, 1936	Dec. 31, 1984	NOAA
Leyendecker	Jan. 1, 1985	Dec. 31, 1990	AWS
State University, NCDC	Jan. 1, 1991	Dec. 31, 1992	Leyendecker data unavailable.
Leyendecker	Jan. 1, 1993	Dec. 31, 2008	AWS (January 1993 air temperatures estimated using NMSU temperatures)
Leyendecker PRSC II*	Jan. 1, 2009	Dec. 31, 2018	AWS

*The Leyendecker PRSC II station was installed in 2009 and was collocated with the original Leyendecker station for several years. The PRSC II station used newer sensors and was therefore adopted over the older original station.

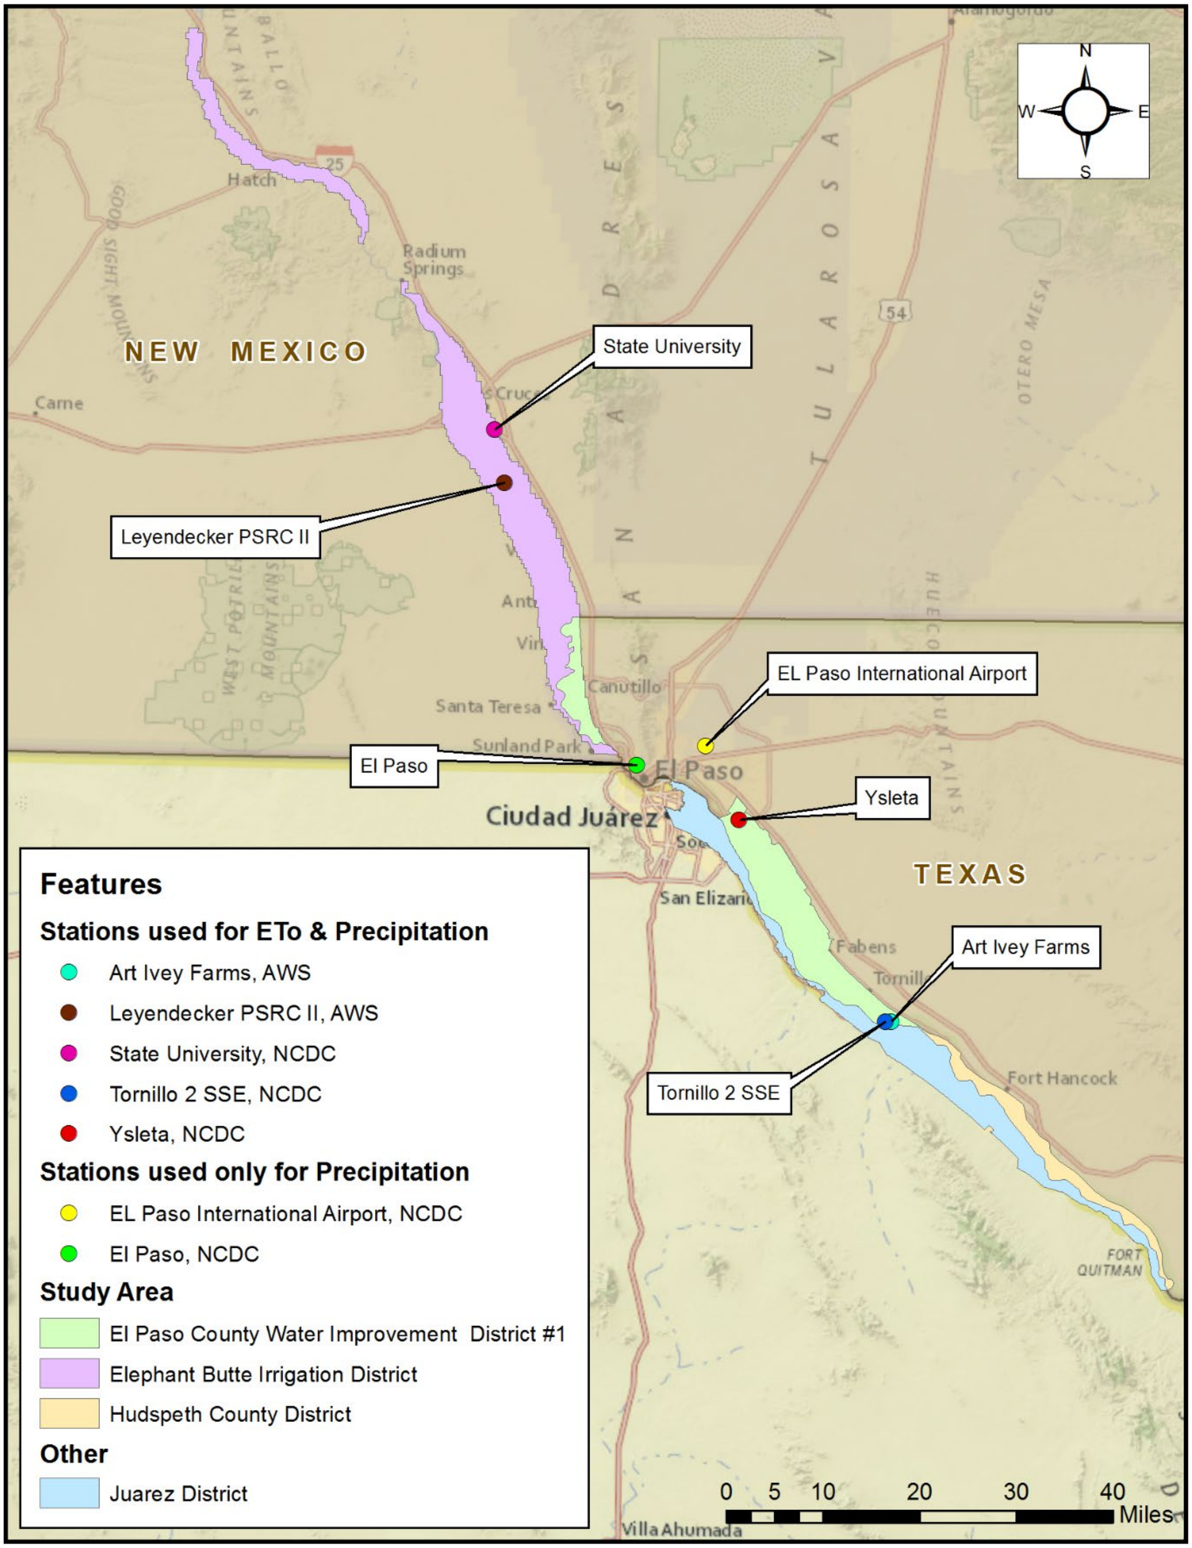

Figure 3-1. Weather Station Used in the Analysis.

In Texas, within EPCWID, the Art Ivey Farms and Tirres Farms sites were found to be located in agricultural settings that best represented the Study Area. The Art Ivey Farms AWS had the most complete record and was located approximately 3.75 miles southeast of the town of Tornillo in El Paso County, Texas at approximate latitude N31.404 degrees, and longitude W106.047 degrees. Latitude and longitude were determined by visually locating the site using Google Earth.

Because the Art Ivey AWS did not begin collecting and recording data until early 2004, NOAA weather stations were used to extend the daily ET_o time series back to 1938. The longest NOAA station data record was at Ysleta, which was discontinued in 2009 and is now located within the city of El Paso. The Tornillo NOAA station is located southeast of the town of Tornillo, only a few miles from the Art Ivey AWS. However, this station did not begin collecting data until 1981. The Tornillo station was used to fill in missing days in the Art Ivey record because an aridity analysis determined that the Tirres Farms station was in an arid environment. For 2013 to 2018, the only available weather data for Texas were at Pebble Hills Park and Westside Sports Complex. Both of these stations are located in urban areas with poor air flow due to limited fetch in the weather station vicinity. An analysis and comparison of the data from these stations to the Art Ivey and the Leyendecker PRSC II station indicated that the Leyendecker PRSC II station, even though it is located in New Mexico, provides the most representative ET_o for the irrigated agricultural areas in Texas and Mexico of the available weather stations for 2013 to 2018. Given the limitations of the available weather data, the daily ET_o time series was developed based on the best available station at any given time (**Table 3-2**).

Table 3-2. Texas ET_o Data Time Series Summary of Sources Used for the Period 1936 – 2018.

Weather Station	Start Date	End Date	Comment
NMSU adjusted	Jan. 1, 1936	Jan. 31, 1939	Adjusted based on overlap with Ysleta/Tornillo data
Ysleta	Feb. 1, 1939	June 30, 1981	Only station available inside irrigated area
Tornillo	Jul. 1, 1981	Dec. 31, 2003	Inside irrigated area, during this time Ysleta is likely becoming urbanized.
Art Ivey	Jan. 1, 2004	Dec. 31, 2004	AWS
Tornillo	Jan. 1, 2005	Dec. 31, 2005	No data at Art Ivey
Art Ivey	Jan. 1, 2006	Dec. 23, 2006	AWS
Tornillo	Dec. 24, 2006	Apr. 16, 2007	Only station inside irrigated areas
Art Ivey	Apr. 17, 2007	Dec. 31, 2007	AWS
Tornillo	Jan. 1, 2008	Jan. 10, 2008	Only station inside irrigated areas
Art Ivey	Jan. 11, 2008	Dec. 15, 2008	AWS
Tornillo	Dec. 16, 2008	Dec. 31, 2008	Only station inside irrigated areas
Art Ivey	Jan. 1, 2009	Dec. 30, 2012	AWS
Leyendecker PRSC II	Dec. 31, 2012	Dec. 31, 2018	AWS No station inside Texas irrigated areas

Weather Data Quality Control

Hourly checks and necessary adjustments performed on AWS station data and daily checks and necessary adjustments performed on NOAA data are described in the following sections.

Daily data were obtained from the NCEI web site for the NOAA stations nearest to the available AWS having data for periods from 1938 up to when the AWS record began. These data were selected to develop the complete daily record (**Table 3-3**). The daily air temperature and precipitation data at these stations were reviewed for missing days and other data errors and appropriate corrections and estimates were made using accepted procedures.

Table 3-3. NOAA Data Stations.

Station Name	State	Record Start Date	Record End Date	No. of Days
STATE UNIVERSITY NM US	NM	1/1/1936	12/31/2018	30,316
TORNILLO 2 SSE TX US	TX	7/1/1981	11/30/2012	11,476
YSLETA TX US	TX	2/1/1939	9/30/2009	25,426

Solar Radiation

Leyendecker AWS solar radiation data were generally of good quality until the last few years of the record. Between 2011 and 2019, the R_s measurements began to fall below the estimated R_{so} curve in a trend suggestive of sensor inaccuracy. The distance below the R_{so} curve continued to increase through the end of 2016. The R_s data were adjusted by dividing by a ratio that continually decreased from 2011 through the end of 2016. The ratio was calculated for approximately 180-day periods and progressively decreased from 0.98 during the second half of 2011 to 0.83 in the first half of 2016. The ratio increased to 0.91 for the second half of 2016. The R_s measurements in 2017 and 2018 were closer to the estimated R_{so} curve than in 2016, but remained slightly lower in both years. During this period, a ratio between 0.89 and 0.97 with an average of 0.92 was used to adjust the R_s data.

Art Ivey and Tirres AWS solar radiation data appear to be of good quality. During spring of 2008 and 2009 and 2011, midday measurements often rose to about 10% above the estimated R_{so} curve, during pre-monsoon periods when the humidity was very low. One reason for R_s data to lie above correct levels might be a tipping of the pyranometer towards the south. R_s data for Art Ivey were adjusted for year 2008 by dividing by a ratio that linearly increased from 1.00 on day of year (DoY) 70 to 1.09 on DoY 110 and remained at 1.09 until DoY 135, when the ratio linearly reduced to 1.00 on DoY 200. Reference ET was recomputed following the adjustment. A ratio of 1.00 means that no adjustment to measured data was needed. Similar adjustments were made to years 2009 – 2012.

Air Temperature

Leyendecker AWS air temperature data were consistent and followed expected values and behavior. No adjustments were made.

Art Ivey and Tirres AWS air temperature data were consistent and followed expected values and behavior. No adjustments were made.

Relative Humidity

Leyendecker AWS humidity data for all years appeared to be reasonable and expected, when assessed using the procedures previously described. Dewpoint temperatures were generally associated with daily minimum air temperature, with RH at night commonly about 60% in spring before the monsoon period and then approaching 100% during the monsoon period of late spring through summer. No adjustments to humidity data were made.

Art Ivey and Tirres AWS humidity data for all years appeared to be reasonable and expected, when assessed using the procedures described. Dewpoint temperatures were generally associated with daily minimum air temperature, with RH at night commonly about 60% in spring before the monsoon period and then approaching 100% during the monsoon period of late spring through summer. No adjustments to humidity data were made.

Wind Speed

Leyendecker AWS wind speed data were generally reasonable and followed expected ranges and patterns, with lower values during nighttime and higher values during the day. However, at the end of July of 2014 the wind speed measurements decreased significantly and many values were missing. A double mass plot comparing valid windspeed data from the Leyendecker and Fabien-Garcia weather stations was developed. Data from the Fabien-Garcia station were used without adjustment based on the double mass comparison to fill the missing measurements and measurements at the Leyendecker station that were below the threshold for the 2014-2016-time period.

The Art Ivey hourly wind speed data were relatively complete. However, many nighttime wind speed values dropped to zero even though daytime values were as high as 6 m/s. The trend toward zero values seems to increase with time in the record. This may suggest a fatiguing of anemometer bearings (ASCE-EWRI 2005). To calculate ET_o, all hourly wind speed values less than 0.5 m/s were set to 0.5 m/s, following the recommendation in ASCE-EWRI (2005) to represent a floor on wind movement and equilibrium boundary layer stability effects in the Penman-Monteith equation.

ET_o Estimates

For the time periods when AWS weather data were not available, the standardized recommended methods (Allen, et al, 1998 and ASCE-EWRI, 2005) for estimating solar radiation, dewpoint temperature, and wind speed were utilized with the results described below.

Solar Radiation

To determine which equation provided a better fit to available measured solar radiation data, the Thornton-Running method and Hargreaves-Samani equation were both used to estimate solar radiation based on the daily air temperature extremes from the available weather stations. These estimates were then compared to the quality controlled measured solar radiation from available AWS data through a ratio of estimated R_s to measured R_s. A value closer to 1.0 indicates closer fit of estimated R_s to measured R_s.

Comparison between the average annual ratio of estimated R_s from NMSU NOAA station temperature data and measured R_s from the Leyendecker AWS indicated that the solar radiation estimated by the Hargreaves-Samani equation more closely matched the measured solar radiation during the overlapping time period than did the Thornton-Running method (**Table 3-4**).

For the shorter overlap between Ysleta NOAA and Art Ivey AWS, the average annual ratio of estimated R_s to measured R_s from the Thornton-Running method (**Equations 3-2 and 3-3**) indicated that the Thornton-Running estimated solar radiation more closely matched measured solar radiation (**Table 3-4**).

Table 3-4. Annual Ratios of Estimated Solar Radiation Based on Air Temperatures to Measured Solar Radiation.

Stations Compared	Period	Ratio of estimated R_s to measured		Number of Days*
		Thornton-Running (Eq. 3-2 and 3-3)	Hargreaves-Samani (Eq. 3-1)	
NMSU-Leyendecker	1985-2014	1.09	1.00	9,962
Ysleta-Art Ivey	2004-2009	1.03	0.95	1,596

*The ratio was only computed for days with both measured temperature and measured solar radiation at the respective sites.

Among the New Mexico weather stations, the Hargreaves-Samani equation had a lower root mean square error (RMSE) compared to the Thornton-Running method (**Table 3-5**), again indicating closer fit between the Hargreaves-Samani estimated R_s and the measured R_s at Leyendecker AWS. This may be due to the generally lower minimum temperatures noted at Leyendecker and Leyendecker PRSC II due to the generally better siting as compared to the Texas weather stations. Thus, for irrigated lands in New Mexico the Hargreaves-Samani equation was used to estimate solar radiation at the NMSU NOAA station for time periods without measured solar radiation.

Among the Texas weather stations, the Thornton-Running universal function had an equal or lower RMSE at Ysleta and Tornillo, indicating better agreement with the measured solar radiation at Art Ivey AWS (**Table 3-5**). Additionally, the Thornton-Running universal function had a similar RMSE to those found in calibrated functions (Allen and Robinson, 2009 (page 83)). Thus, the universal function was selected for use to estimate solar radiation at those two NOAA stations for time periods without measured solar radiation.

Table 3-5. RMSE values (MJ m^{-2} d^{-1}) for Daily Estimates of Solar Radiation for the Thornton-Running Universal Function Method and the Hargreaves-Samani Equation.

Station Compared	R_s (Thornton-Running)	R_s (Hargreaves-Samani)	n – Number of Measurements
NMSU-Leyendecker	2.4	2.2	9,962
Ysleta-Art Ivey	3.54	3.66	1,596
Tornillo-Art Ivey	2.93	3.16	2,753

Dewpoint Temperature

The values to calculate K_o for the NMSU weather station (**Table 3-6**) are estimated as the minimum temperature from NMSU NOAA station minus the dewpoint temperature calculated from the reported temperature and relative humidity data from Leyendecker AWS using **Equations 3-5, 3-6 and 3-7**. Although the results are larger than the typical values of 2 to 5 °C found for irrigated agricultural areas, ASCE (2016) notes that K_o may have values of five to ten °C under extremely dry conditions of the American Southwest. In Texas, the Tornillo NOAA station was used to determine the K_o offset. The monthly K_o shown in **Table 3-6** is estimated as the minimum temperature from Tornillo NOAA station minus the dewpoint temperature calculated from the reported temperature and relative humidity data from Art Ivey AWS using **Equations 3-5, 3-6 and 3-7**.

Table 3-6. Mean Monthly Values for the K_o Offset, °C, for use in Equation 3-4 for Estimating Daily Average Dewpoint Temperature at NOAA stations in New Mexico and Texas.

Month	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
New Mexico--NMSU	4.3	5.4	8.1	9.6	10.7	10.6	8.1	6.1	5.5	3.7	4.4	3.9
Texas--Tornillo	0.7	2.8	5.1	7.1	5.1	3.8	0.8	-0.6	-1.7	-2.5	-1.3	-1.6

Wind Speed

Table 3-7 lists the mean monthly wind speed values used for each NOAA station as estimated for each station by using the mean monthly value for wind speed from the nearby Leyendecker AWS in New Mexico and Art Ivey and Tirres AWS in Texas. These monthly values bracket the global average wind speed of 2 m s^{-1} reported in the FAO-56 guidelines (Allen et al., 1998).

Table 3-7. Mean Monthly Wind Speed Values, m s^{-1} at 2m Height, for Estimating Daily ET_o at NCEI Stations in New Mexico and Texas

Month	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
New Mexico (NMSU) from Leyendecker	1.67	1.97	2.28	2.26	1.93	1.72	1.63	1.38	1.42	1.39	1.48	1.50
Texas (Ysleta & Tornillo) from Art Ivey and Tirres	1.63	2.12	2.24	2.35	1.84	1.50	1.36	1.17	1.19	1.14	1.30	1.56

ET_o Variance with Estimated Weather Parameters

To assess the impact of estimating solar radiation, dewpoint temperature and wind speed int ET_o estimates, the ET_o estimates were compared to the ET_o calculated using the full suite of measured weather parameters from the nearby AWS station. The statistics comparing the ET_o calculated with measured weather parameters to the ET_o calculated for the nearby NOAA station using measured air temperature and estimated solar radiation, wind speed and dewpoint temperature are shown in **Tables 3-8 through 3-10**.

Table 3-8. Statistics Comparing the ET_o Calculated with Measured Weather Parameters at Art Ivey to the ET_o Calculated with Temperature for Ysleta*.

Site	Mean mm/day	Ratio of mean ET_o	Std. Dev. mm/day	Coeff of Variation	RMSE, mm/day
Art Ivey Measured	4.74	----	2.07	0.44	----
Ysleta Estimated	4.70	0.99	2.02	0.43	1.03
Difference	0.04			0.01	
*For the period 1/1/2004-9/30/2009 (1,596 days)					

Table 3-9. Statistics Comparing the ET_o Calculated with Measured Weather Parameters at Art Ivey to the ET_o Calculated with Measured Air Temperature for Tornillo and Leyendecker*.

Site	Mean mm/day	Ratio of mean ET_o	Std. Dev. mm/day	Coeff of Variation	RMSE, mm/day
Art Ivey Measured	4.62	---	2.04	0.44	----
Tornillo Estimated	4.47	0.97	1.91	0.43	0.83
Leyendecker Measured	4.52	0.98	2.00	0.44	0.77
Diff Art Ivey - Tornillo	0.15			0.01	
Diff Art Ivey - Leyendecker	0.10			0.00	

*For the period 1/1/2004-11/30/2012 (2,753 days)

Table 3-10a. Statistics Comparing the ET_o Calculated with Measured Weather Parameters at Leyendecker to the ET_o Calculated with Air Temperature for NMSU*.

Site	Mean mm/day	Ratio to meas. params	Std. Dev. Mm/day	Coeff of Variation	RMSE, mm/day
Leyendecker Measured	4.29	---	2.01	0.47	----
NMSU Estimated	4.41	1.03	1.87	0.42	0.82
Difference	-0.12			-0.89	

*For the period 1/1/1985-4/22/2014 (9,973 days)

Table 3-10b. Statistics Comparing the ET_o Calculated with Measured Weather Parameters to the ET_o Calculated with Air Temperature for Leyendecker and NMSU*.

Site	Mean mm/day	Ratio to meas. params	Std. Dev. Mm/day	Coeff of Variation	RMSE, mm/day
Leyendecker Measured	4.51	---	1.86	0.41	---
NMSU Estimated	4.52	1.00	2.00	0.44	0.79
Difference	-0.01			-0.03	

*For the period 1/1/2004-9/30/2009 (2,753 days)

The statistical summaries show that the ratios of ET_o calculated with all parameters other than temperatures estimated to the ET_o calculated from all measured parameters is close to 1.00. This indicates relatively high accuracy and consistency in the estimation of secondary parameters using the ASCE methods. The days in the overlap period between the NMSU and Leyendecker stations total nearly four times that for the Art Ivey-Tornillo overlap. This greater overlap is likely the reason that the coefficient of variation is 0.05 lower for the ET_o from calculated as compared to from estimated parameters. The ratio between the ET_o from calculated parameters to ET_o from measured parameters is also likely affected by the greater overlap period with greater range in ET_o values. RMSE values ranged from 0.79 to 1.03 mm per day. This is typical of the increase for individual days found with other data sets, and the RMSE drops significantly when ET_o values are averaged over five-day periods when applied to estimate ET during typical irrigation intervals. Similar results were obtained when averaged over seven-day intervals. Additionally, the application of the ASCE-PM at NOAA stations with estimated parameters is congruent with the application of the same ASCE-PM equation to the New Mexico and Texas AWS weather data sets when all required parameters are measured and available.

ET_o Results Summary

The average annual ET_o for 1938 through 2018 was 63.2 inches (1,604 mm) and 63.5 inches (1,614 mm) in New Mexico and Texas, respectively. It is not surprising that the average annual ET_o record is this close, given that the weather data are from weather stations that are all located in or near agricultural areas near Las Cruces, New Mexico and near Tornillo, Texas and that the Tornillo station is less than 90 miles southeast of Las Cruces. The four-year period, 2008 through 2012, having full weather data sets from Art Ivey in Texas and Leyendecker II in New Mexico averages two and five percent above the longer term 1936-2016 average, respectively. Also, noteworthy is the higher ET_o at Leyendecker II compared to Leyendecker, though these estimates cover different periods of record. It should be noted that there is a three-year period from 1994 to 1996 where the Leyendecker ET_o also averaged 66.2 inches compared to the 66.2 inch four-year average at Leyendecker II. Interestingly, the 2013 Leyendecker II ET_o was about eight percent lower than the recent (2013 through 2016) three-year average and, at 60.9 inches, corresponds closely with the 1982-2003 Leyendecker average. This indicates that the differences in the average ET_o values computed from the weather data collected at the various stations (**Table 3-11**) is most likely due to natural and expected variability in the record.

Table 3-11. Comparison of Full Year Annual Average Totals for ET_o for the Time Period of Data Available in New Mexico and Texas. All Units in Inches.

Averages	Art Ivey	Leyendecker	Leyendecker PSRC II	State University	Tornillo	Ysleta	New Mexico	Texas
1936-1939				62.6			62.6	62.6
1940-1980				64.0		63.3	64.0	63.3
1982-2003		60.9		63.3	63.2	64.9	61.4	63.2
2008-2012	64.9		66.2	64.4	63.0		65.6	64.6
1936-2013				63.6			63.0	63.4
1938-2018							63.2	63.5

Annual ET_o totals for the complete 1938 to 2018 record for the New Mexico and Texas areas of the project are included in **Appendix 3A**.

Precipitation Results Summary

The longest NOAA station data record for precipitation and air temperature was at Ysleta, which began on February 1, 1939 and was discontinued in 2009. The location of the discontinued station is now within the city of El Paso. Prior to the beginning of the Ysleta record, the precipitation record at the El Paso Texas NOAA weather station was used. After the Ysleta weather station was discontinued, the El Paso International Airport NOAA weather station was used for precipitation in Texas (**Table 3-12**). Additionally, the El Paso International Airport NOAA weather station record was used to fill in missing data in the Ysleta NOAA station precipitation record. In New Mexico, an evaluation of weather stations (Allen, 2009) selected the State University NOAA weather station as having the best precipitation record for the New Mexico irrigated area. Missing data at this station were filled in with data from the nearby Leyendecker AWS weather station.

Table 3-12. Summary of Data Time Series Periods used for Texas and New Mexico Precipitation Data.

State	NOAA Weather Station	Begin Date	End Date	Total Days
New Mexico	STATE UNIVERSITY NM US	1/1/1936	12/31/2018	30,316
Texas	EL PASO TX US	1/1/1936	1/31/1939	1,127
Texas	YSLETA TX US	2/1/1939	9/30/2009	25,810
Texas	EL PASO INTERNATIONAL AIRPORT TX US	10/1/2009	12/31/2018	3,379

The 81-year average precipitation from 1938 to 2018 was 8.88 (226 mm) and 8.67 inches (220 mm) in New Mexico and Texas, respectively (**Table 3-13**). The annual precipitation in New Mexico varied from 3.45 to 19.60 inches over the 81-year period. In comparison, the minimum annual precipitation in Texas was slightly higher at 3.57 inches and the maximum was nearly 3 inches less at 16.78 inches. As shown by the difference column, the minimum and maximums did not occur in the same year for the two states. In one year, the reported Texas precipitation was 4.93 inches *greater* than the New Mexico precipitation total. Conversely, in another year, the reported New Mexico precipitation was 6.85 inches greater than the Texas precipitation. The annual precipitation totals are included in **Appendix 3A**.

Table 3-13. Texas and New Mexico Annual Precipitation Statistics for 1938-2018.

Parameter	New Mexico	Texas	Difference, NM-TX*
Average, inches	8.88	8.67	0.21
Minimum, inches	3.45 (1970)	3.57 (1956)	-4.93 (2008)
Maximum, inches	19.60 (1941)	16.78 (1974)	6.85 (1969)
No. of Years	81	81	81

*Calculated each year and then summarized.

Opinions

Daily precipitation data and reference evapotranspiration for a clipped cool season grass reference crop (ET_o) were developed from representative weather station measurements in the Study Area. Annual precipitation and ETo data for 1938 through 2018 are presented in Appendix 3A.

Following visual inspection of all-weather stations in the New Mexico Study Area region, the Leyendecker Automated Weather Station (AWS) was found to be the most representative station for irrigated areas in New Mexico because of its location interior to and surrounded by irrigated agricultural areas and a greater abundance of low growing crops that permitted open flow of wind over the station. This site is located in an agricultural area about 20 miles south of Las Cruces. During years when data were unavailable from Leyendecker AWS, the New Mexico State University (NMSU) weather station was used.

In Texas, visual inspection and data review found the Art Ivey Farms AWS site within EPCWID to have the most complete weather data record and to be the most representative station for Texas irrigated areas also because of its proximity to irrigated agricultural land. The Art Ivey Farms AWS site is located approximately four miles southeast of the town of Tornillo in El Paso County. During years when data were unavailable from Art Ivey Farms AWS, other stations in the Tornillo and Ysleta areas of El Paso County were used.

Quality control and quality assessment protocols were followed and necessary adjustments were performed for hourly AWS data and daily NOAA data. Generally, some solar radiation record at both the Leyendecker and Art Ivey AWS sites were found to be artificially low and required adjustment for consistency with computed clear sky envelopes of solar radiation on cloudless days (R_{so}, the maximum Rs value that should be achieved on cloud-free days). The air temperature and humidity data at both sites were found to be consistent and not need adjustment.   Some periods of consistently low wind speed data required minor adjustment for consistency with nearby station data during short periods at both sites.

For the time periods when AWS weather data were not available, the standardized recommended methods (Allen, et al, 1998 and ASCE-EWRI, 2005) for estimating solar radiation, dewpoint temperature, and wind speed were utilized. These estimates resulted in ET_o values that were not significantly different from ET_o calculated from measured parameters (within 3 percent).

Following quality control and quality assessment of all-weather data, daily precipitation and ET_o timeseries were developed as inputs for the ET Demands model. The average annual ET_o for 1938 through 2018 was 63.2 (1,604 mm) and 63.5 inches (1,614 mm) in New Mexico and Texas, respectively. The 81-year average annual precipitation from 1938 to 2018 was 8.88 (226 mm) and 8.67 inches (220 mm) in New Mexico and Texas, respectively.

IV. Validation of Remote Sensing Based Processes Used to Classify Irrigation Status and Crop Type

The New Mexico Interstate Stream Commission (NMISC), New Mexico Office of the State Engineer (NMOSE) and INTERA Inc. (INTERA) have developed and utilized a Normalized Difference Vegetation Index (NDVI) remote sensing methodology using Landsat satellite data to classify agricultural fields as irrigated or non-irrigated. This methodology is important to crop consumptive use investigations as it helps to delineate total irrigated crop acreage over time and across large areas for which land use data may be incomplete or only sporadically available. The methodology has been applied along the Rio Grande in the Rincon, Mesilla and El Paso Valleys in New Mexico and Texas. Jordan and Barroll (2013) describe two previous accuracy assessments (or validations) of the remote sensing methodology in New Mexico using: 1) 2006 ground-based observations from approximately 100 fields in the Mesilla Valley in New Mexico and 2) 2008 ground-based crop survey data collected by NMOSE. The NMOSE conducted a third validation in 2016 to further assess the reliability of the methodology under current field conditions.

The United States Department of Agriculture (USDA) National Agricultural Statistics Service (NASS) has developed and provided the Cropland Data Layer (CDL) datasets available for the Study Area in 2008 through 2018. The CDL is a raster, geo-referenced, crop-specific land cover data layer. The CDL has a ground resolution of 30 meters, though before 2010, the resolution was 56-meters. The CDL is produced using satellite imagery from Landsat 5 TM sensor, Landsat 7 ETM+ sensor, and the Indian Remote Sensing RESOURCESAT-1 (IRS-P6) Advanced Wide Field Sensor (AWiFS) collected during the growing season. The 2016 field survey also is an opportunity to validate the CDL in the LRG.

Methodology

The 2016 ground-truthing exercise and validation survey followed the steps recommended for sample-based field verification studies as described by Gilbert (1987) and for a statistically representative selection of a stratified, random sample as described by Stehman and Milliken (2007). The methodology describes the objectives, area of interest, physical environment, information to be collected, quality assurance protocols, field sampling designs and planned statistical analyses.

Objectives

The two main objectives of the 2016 validation were to:

1. Assess and verify the accuracy of the remotely sensed NDVI methodology for classifying a field as irrigated or non-irrigated in the LRG and
2. Assess and verify the accuracy of the remotely sensed National Agricultural Statistics Service (NASS) Crop Data Layer (CDL) for classifying crop types in the LRG.

The 2016 validation calculated the overall accuracy (number of fields correctly classified divided by total number of fields sampled) and 95 percent confidence interval of the remotely sensed classifications for the following classifications of fields:

- irrigated or non-irrigated
- total crop area
- each crop type

Three field surveys were conducted for the 2016 validation, scheduled at different times during the crop season. The protocol followed during the field surveys is briefly summarized in the following sections and described in more detail in **Appendix 4A**. For each survey, field information was collected with a GIS/GPS computer system with drop down boxes to standardize the information to enable validation of each of the three classifications listed above. Additionally, irrigation method, crop growth stage and production stage were observed for each field to support consumptive use determinations.

A stratified, random sample of fields was developed to achieve a 95 percent confidence interval on the overall accuracy of the classifications listed above through direct observation during the field survey. The fields were randomly selected and stratified with respect to geographic region and field size, as described in detail below. Fields less than five acres were not considered for the random sample. The survey results were compared to a 2016 NDVI based analysis of irrigated acreage that used the Jordan and Barroll (2013) method to classify fields as irrigated or non-irrigated.

Area of Interest

The geographic area for the 2016 validation survey was primarily within the boundaries of the Elephant Butte Irrigation District (EBID) in New Mexico, the El Paso County Water Improvement District #1 (EPCWID); and Hudspeth County Conservation & Reclamation District #1 (Hudspeth) in Texas. The Study Area extends from Caballo Dam in New Mexico to Ft. Quitman, Texas.

Physical Environment

Agricultural fields in the Study Area are generally located on valley lowlands next to the Rio Grande. The agricultural fields typically are level or have gentle slopes generally conducive to surface irrigation methods. Fields less than five acres in size comprise 63 percent of the total number of fields, but only 16 percent of the irrigated land area. Average field sizes are smaller in the Mesilla Valley averaging 5.3 acres compared to 6.2, 8.6 and 13.3 acres in Rincon, EPCWID and Hudspeth, respectively.

Data Collected

During each of the three surveys, the following parameters were observed for each selected field: evidence of irrigation; crop type and growth/development stage; and irrigation method. Evidence of irrigation included observation of: ongoing irrigation events; signs of a recently completed irrigation event (such as wet soil or ditches); presence of irrigation facilities (head ditches, field borders, etc.); presence and vigor of crop. Crop type was also recorded. Irrigation method was classified as drip, sprinkler, basin, border or furrow. Additional information collected for pecan fields included: approximate tree height, tree structure, and approximate groundcover. Descriptions of the field survey teams, GIS processes, and field survey procedures, including GIS and crop ID manuals and handbooks, are described in **Appendix 4A**.

Quality Assurance Protocols

GPS coordinates were recorded at the point of observation of each sampled field to confirm that the correct field was observed, and that the same field polygon delineation was used for the ground survey data collection and the remote sensing based irrigated versus non-irrigated classification. Digital data entry forms were developed to minimize data entry errors. Additionally, the data collected each day were reviewed at the end of the day to ensure that complete and clear information was recorded for all fields visited. Each field team developed tables summarizing the number of fields and total area for each observed parameter. The teams met briefly and discussed the day’s observations. If data were determined to be missing on any field, or other unusual circumstances were noted (for example: observed irrigation on bare ground in July), the field was revisited within the next two weeks.

After completion of each of the three surveys, summary tables of field parameters were developed and reviewed. In addition, after the second and third surveys, field parameters for the current and prior surveys were compared and any implausible changes or inconsistencies (for example, a field that was observed to have bare ground in April and mature pecans in July) were flagged, and the field revisited within the next two weeks.

Other Validation Studies

The NMOSE performed a comprehensive ground survey of crops in the LRG in New Mexico in 2008. All fields were observed in the spring and summer of 2008 and then again in the spring of 2009. Selected fields were observed again in the fall of 2008. This field study was completed to determine irrigated area and cropping patterns for the Lower Rio Grande Basin Adjudication. Based on the 2008 and 2009 data, Jordan and Barroll (2013) found an overall accuracy of 90 percent for the NDVI method of classifying agricultural fields as irrigated or non-irrigated.

Stehman and Milliken (2007) assessed the accuracy of crop classifications for fields in the areas irrigated with Colorado River water downstream of Hoover Dam. They used a random sampling plan stratified by agricultural field size within four geographically separate irrigated areas. The total area sampled was about five percent of the total irrigated area. The results of the accuracy analysis were used to estimate the effect of crop classification error on evapotranspiration estimates.

Melton, et al. (2015) used a remote sensing NDVI methodology to classify agricultural fields as fallow or irrigated in California's Central Valley. They performed one accuracy assessment based on confidential Farm Services Agency (FSA) data and a second accuracy assessment based on monthly ground surveys. The ground surveys recorded observations of fields along eight east to west transects across the Central Valley. Data collected included information on crop presence or absence, crop type, crop height, visual estimates of canopy cover, soil condition, and observations of evidence of irrigation, weed control, or other field maintenance. Digital photographs and GPS readings were collected at each field survey site. Overall accuracy was calculated as the percent of fields correctly classified as fallow or irrigated.

Field Sampling Designs

The 2016 validation was based on a probability sample of fields. The sample was designed with the objective to develop a 95 percent confidence interval on the overall accuracy of classifying agricultural fields as irrigated or non-irrigated. Standard accepted practices use a stratified, random sample of fields (Gilbert, 1987; Stehman and Milliken, 2007 and Congalton and Green, 2009). Fields were defined as consisting of a single crop and selection is stratified by field area within each of four geographic regions. The field polygon data, revised in 2016 to reflect current field configurations, was used to develop the sampling plan. As previously noted, field polygons less than five acres in size represent 63 percent of the total number of fields, but only 16 percent of the total field area. These fields are predominately rural ranch parcels (i.e. ranchettes), or "hobby" farmers and were not included in the survey.

First, the total sample size required to estimate the overall accuracy with a 95 percent confidence was determined. Since the population of irrigated and non-irrigated fields was unknown when the sample were selected, the total sample size was estimated by determining the sample size required to estimate the average field size to within one acre with 95 percent confidence using the prespecified margin of error method described by Cochran (1977) as described by Gilbert (1987). The sample size was estimated to be 475 fields or six percent of the total fields available. The ground survey was planned to sample a total of 1,200 fields to ensure that a sufficient number of fields were sampled.

Next, four geographic regions were used as the upper level strata of the stratified random sample, with each region representing similar, but separate physical environments:

- Rincon Valley
- Mesilla Valley
- El Paso Valley, and
- Hudspeth.

The total sample is allocated to the regional strata proportionally using the Neyman allocation (Cochran, 1977). The Neyman allocation minimizes the variance and, in this case, results in sample sizes in each regional strata approximately proportional to the total field area in each region.

The population of fields within each geographic region is similar. These populations are highly skewed, with large numbers of small fields (less than 5 acres each), but the greatest total area is represented by fields between 11 and 23 acres each (**Figure 4-1**). The highest accuracy from samples for skewed populations is obtained by setting an upper stratum that is fully (100 percent) sampled (Hidiriglou, 1986). In addition to the upper strata, three additional field size strata, unique for each region, were developed based on the cumulative area of the population of fields in each region using the cumulative square root of the frequency method (Cochran, 1977). All fields in the upper strata were selected for the sample. As for the regions, the Neyman allocation was used to allocate the remaining region sample among the three remaining field size strata. The fields in the remaining strata were assigned a random number by a random number generator and the lowest random numbers were selected. Additionally, in Texas, because access to fields not near public roads is restricted, the fields with the lowest random numbers that are also near public roads were selected.

Statistical Analysis

Well established and widely accepted accuracy assessment methods (Gilbert, 1987; Stehman and Milliken, 2007, Congalton and Green, 2009, and Rossiter, 2014) were used to evaluate the accuracy of irrigated field identification by the NDVI remote sensing methodology and to evaluate the accuracy of CDL crop mapping by crop class. Summary tables were prepared assessing the accuracy of field classification as irrigated by the NDVI methodology and by the CDL crop mapping.

A 95 percent confidence interval was prepared for the overall accuracy of field identification as irrigated. Additionally, 95 percent confidence intervals were calculated for each crop evaluated. The analysis followed standard accuracy assessment principles and practices described by Congalton and Green (2009) and Rossiter (2014).

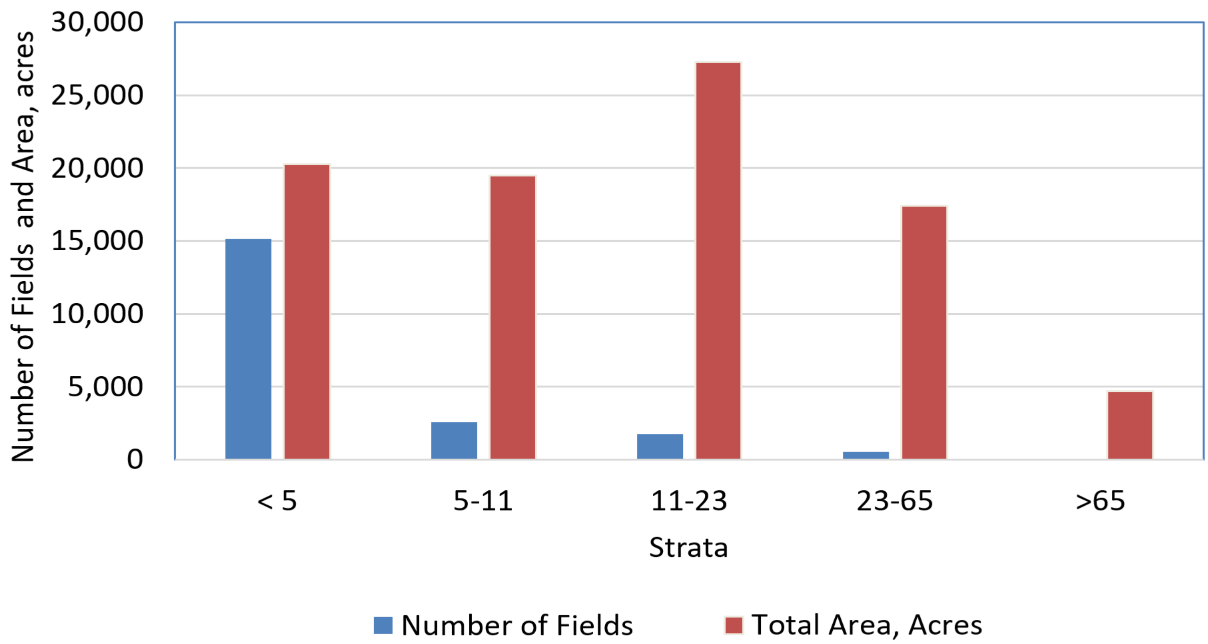

Figure 4-1. Sample Distributions of Number of Fields and Field Area Based on Mesilla Valley Field Population.

Results

The survey found 21,196 acres out of 24,295 acres observed, or about 87.2 percent, to be irrigated in 2016 (**Table 4-1**). The NDVI methodology to identify irrigated fields found 20,705 acres of the 24,295 acres observed, or 85.2 percent, to be irrigated. The NDVI methodology under estimated the irrigated area by two percent. The irrigated field classification using the USDA NASS Cropland Data Layer results can also be grouped into irrigated and not irrigated fields for comparison to the ground-based survey. The CDL methodology found 20,590 acres out of 24,295 acres observed, or 84.7 percent, to be irrigated. The CDL methodology under estimated the irrigated area by 2.5 percent.

The estimated divergence of the NDVI and CDL methodologies from the ground-truth verification study results is considered to be well within the expected confidence range of the respective methodologies (generally ±2 to 10 percent for NDVI (Wardlow and Egbert, 2005; Ozdogan et al, 2005; and Taufik et al, 2016) and for CDL (Luman and Tweddale, 2008)). Therefore, no adjustment was made to these estimates based on the 2016 verification study.

Table 4-1. Irrigated Area Field Observation Results Compared to NDVI Results

Irrigation Status	Area by Survey, Acres	Area by NDVI, Acres	Area by CDL, Acres
Irrigated	21,196	20,705	20,590
Not Irrigated	3,099	3,590	3,705
Total	24,295	24,295	24,295
Percent Irrigated	87.2%	85.2%	84.7%

The NDVI methodology misidentified a limited amount of irrigated area as not irrigated due primarily to two situations:

1. The interval between the early summer Landsat image date and fall Landsat image date in 2016 was long enough for some crops, when managed for a quick turn-around, to have low NDVI in both the early summer and fall Landsat images. Some varieties of corn, cotton, and chile can be managed this way. Since the Landsat date images vary from year to year (primarily driven by clouds on the date of the image), the occurrence of this problem may or may not occur in a given year.
2. Young pecan trees with little green vegetation have a low NDVI score.

Considering the accuracy of identifying all crop areas, the overall accuracy by the CDL remote sensing methodology is 85.5 percent (**Table 4-2**). When calculating the confidence interval, the observed proportions in the crop survey were considered to be the best estimate of the overall proportions of each crop in the study area for the calculation of a 95 percent confidence interval. The overall accuracy of 85.5 percent had a 95 percent confidence interval of plus or minus one percent. This narrow confidence range is primarily due to the large sample survey of 14 percent of the total agricultural area within the Study Area.

The CDL correctly identified more than 90 percent of the observed areas for alfalfa hay, cotton, not irrigated and water and pecans. These are the three crops with the greatest area observed in the crop survey. The CDL had the most difficulty correctly identifying irrigated pasture and miscellaneous vegetables. Although the CDL only correctly identified 85.5 percent of the crops, the 14.5 percent of the area with incorrectly identified crops did have a crop identified and thus water consumption was calculated for that 14.5 percent of the area also.

Table 4-2. Survey Observed Crop Areas Correctly Identified by the CDL.

Crop	Crop Survey Total Area, Acres	CDL Area Correctly Identified, Acres	CDL Correctly Identified, Percent
Alfalfa Hay	1,679	1,528	91.0%
Chile (Peppers)	359	148	41.2%
Corn, Sweet Corn, and Silage	762	634	83.2%
Cotton	3,976	3,867	97.3%
Irrigated Pasture	642	10	1.6%
Miscellaneous Vegetables	156	24	15.4%
Not Irrigated and Water	3,099	2,792	90.1%
Onions	261	195	74.7%
Pecans	12,463	11,348	91.1%
Wheat and Small Grains	897	234	26.1%
Total Areas, Acres	24,294	20,780	85.5%

Opinions

The 2016 NMOSE survey found 21,196 acres out of 24,295 acres surveyed, or about 87.2 percent, to be irrigated in 2016. In comparison, the NDVI methodology to identify irrigated fields found 20,705 acres out of 24,295 acres observed, or 85.2 percent, to be irrigated. The NDVI methodology under estimated the irrigated area by two percent. This is well within the expected confidence range of the respective methodologies (generally plus or minus 5 percent). Therefore, no adjustment was made to these estimates based on the 2016 verification study.

The 2016 CDL methodology to identify irrigated fields found 20,590 acres out of 24,295 acres, surveyed, or 84.7 percent, to be irrigated. The CDL methodology under estimated the irrigated area by 2.3 percent and is also within the expected confidence range of these methodologies.

The overall accuracy of the CDL methodology to identify the nine crop groups adjusted based on the best estimate of the proportion of crop areas in the Study Area was 85.5 percent with a 95 percent confidence interval of plus or minus one percent.

V. Development of Annual Irrigated Crop Areas for 1938 through 2018

Purpose

The purpose of this section is to document the development of annual irrigated crop areas for 1938 through 2018 in the Study Area for the purpose of calculating annual volumes of evapotranspiration of applied water (ET_{aw}). The total irrigated area was developed by INTERA (2018) and provided to Davids Engineering to determine the irrigated area of each crop.

This section describes an inventory of available sources of information on irrigated crop areas in the Study Area, and the methodology used to define crop categories, the results of the analysis, and findings. Supporting information is appended and referenced where applicable.

Available Irrigated Crop Area Information

Table 5-1 lists and summarizes key information pertaining to the various sources of irrigated crop data available within the Study Area. The various data sources are briefly described in the following sections.

District Crop Reports Submitted to Reclamation

The United States Bureau of Reclamation (Reclamation) publishes an annual report of "Summary Statistics, Water, Land and Related Data" based on crop census data reported by Districts receiving Reclamation project surface water supplies (Jachens and Albertson, 1999). Districts complete annual crop acreage reports using Reclamation Crop and Data Forms 7-316 and 7-2045, which document the area of each crop that receives surface water. These reports generally include only the crops irrigated by surface water and generally exclude any crops irrigated exclusively with groundwater. However, in certain years from 1948 through 1959, crop and irrigated acreage for fields irrigated with groundwater only were reported in Reclamation reports. The most recent crop reports available for the Study Area are for 2010. Davids Engineering (2015) compiled available Reclamation Crop Reports for 1971 through 2010 and 1938 through 1975, respectively. The annual District crop reports are available for the period from 1938 through 2010 and generally provide the most consistent and reliable estimates of areas of crops irrigated by surface water supplied by the Districts.

New Mexico Office of the State Engineer Crop Survey

The New Mexico Office of the State Engineer (NMOSE) conducted ground surveys of crops in EBID in 2008. The survey included three field visits in the spring, summer and fall of 2008 and one visit in the spring of 2009. The crops observed in each field during each of the four field visits were assigned to field polygons in a GIS database. Field observers were trained and the data were subjected to rigorous review and quality control. These surveys provide a comprehensive representation of ground-based crop data in EBID and provide a basis of comparison to other crop data sources.

Table 5-1. Summary of Crop Data Sources

Crop Data Source	Description	Comments
District Crop Reports Submitted to Reclamation.	Report area by crop receiving surface water from the district in each year. Double cropped area is included twice, once in each crop category.	Only includes cropped area receiving district surface water, with some exceptions from 1937 to 1959.
NMOSE crop survey	Extensive field survey with spatial information on crop locations for EBID only.	None.
NASS Cropland Data Layer	Crops identified by satellite algorithms, accuracy varies by crop generally improving from year to year, includes spatial information on crop locations.	Accuracy on minor crops is relatively low.
Remotely Sensed NDVI Irrigated Area Analysis	INTERA: Evaluation and Analysis of Rio Grande Project Irrigated Acreages (2018 Estimates of irrigated areas based on satellite (Landsat) NDVI values with spatial information on location of irrigated area; identifies orchards (mostly pecans) in 1976, 1996, 2004, and 2010; includes areas irrigated by groundwater that are not found in district crop reports to Reclamation. Includes Juarez Irrigation District.	Only identifies irrigated area; crop type is mostly unknown, except for orchards (mostly pecans) in four select years.
NM OSE Hydrographic Survey	Map of tracts within New Mexico that potentially have irrigation water rights, including information on the source of irrigation water available to each tract. ESRI shapefile format.	Does not identify crop type. Some uncertainty with field boundaries containing developed area (houses, shops, roads, etc.)
Carreno 1957*	Irrigated acres within Juarez Valley Irrigation District from 1938-1947.	Methodology and accuracy unknown.
Groundwater Conditions and Resources in El Paso/Juarez Valley IBWC 1989	Cropped and irrigated acres within Juarez Valley Irrigation District from 1950-1984.	Methodology and accuracy unknown.
El Servicio de Informacion Agroalimentaria y Pesquera (SIAP)	Cropped and irrigated acres within Juarez Valley Irrigation District from 1999 to 2017. (2018 not available as of June 2019, estimated as 2017 irrigated areas)	Methodology and accuracy unknown.
County Crop Reports	Contain total acres in a given county with no spatial information.	Crop areas include areas both inside and outside the Study Area with no information separate the area inside the study area from the area outside the study area.
USDA Ag Census	Contain total acres by crop in a given county with no spatial information.	Crop areas include areas both inside and outside the Study Area with no information separate the area inside the study area from the area outside the study area.

National Agricultural Statistics Service Crop Data Layer

The Cropland Data Layer (CDL) datasets are developed and published by the United States Department of Agriculture (USDA) National Agricultural Statistics Service (NASS). The CDL is a raster, geo-referenced, crop-specific land cover data layer. Beginning in 2010 the CDL is based on a spatial resolution of 30 meters; and for 2008 and 2009 is based on a resolution of 56-meters. The CDL is produced using satellite imagery from the Landsat 5 Thematic Mapper (TM) sensor, Landsat 7 Enhanced Thematic Mapper Plus (ETM+) sensor, and the Indian Remote Sensing RESOURCESAT-1 (IRS-P6) Advanced Wide Field Sensor (AWiFS) collected during the growing season, or seasons, of interest. Additional data sources sometimes used to improve classification accuracy include the United States Geological Survey (USGS) National Elevation Dataset (NED), the USGS National Land Cover Database 2001 (NLCD 2001), and the National Aeronautics and Space Administration (NASA) Moderate Resolution Imaging Spectroradiometer (MODIS) Normalized Difference Vegetation Index (NDVI) composite images. The MODIS images have a spatial resolution of 250 meters.

Agricultural crop classification training and validation data are derived from the Farm Service Agency (FSA) Common Land Unit (CLU) Program. Non-agricultural land cover classification training and validation is derived from NLCD 2001 data. Metadata files describing all imagery, ancillary data, and training and validation data used to generate each state's CDL are available at: https://nassgeodata.gmu.edu/CropScape/.

Complete CDL land use coverages for New Mexico and Texas are available for 2008 through 2018. The CDL datasets have varying accuracy in the identification of crops that generally depends on the specificity of the crop to be identified, as documented in the metadata provided with the CDL data (USDA, 2014). In other words, the more specific the crop identification is (apples versus pecans, for example, as compared to orchards versus field crops), the less accurate the results. The most recent CDL data layer evaluated from NASS is for 2013 for both New Mexico and Texas.

CDL crop classification procedures are still accepted, but should be deferred to higher-resolution classifications when available. CDL datasets are available for 2008 through 2018 for areas within the United States and every year in early February, the most recent completed year is added to the dataset.

Remotely Sensed NDVI Irrigated Area Analysis

INTERA (2014 and 2018) used the Normalized Difference Vegetation Index (NDVI), a commonly used measure of vegetation greenness (a surrogate for vegetation health and vigor), to identify irrigated crop areas in Landsat images of the Study Area. Urban greenery and native vegetation were eliminated through the use of digital coverages that define historical agricultural fields. Additionally, INTERA used data from the NMOSE Hydrographic Survey to differentiate New Mexico lands supplied by groundwater only, in contrast to lands that also have access to surface water. Lands irrigated with groundwater only are not included in District crop reports.

Delineating irrigated areas in arid environments using NDVI calculated from Landsat data has been shown to be scientifically sound and is an accepted procedure (Melton, et al. 2015; Jordan and Barroll, 2013; Clark et al., 2014; and others). When possible, other data sources are used to verify the irrigated area and crop area estimates developed.

Methodology

The methodology for estimating irrigated crops areas for EBID, EPCWID, Hudspeth and Juarez is described in this section.

A total of 35 different crops are identified in the historical crop records for the Study Area, including several major crops and many minor crops based on acreage. An appropriate and reasonable accepted practice (ASCE, 2016, p. 365) is to group into a smaller number of crop categories based on similarity in factors that influence crop water use and applied water requirements, including growing season, cultural practices and water requirements. The nine crop categories defined are the same for all parts of the Study Area, although not all crops are present in all areas in all years. Each of the individual crops was placed in one of the nine crop categories.

The various irrigated crop data sources were assessed for consistency and reliability, revealing that District crop reports provide the most complete, consistent and reliable basis for establishing irrigated crop areas over time. However, recognizing that the District crop reports have certain limitations, adjustments were made to provide a more accurate representation of irrigated crop history. In particular, as previously noted, the District crop reports only account for crops supplied with surface water supplied by Reclamation, and generally do not account for crops irrigated with groundwater only. When one crop follows another crop on the same area in the same year, a practice known as double-cropping, the area is reported to have the first crop. The methodology used to develop the crop coefficient (described in Section 5) includes the second crop where it exists.

In some years, slight differences between the total cropped acreage in some valleys and the irrigated area received from INTERA were observed. Therefore, the total irrigated crop areas determined from adjusted District crop reports were adjusted to match the irrigated area received from INTERA, while preserving the proportion of acres in the nine crop groups.

For Juarez, three technical reports and the NDVI analysis of Landsat imagery were available. Similar to the US Districts, total reported Juarez crop areas were slightly different than the irrigated areas received from INTERA. In all cases, the total irrigated crop areas from the available reports were adjusted to match the irrigated area received from INTERA, while preserving the proportion of acres in the crop groups.

Results

The irrigated crop areas from the data sources described in the previous section and the estimates of total irrigated crop areas are described in the following sections.

Crop Groups

Reclamation Crop Reports have acreage for up to 35 different crops in EBID, EPCWID, and Hudspeth. The 35 individual crops were each assigned to one of nine crop groups with similar growing seasons, cultural practices and water requirements as indicated in appendices B through F of ASCE (2016). These nine primary crop groups represent 94, 96, and 92 percent of the total irrigated area in EBID, EPCWID, and Hudspeth, respectively (**Tables 5-2, 5-3, and 5-4 for the period 1975 through 2010 as an illustrative example**). With the area of each remaining crop assigned to one of these groups, 100 percent of the area in each district is included every year that is evaluated. The nine crop categories defined are the same for all parts of the Study Area, although not all crops are present in all areas in all years. A list of detailed crop types included in the Reclamation crop reports as reported by Davids Engineering and corresponding crop group assignments for calculating ET are provided in **Appendix 5A**.

Crop Areas

The annual distribution of crop areas for EBID, EPCWID and Hudspeth were calculated from District Crop Reports for the years 1938-2010. (District Crop Reports were not available for EPCWID and Hudspeth for 2009; the average of 2008 and 2010 data was used for that year.) Crops listed in District Crop Reports were assigned to one of nine crop groups with similar growth characteristics and cultural practices as described previously and detailed in **Appendix 5A**. First the reported crop acreages for each District were compiled for each year, for each crop group. Annual crop distributions for each district were calculated by dividing the area in each crop group by the total cropped area in each District. The sums of the crop group distributions for each year add up to 100% for each District. The annual crop distribution percentages were used to estimate irrigated crop areas in model sub regions within each District.

For years 2011-2018, crop distributions for EBID, EPCWID and Hudspeth were determined using the NASS CDL reported crop acres and the procedure described in the previous paragraph.

Estimates of the crop distribution for New Mexico groundwater only fields were developed according to the following steps:

- 'Pecan' acreage from 1938 to 2018 was estimated using the following sources:
  - Intera 'Pecan' identification, available for the following years: 1976, 1996, 2004, and 2010.
  - Reclamation reports were used for the following years: 1937, 1939, 1945-1956, and 1959.
  - The New Mexico field survey was used for the area in New Mexico in 2008.
  - The remaining years were estimated by linear interpolation between adjacent years.

- The percentages of all crop groups, except for 'Pecans' (described above) were based on the 2008 New Mexico field survey.
- The percentages from foregoing step were applied, to all years to determine annual irrigated acreage by crop group from 1938 to 2018.

Estimates of the crop distribution for Juarez were developed for years with NDVI data by preserving the proportional area representing each crop group across the total cropped area in the Juarez determined from NDVI analysis. For the years before the NDVI analysis was available, the crop areas reported in the available reports were used.

Crops listed in District Crop Reports were assigned to one of nine crop groups with similar growth characteristics and cultural practices as described previously and detailed in **Appendix 5A**. The total irrigated area for EBID - SW (surface water), EBID - GO (groundwater only), EPCWID, Hudspeth and Juarez are provided in **Appendix 5B**. Annual irrigated crop areas by crop group are provided in **Appendix 5C** and **Appendix 5D** for each District. The acreages by crop group for the last 81 years (1938 through 2018) are shown in **Figures 5-1 through 5-5** for EBID - SW (surface water), EBID - GO (groundwater only), EPCWID, Hudspeth and Juarez, respectively. Agricultural land use classes that are not irrigated are not included in the analysis and not assigned to a crop group.

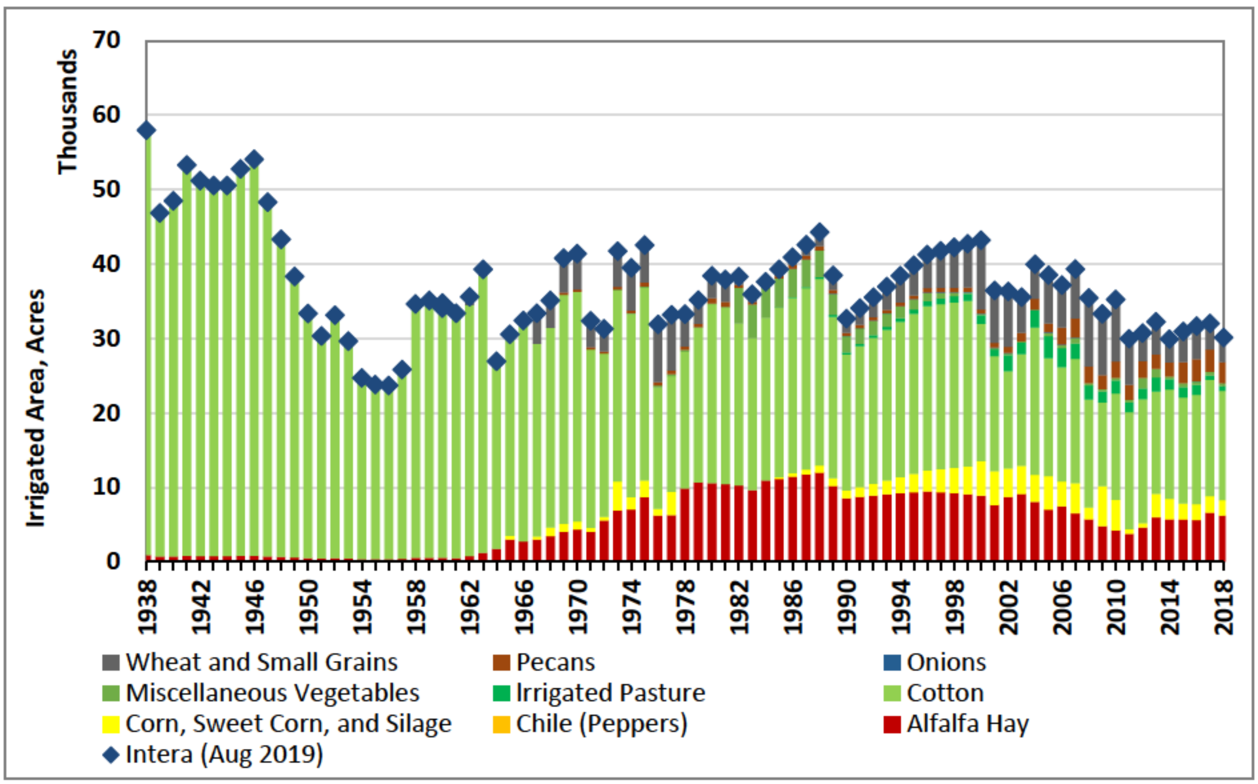

Figure 5-5. Juarez Cropping by Crop Group and Irrigated Area by Source.

Opinions

Over time, there has been an overall decline in irrigated acreage in the Study Area with some variability among the Districts, as summarized below.

For example, EBID irrigated area with access to surface water averaged about 72,800 acres from 2004 through 2018 and has been generally declining since the early 1950s, when it averaged 93,100 acres.

Irrigated area within and in the vicinity of EBID with access to groundwater only (no access to surface water) averaged about 4,700 acres from 2004 through 2018 and in recent years has been generally declining after a peak at about 5,500 acres in 2000.

EPCWID irrigated area averaged about 36,400 acres from 2004 through 2018 and has been generally declining since the early 1950s, when it averaged 66,700 acres.

Hudspeth irrigated area averaged about 9,500 acres from 2004 through 2016 compared to irrigated areas between about 14,000 and 16,000 acres in the 80’s and 90’s.

Juarez irrigated area averaged about 33,800 acres from 2004 through 2018 and has been generally declining in recent years since its peak of 54,000 in 1986.

Since the early 1950s, the predominant crop has generally shifted from cotton to pecans in both EBID and EPCWID.

In EBID, the alfalfa crop acreage has remained about the same while it has decreased in EPCWID.

In Hudspeth, the main crop has remained cotton with some decrease in alfalfa since the early 1950s.

The main crop in Juarez remains cotton with an increase in alfalfa acreage from the early 1950s to the 1980s. Pecan area in Juarez has been increasing in recent years, but still is considerably less than cotton and alfalfa.

VI. Local Calibration of Basal Crop Coefficients

Purpose

The purpose of this section is to describe the methodology used to develop basal crop coefficients for use in the ET Demands root zone water balance model, including the data analyzed and the results. The ET Demands model is used to estimate consumptive use of irrigation water, often referred to as evapotranspiration (ET) of applied water (ET_{aw}), under full water supply (full supply) conditions for irrigated lands in the Study Area. “Full supply” is generally understood to mean that available water supplies are sufficient to fully satisfy irrigation water demands for all lands irrigated. This ET_{aw} can be viewed as an average of the variability in ET_{aw} that occurs among fields under full supply conditions. This variability is attributed to variations within individual fields due to soil water availability, irrigation management, salinity effects, crop disease, and other non-water supply factors. This section describes the methodology used to develop basal crop coefficients and the results.

Methodology

The development of basal crop coefficients described in this section is the first step in a four-step process (**Figure 6-1**) to calibrate ET Demands results to remotely sensed surface energy balance ET estimates. The objective of the calibrated model is to estimate ET_c when under full supply conditions and to apportion ET_c between ET of precipitation (ET_{pr}) and ET_{aw}. To this end, the objective of the calibration process is to develop crop season ET results from the ET Demands model that are within 10 percent of the energy balance ET estimates. Ten percent is a reasonable goal that can be achieved with reasonable effort given typical errors in ET measurement and estimation methods as reported by Allen, et al (2011). The final three steps in the process involve comparing ET results from ET Demands to three years of remotely sensed ET results and are described in the following section describing ET Demands calibration.

In the first calibration step, basal crop coefficients were developed based on actual consumptive use of crops cultivated within the Study Area, as estimated by METRIC analyses. Following the procedure described in this section, these basal crop coefficients were derived from spatial METRIC analyses of irrigated lands in EBID during 2008.

In the second, third, and fourth calibration steps, crop consumptive use characteristics were first provided as inputs to the ET Demands model based on the 2008 METRIC analysis. Then, the resulting ET estimates from the ET Demands model were compared back to METRIC ET estimates from 2008, 2013, and 2002. Years 2002 and 2008 represent approximately full supply conditions in the Study Area, the conditions considered in this report. The third year, 2013 was selected to validate the methodology’s accuracy during a limited supply year. At each step, if the ET results from ET Demands were not within 10 percent of the METRIC ET estimates, the crop inputs to the ET Demands model were revised and the calibration step was repeated again. At the conclusion of this calibration process, ET results from ET Demands were within 10 percent of METRIC ET estimates across the Study Area during 2008, 2013, and 2002.

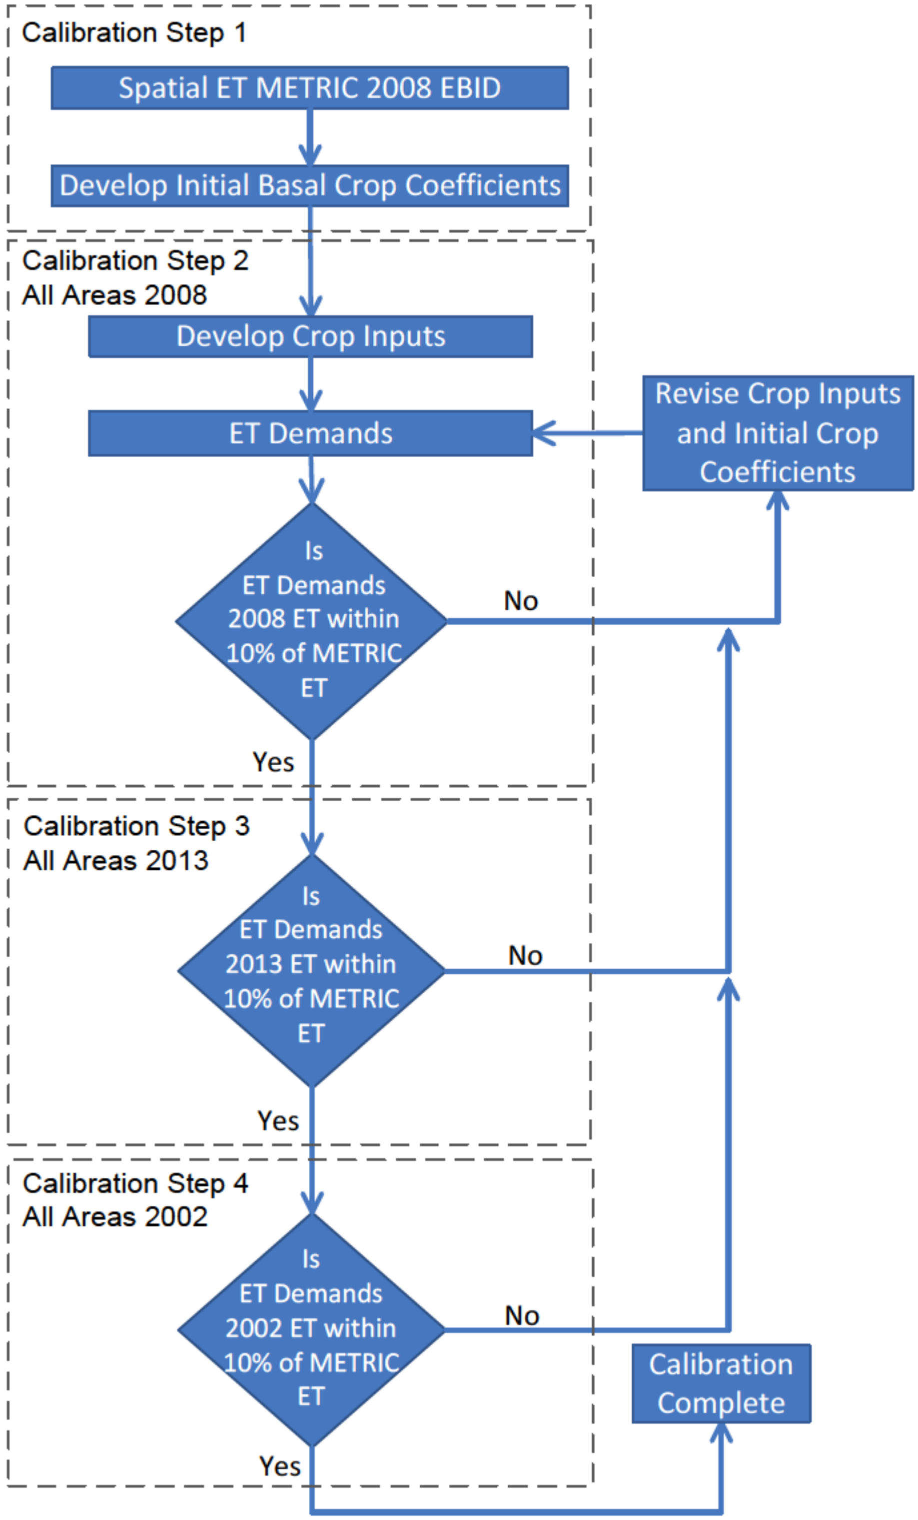

Figure 6-1. ET Demands Calibration Process Including Development of Basal Crop Coefficients

The basal crop coefficients developed for this analysis differ from the basal crop coefficients reported in research reports and technical practice manuals like Allen, et al (FAO 1998), ASABE (2007) and ASCE (2016) in two important ways:

1. These are historical basal crop coefficients that reflect “actual” local conditions in commercial agriculture under full supply conditions at a District-wide scale in contrast to basal crop coefficients used to determine “potential” consumptive use under idealized conditions. As such, they represent the best estimates of the actual ET that occurred under full water supply or would have occurred if a full water supply had been available, taking into account all factors that impact crop growth and ET, including water availability, water quality, pest and disease infestations.
2. These basal crop coefficients represent the average of numerous fields compared to typically reported crop coefficients that are developed from, and for use on, a single field at a uniform stage of development. Each remotely sensed snapshot used in their development consists of many fields at different stages of growth, depending on planting date and management.

Because of these two important differences from typically reported basal crop coefficients, the basal crop coefficients developed for this work tend to be somewhat lower and begin earlier and end later than typically reported crop coefficients. The curves begin earlier and end later because they include the earliest and latest actual planted fields in contrast to curves based on a predefined plant date.

The crop coefficient-reference ET method for estimating crop ET, spatial cropping information, spatial ET_{act}, reference ET (ET_{ref}) and crop coefficient (K_c) curves supporting basal crop coefficient development are described. The last section describes the methodology for determining basal crop coefficients.

Crop Coefficient – Reference ET Method

Crop ET is estimated using the crop coefficient – reference ET method, which generally involves multiplying ET_{ref} by crop-specific and time varying coefficients, crop coefficients (K_c). The method has proven to be accurate, robust, consistent, and relatively straightforward to apply (ASCE, 2016) and is widely accepted and used throughout the western United States and in similar arid, irrigated regions worldwide. Additionally, the method has been standardized through the FAO-56 (Allen, et al., 1998) and ASCE-EWRI (2005) conventions and has a long record of successful application in irrigation water management and irrigation scheduling. In this case, basal crop coefficients were derived from mean crop coefficients developed from actual crop ET estimates for the EBID area generated from satellite-based surface energy balance analyses, as described in the following paragraphs.

The K_c varies by crop and the stage of crop development and relates the ET of a specific crop or land cover class to the ET_{ref}. As the growing season progresses, plants grow and develop and the fraction of land covered by vegetation changes, causing the K_c to change. Precipitation and irrigation change the wetness of the soil adjacent to the crop also leading to changes in K_c. Two approaches for estimating ET values that are scientifically accepted and commonly applied are the single crop coefficient approach and the dual crop coefficient approach (Allen et al., 1998 and ASCE, 2016). The single crop coefficient approach accounts for total evaporation and transpiration from precipitation and irrigation averaged over time into a single, “mean” crop coefficient (K_{cm}). The dual crop coefficient approach separates the crop coefficient into a “basal” crop coefficient (K_{cb}) that accounts for plant transpiration and some residual evaporation from soil, and a second coefficient accounting for soil evaporation (K_e) occurring following soil wetting. The dual crop coefficient approach was chosen to develop ET_{aw} estimates because it allows for separate and more precise accounting for evaporation and transpiration resulting from rainfall and irrigation. The dual crop coefficient approach requires a daily computational time step.

ET_{act} can be estimated from a surface energy balance (Allen, 2003; Bastiaanssen, 2005; Cassel, 2006; Thoreson, 2009). By computing ET from the energy consumed by evaporation of water from soil and plant surfaces, the surface energy balance inherently accounts for the effects of salinity, deficit irrigation, disease, poor plant stands, and other field conditions that typically cause ET_{act} to be less than potential (ET_{pot}) on a field, farm, or district scale. Thus, ET generated from satellite-based surface balances better represents local management practices and water availability. Mapping ET at high Resolution with Internalized Calibration (METRIC) is a widely used and accepted surface energy balance methodology with numerous applications, both in the western US (Wyoming, Idaho, Nevada, Colorado and California) and internationally (Australia, Spain, Portugal, China and Morocco), some of which are described in Serbina and Miller (2014). METRIC uses spectral radiances recorded by satellite-based sensors, including a thermal sensor, along with ground-based weather data to solve the energy balance at the Earth's surface, yielding spatially distributed estimates of ET_{act} from vegetation and land surfaces. ET_{act} is computed for each pixel in a multispectral satellite image by applying energy balance physics. Daily results are provided for each satellite image. Time-integrated monthly, seasonal and annual totals are generated for multiple images across a crop growing season or year by developing crop coefficient curves that are used to estimate ET_{act} throughout the season, including on days between satellite images. METRIC ET_{act} estimates have been validated extensively in irrigated agriculture environments (Allen, et al., 2007a and Singh and Senay, 2016). A detailed description of METRIC is provided by Allen, et al. (2007b).

For this analysis, the METRIC daily results have been used to provide information on the timing of crop coefficient development throughout the growing season. To develop K_{cm} values for individual crops and crop groups, the crop in each field on the image date must be known. The source for this information is described in the following section.

Spatial Cropping Information

In 2008, the crop in each field was determined from a ground-based crop survey for EBID and the geospatial crop data layer (CDL) from the United States Department of Agriculture National Agricultural Statistics Service (USDA NASS) for EPCWID and Hudspeth. In 2013, the crop in each field was assigned based on the CDL for EBID, EPCWID and Hudspeth. The following paragraphs briefly describe these two data sources. Data identifying the crop in the field was not available for Juarez in any of the three years.

The New Mexico Office of the State Engineer/Interstate Stream Commission (NMOSE/ISC) staff identified the crop that was present in each EBID field during four field visits, including the spring, summer and fall of 2008 and the spring of 2009. The purpose of the field visits was to characterize the complex cropping patterns in EBID (Longworth, 2011). The use of a geographic information system (GIS) linked to the Global Positioning System (GPS) located each field and stored the crop identified as growing in the field providing the crop location information needed to support the development of crop coefficients from METRIC. The 2008 EBID crop survey results are summarized in **Table 6-1**.

The CDL is a GIS raster layer and the only data available for EPCWID and Hudspeth in 2008 and 2013 and for EBID in 2013. A GIS raster layer contains an independent value for each pixel in the data layer. The 2008 CDL for New Mexico and Texas utilized multiple satellites to estimate the crop type for each 56-meter square pixel. Fields contain many pixels, so it is possible that not all pixels within each field are assigned the same crop classification. Generally, the crop classification of the majority of pixels within a field is assigned to the entire field. Details of the method used to assign one crop to each field from the CDL pixels within the field boundaries are described in **Appendix 6A**.

Table 6-1. EBID 2008 Major Crop Types, Number of Field Polygons, and Acres Represented (NMOSE/NMISC Ground Survey).

Crop Category	Field Area (acres)	Number of Fields	Average Area per field (acres)
Pecans	28,643	3,612	8
Alfalfa Hay	17,529	1,700	10
Cotton	11,727	721	16
Irrigated Pasture	7,205	2,505	3
Corn, Sweet Corn, and Silage	6,701	417	16
Chile (Peppers)	4,118	360	11
Onions	872	50	17
Wheat and Small Grains	816	54	15
Miscellaneous Vegetables	593	104	6
Total:	78,204	9,523	8.2

Spatially Distributed ET_{act}

Spatially distributed ET_{act} was calculated for the Study Area for 2008 using the METRIC energy balance algorithm (Allen Engineering, 2008 and ET Plus, 2014). Because of the availability of a ground-based crop survey identifying crops in the field, only EBID METRIC results were used for developing K_{cb} values. METRIC solves the energy balance at the Earth's surface for ET using data collected by satellite and weather stations. METRIC first determines the available energy from the Sun and atmosphere (net radiation, R_n), then calculates two of the three significant energy uses (1) heating of the ground surface (soil heat flux, G), and (2) heating of air at the surface (sensible heat flux, H). Then, the energy used to evapotranspire water (the third significant use of energy) is calculated as the difference between the available energy from the Sun and the amount of energy used to heat the ground surface and the air. METRIC ET_{act} estimates have been validated extensively in agricultural environments. A detailed description of METRIC is provided by Allen, et al. (2007a,b). Daily, monthly and seasonal estimates of ET_{act} were developed for each 30-meter satellite pixel within the Study Area.

Reference ET

Quality-controlled weather data from the Leyendecker Automatic Weather Station (AWS) were used to calculate alfalfa reference ET (ET_r) and ET_o for the EBID area.

Mean Crop Coefficients Derived from METRIC Results

METRIC results provide mean crop coefficients for each pixel based on ET_r. Prior to beginning the crop coefficient analysis, the METRIC mean crop coefficients based on ET_r were converted to mean crop coefficients based on ET_o by multiplying by the ratio of ET_o to ET_r on the day of each image. This ratio was provided with the METRIC results. To facilitate the analysis of K_{cm} over time, the data were organized in a Microsoft Access database containing field-specific and date-specific K_{cm} and Normalized Difference Vegetation Index[4] (NDVI) values.

The database for analysis of K_{cm} values was created by overlaying EBID, EPCWID and Hudspeth field polygon layers over crop coefficient and NDVI raster images. Data were extracted using ArcMap's spatial analyst tool and organized in a database. **Appendix 6A** describes the detailed step by step

[4] An index sensitive to changes in crop canopy cover.

process of extracting the data using ArcMap to develop the database. The EBID data was used to develop the crop coefficients.

Estimation of Basal Crop Coefficients

The K_{cm} discussed in the preceding section includes evaporation from the soil which depends on the stage of crop development and the wetting frequency and depth from irrigation and rainfall. To obtain more accurate estimates of ET and effective precipitation, a dual crop coefficient and a daily root zone model (ASABE, 2007 and ASCE, 2016) is used. The dual crop coefficient approach requires a basal crop coefficient (K_{cb}), crop transpiration divided by ET_o, to estimate transpiration and an evaporation coefficient (K_e) to estimate evaporation following wetting events. For each crop and image date, to relate K_{cb} to crop vegetative development, K_{cb} was estimated based on the average NDVI of fields in EBID. A relationship between NDVI and K_{cb} was developed for each crop based on observed field scale relationships between NDVI and ET_oF[5] from the 2008 METRIC results. Four methods of defining the relationship between NDVI and K_{cb} (Tasumi, et al., 2006 and Er-Raki, et al., 2007) were considered:

Method 1: $$k_{cb} = 1.2 \times NDVI \qquad \textbf{(Eq. 6-1)}$$

Method 2: $$k_{cb} = 1.4 \times NDVI \qquad \textbf{(Eq. 6-2)}$$

Method 3: $$k_{cb} = m \times NDVI + b \qquad \textbf{(Eq. 6-3)}$$

Method 4 (Er-Raki): $$k_{cb} = k_{cb,max}\left[1 - \left(\frac{NDVI_{max} - NDVI}{NDVI_{max} - NDVI_{min}}\right)^{1.56}\right] \qquad \textbf{(Eq. 6-4)}$$

These four methods were compared against average METRIC ET_oF and NDVI results to select an appropriate method that most accurately reflected average crop growth conditions observed in fields across the Study Area.

In **Equation 6-3**, m represents the slope of a linear relationship between NDVI and k_{cb} and is calculated as $\frac{k_{cb,max} - k_{cb,min}}{NDVI_{max} - NDVI_{min}}$, where $k_{cb,max}$ is the maximum expected value of K_{cb} among a population of fields and occurs at $NDVI_{max}$ (maximum expected NDVI), and $k_{cb,min}$ is the minimum expected value of K_{cb} (set as zero, which occurs when no transpiring vegetation is present) among a population of fields and occurs at $NDVI_{min}$ (NDVI value corresponding to bare soil). The intercept, b, is then calculated as $b = k_{cb,max} - m \times NDVI_{max}$. **Equation 6-4** represents a curvilinear relationship between NDVI and K_{cb} as described by Er-Raki et al. (2007). In **Equations 6-3 and 6-4**, the minimum allowable value of K_{cb} was set to zero for the time before the crop is planted and prior to emergence.

Average METRIC ET_oF, NDVI, and estimated K_{cb} for EBID cotton fields in 2008 based on each method (**Equations 6-1 through 6-4**) are shown in **Figure 6-2**. Similar graphs were prepared for all crops in the Study Area. Results for individual image dates are connected by a smoothed line, essentially equivalent to a cubic spline. The METRIC ET_oF results correspond to a combination of evaporation and transpiration, with evaporation representing all of the ET early in the growing season (note impacts of pre-irrigation in the March, April, and May images), and transpiration representing most of the ET during mid-season (July, August, and September). During peak season, it is expected that the K_{cb} would be approximately equal to ET_oF due to full or nearly full shading of the soil surface by the crop, limiting

[5] Grass reference ET fraction, synonymous with K_{cm} and generally refers to K_{cm} values from METRIC results.

evaporation. Prior to planting, it is expected that K_{cb} would be approximately zero as no crops would be available to transpire.

Based on review of these crop season graphs, **Equation 6-4** (the Er-Raki method) was selected to estimate the basal crop coefficient corresponding to each image date. This methodology was chosen because it results in a K_{cb} value at peak season equal to the average ET_oF, while producing K_{cb} values of zero prior to planting, accurately reflecting the trend of crop evapotranspiration throughout the year.

As indicated in the figure, the methodologies of **Equations 6-1 and 6-2** result in K_{cb} values of approximately 0.15 to 0.20 early in the season, when vegetation is not believed to be present, and the K_{cb} would be expected to be near zero. Additionally, K_{cb} values from **Equations 6-1 and 6-2** reach approximately 0.85 to 1.00 during mid-season, which is substantially less than the average ET_oF of approximately 1.05. During peak season, it is expected that the K_{cb} would be approximately equal to ET_oF due to full or nearly full shading of the soil surface by the crop, limiting evaporation. **Equation 6-3** results in a K_{cb} of zero prior to planting but reaches only approximately 0.9 at peak season.

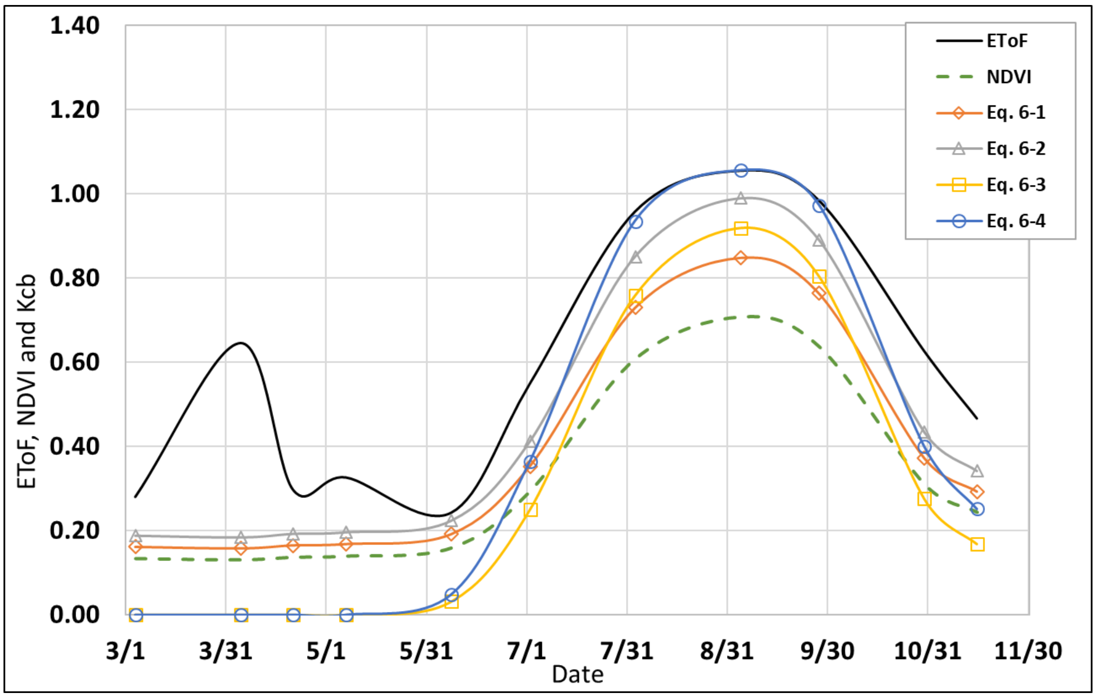

Figure 6-2. 2008 Average ET_oF, NDVI, and K_{cb} Estimates for EBID Cotton.

The following steps were completed for each crop to parameterize **Equation 6-4**:

1. Review relationships between NDVI and ET_oF.
2. Combine the distributions of average field NDVI and ET_oF values for image dates occurring during the primary growing season (June to September) on a single scatter plot.
3. Iteratively revise the initial parameters used in **Equation 6-4** until the resulting basal crop coefficient curve fits the METRIC results for the image dates corresponding to full cover.

Results

Crop coefficient curves based on the METRIC results are discussed and the results of the three steps followed to develop a K_{cb} curve from METRIC using the Er-Raki equation for cotton are described in the following sections.

K_{cm} Curves

Figure 6-3 is an example K_{cm} curve from the METRIC results that includes evaporation from rainfall and irrigation and shows how K_{cm} varies with time for about 600 fields identified as cotton by the NMOSE ground-based crop survey. Mean and median values of K_{cm} were determined for all cotton fields on each image date and then plotted. Plots of mean and median values of K_{cm} on each image date for all fields for each crop are included in **Appendix 6B**.

METRIC ET estimates combined with field polygons and crop information for each field in the Study Area make it possible to develop crop coefficients that represent local conditions. Variability in ET from field to field as seen in the METRIC results is typical of most irrigated areas. This variability is due to a number of factors including difference in planting dates, soil conditions, irrigation management, and plant health. METRIC observes this variability for the particular historical conditions that existed in the year of the METRIC analysis. Limitations of the METRIC are that it takes considerable time and experience, and is limited to recent years when Landsat images are available. The crop coefficients developed from this information represent the mean ET that would occur under full supply conditions, recognizing that some individual fields will have ET greater and others less than the computed mean ET value.

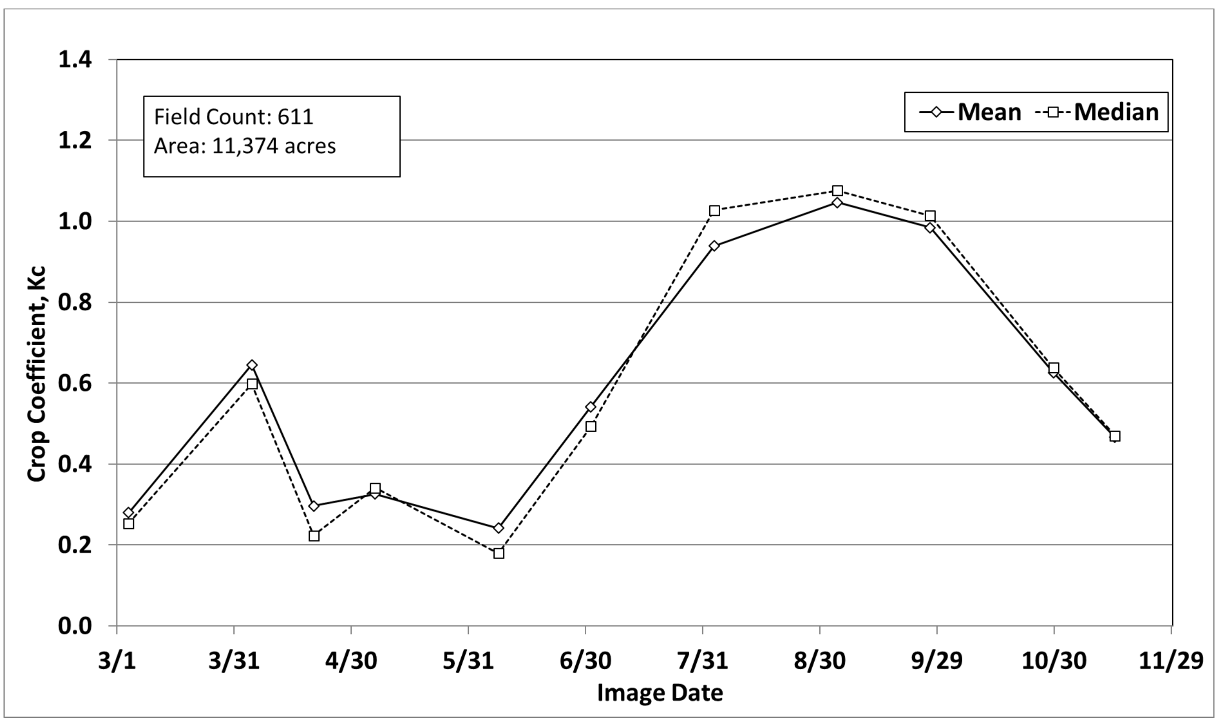

Figure 6-3. 2008 METRIC - Derived Crop Coefficients (ET_c/ET_o) for Fields Identified with Cotton by NM Field Survey.

NDVI Curves

The Normalized Difference Vegetation Index (NDVI) is sensitive to changes in crop canopy cover. **Figure 6-4** is an example of how NDVI changes with time for cotton fields in EBID. Comparing **Figures 6-3 and 6-4** side-by-side, pre-irrigation and approximate green up time can be detected. The relatively high K_c values (**Figure 6-3**) in early April are due to high evaporation resulting from pre-irrigation of many fields at that time. The mean and median NDVI for the same time period is low indicating there is little green vegetation, or cotton growth, present. Field observations, literature review and interviews with local growers confirm that nearly all cotton fields pre-irrigate during a one to two-week period in late March and early April to assist in seed germination. After planting between mid-April and mid-May the NDVI begins to slowly increase and by early July most fields have NDVI between 0.2 and 0.4 (**Figure 6-4**). Crop coefficients and NDVI decline around the same time as plants become mature and harvest approaches.

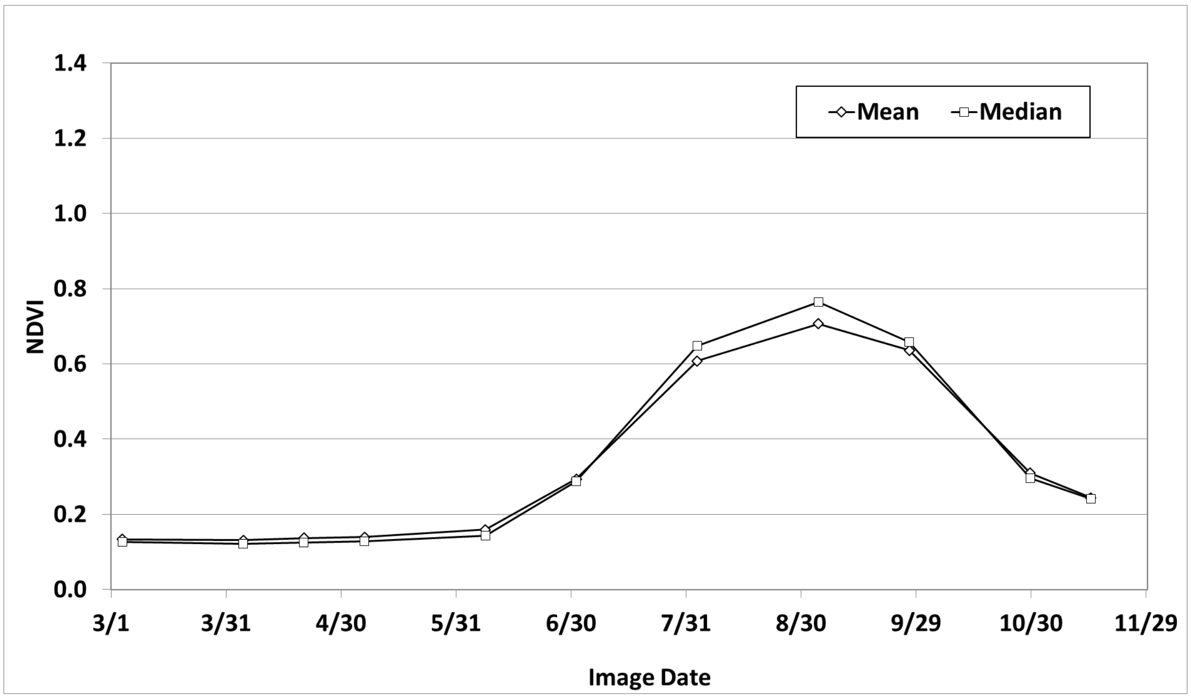

Figure 6-4. NDVI for Fields Identified to have Cotton by NM Field Survey.

Relationships between NDVI and ET_oF

The relationships between NDVI and ET_oF for cotton are shown in **Figure 6-5** for eight image dates from May 7 to November 15, 2008. In each graph, average NDVI for individual fields is shown on the x-axis, and average ET_oF is shown on the y-axis.

The majority of fields have an NDVI of 0.1 to 0.15 in the May image and 0.1 to 0.2 in the June image, suggesting little or no presence of green vegetation. The wide variability in ET_oF denotes differences in soil wetness and resulting evaporation rates resulting from early season irrigations or precipitation. Fields with greater NDVI have green vegetation present, with the "base" of the ET_oF distribution representing the relationship between K_{cb} and NDVI (see notes in **Figure 6-5.1 and 6-5.3**). As the growing season progresses, transpiration becomes the dominant component of ET, as indicated in **Figure 6-5.4 and 6-5.5**, with fields with greater NDVI having a greater K_{cb} (and ET_oF). Close to and following harvest in October and November, NDVI and ET_oF values tend to decrease and are again largely influenced by evaporation.

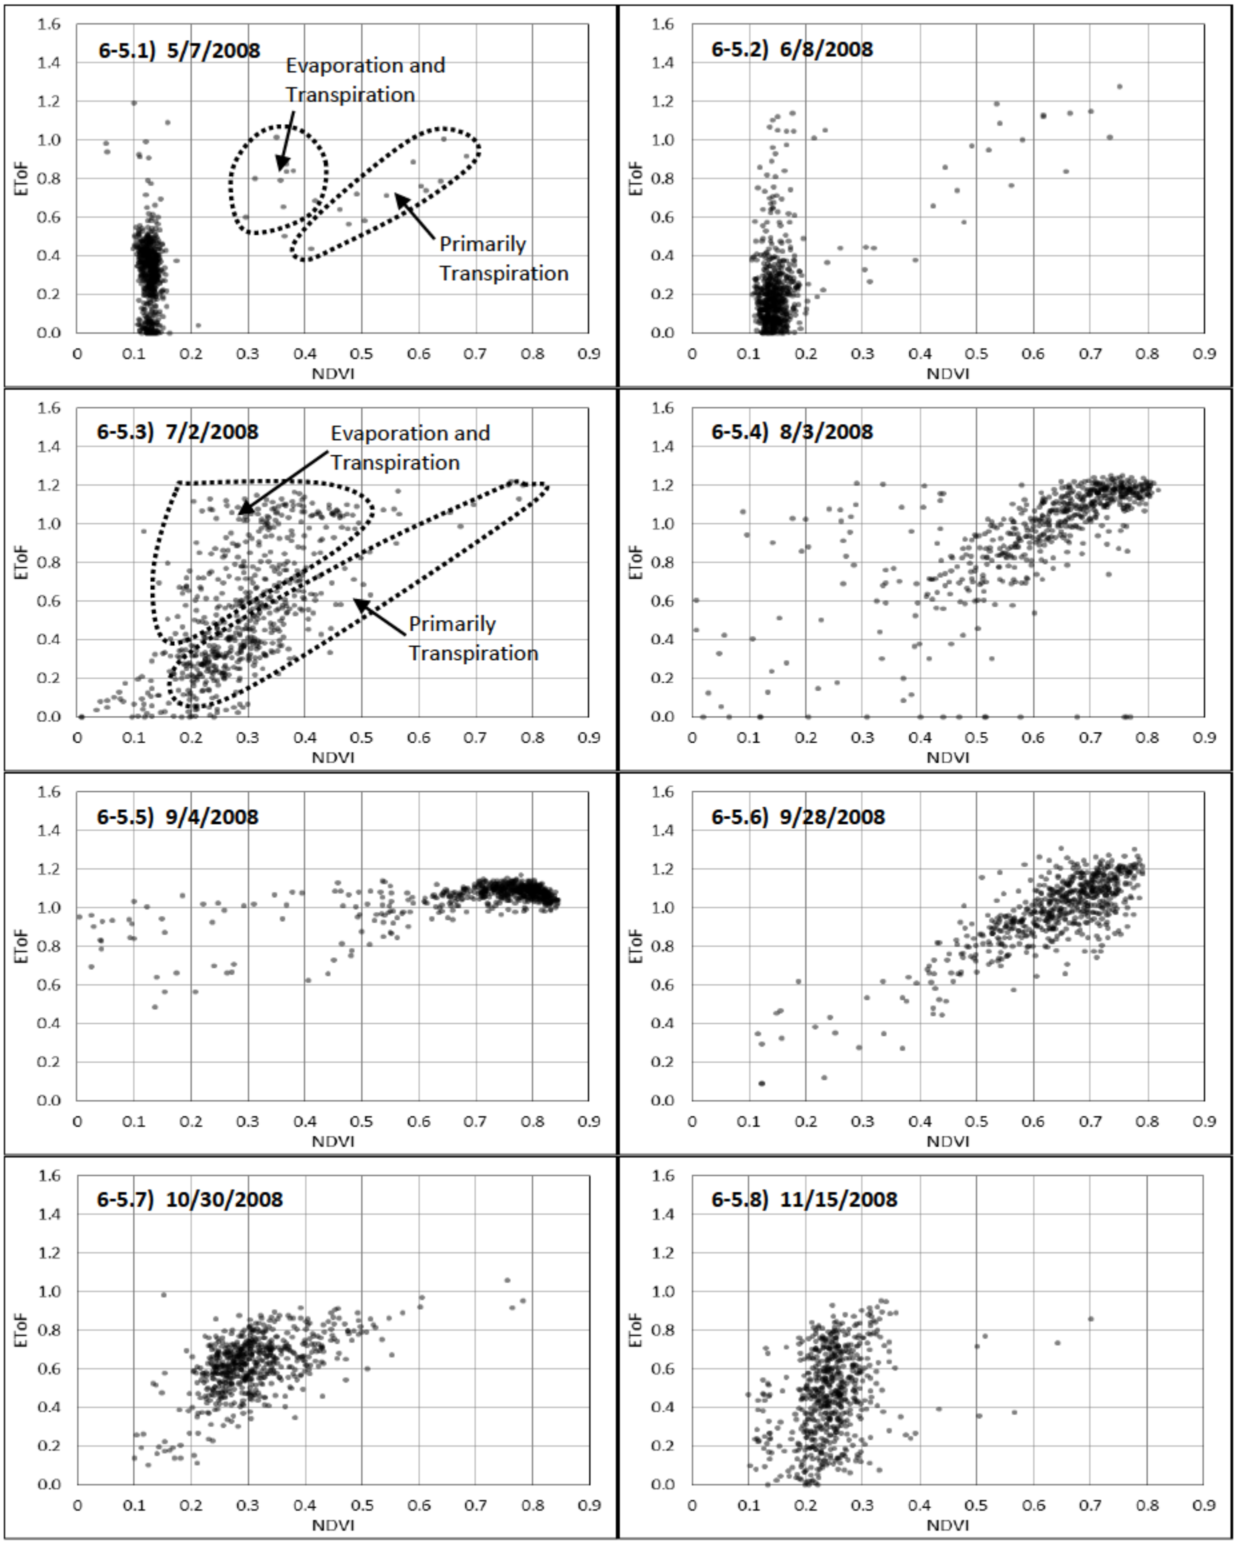

Figure 6-5. NDVI and ET_oF for EBID Cotton Fields, May 7 to November 15, 2008.

The relationships between NDVI and ET_oF for the remaining crops are shown in **Appendix 6C** for image dates for the 2008 growing season. The annual crop NDVI generally follows a pattern similar to cotton with low NDVI and ET_oF varying from low to high for dry and wet soil conditions, respectively, early in the season. As the growing season progresses, NDVI and ET_oF increase as the crop shades the soil and transpiration becomes dominant. Following harvest, NDVI values decrease and ET_oF depends on soil moisture conditions. Alfalfa and pasture have less variability in ET_oF at the low NDVI values because these crops shade the soil year round limiting evaporation.

Combined Distributions of Average Field NDVI and ET_oF Values

To parameterize K_{cb} through **Equations 6-3 and 6-4**, first the distributions of average field NDVI and ET_oF values for image dates occurring during the primary growing season (June to September) were combined on a single scatter plot (**Figure 6-6** and **Appendix 6D**). $NDVI_{min}$, which corresponds to a k_{cbmin} value of zero, was estimated to be 0.14. $NDVI_{max}$ and k_{cbmax} were estimated to be 0.85 and 1.15, respectively. Variability in ET_oF at a given value of NDVI results from factors including primarily differences in wetness of exposed soil and resulting evaporation rates and minor differences in water stress among fields. The average ET_oF value at upper values of NDVI (e.g. above 0.7) is reflective of average stress levels among the population of fields.

Iterative Refinement of K_{cb} Parameters

Parameters selected from review of single scatter plots similar to **Figure 6-6** for each crop group were then used with the Er-Raki equation (**Equation 6-4**) to estimate basal crop coefficients reflective of the population of fields. These initial parameter values varied by crop within narrow ranges and were iteratively revised until the resulting basal crop coefficient curve fit the METRIC results for the image dates corresponding to full cover (**Figure 6-7**). The curve labeled ASCE 2016 is the K_{cb} for cotton found in Appendix D of the ASCE Manual 70, Evaporation, Evapotranspiration, and Irrigation Water Requirements. This K_{cb} is for "well-managed" crops and is often referred to as a potential K_{cb}. The K_{cb} curves have the same general shape. Although the K_{cb} values averaged across large numbers of fields are slightly less than the "book", or potential, K_{cb}, it is important to note that many individual fields have ET_oF values equal to, or even slightly greater than the "book" K_{cb}.

Parameters for All Crops

$NDVI_{min}$ and $NDVI_{max}$ and $K_{cb,min}$ and $k_{cb,max}$ were selected for each of the nine crop groups for the ET Demands model. $NDVI_{min}$ and $NDVI_{max}$ were selected to be 0.14 and 0.85, respectively for each crop[6]. $K_{cb,min}$ and $k_{cb,max}$ were selected to be 0.00 and 1.15 for each crop, respectively, with the exception of pecans, for which $k_{cb,max}$ was selected to be 1.05. This lesser value of $k_{cb,max}$ was selected so the resulting basal crop coefficient curve fit the METRIC results for the image dates corresponding to full cover. Information on the age of the pecan trees was only available for EBID in 2008, so the young pecan orchards are included in the average METRIC ET_oF results to allow use of the crop coefficient when information on pecan tree age is not available.

[6] The $NDVI_{min}$ represents bare ground before the crop emerges, so it is the same for each crop. Although the $NDVI_{max}$ can vary slightly by crop, for the crop groups chosen, the observed value on the NDVI graphs was 0.85.

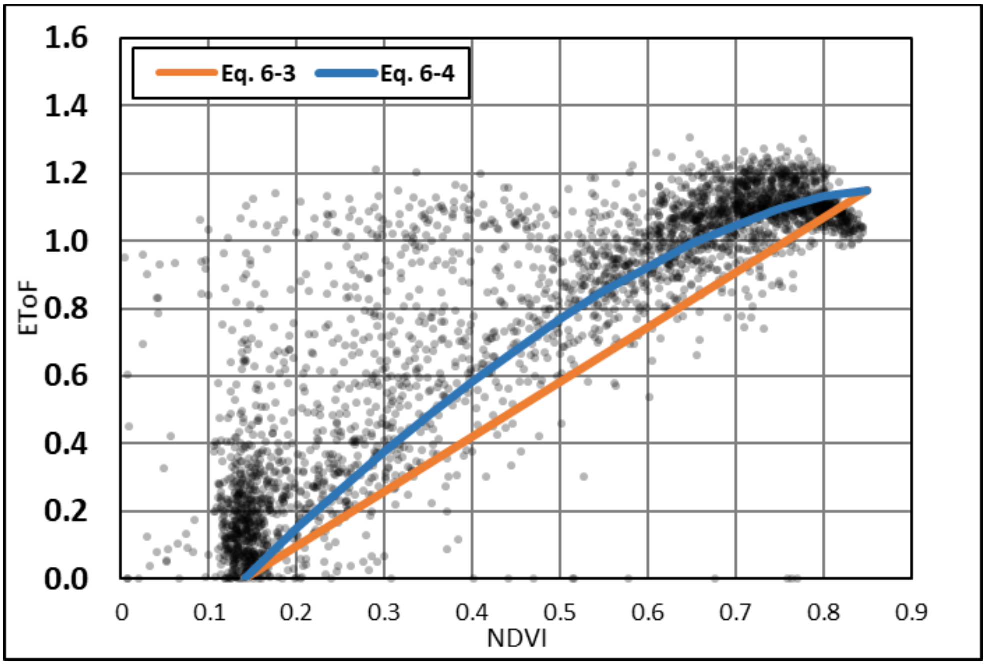

Figure 6-6. NDVI, ET_oF, and Estimated Relationships of K_{cb} to NDVI for EBID Cotton Fields, June 4 to September 28, 2008.

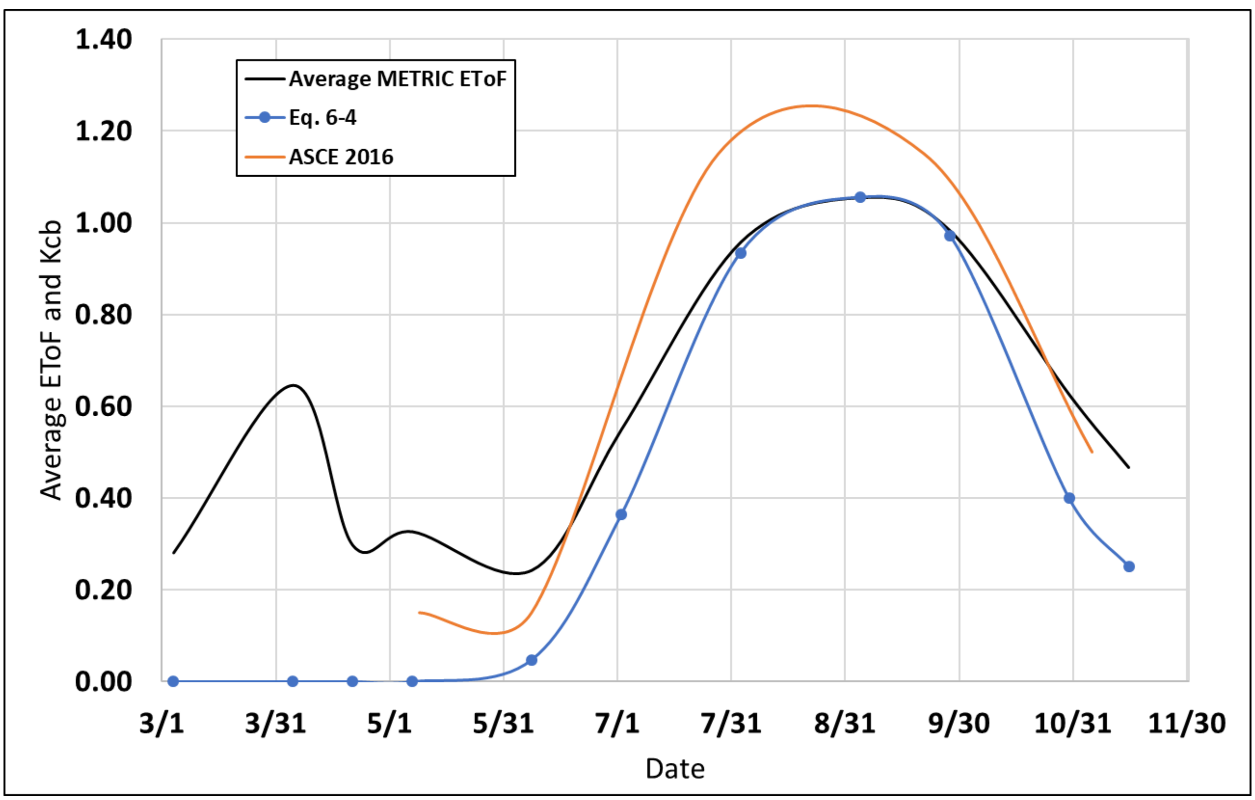

Figure 6-7. 2008 ET_oF and K_{cb} Estimates for EBID Cotton

For alfalfa, the METRIC average ET_oF values, average NDVI values, and estimated K_{cb} values represent an average of alfalfa fields in EBID during 2008. In each image these average values include fields at all stages of development from just after cutting to just before cutting. To parameterize ET Demands for alfalfa, a representative, individual field was simulated including specific hay cutting cycles. Within the ET Demands, K_{cb} values were calculated on a daily basis based on Cumulative Growing Degree Days (CGDD). Two relationships between CGDD and K_{cb} were estimated, one for the period from initial growth to full cover prior to the first cutting, and one for all subsequent cuttings following Allen and Robison (2009). The timing of cuttings was based on the actual CGDD accumulated, and thus varied slightly from year to year. Within ET Demands, the K_{cb} value is set to zero following a killing frost every year according to daily temperature data from Leyendecker Automatic Weather Station (AWS) for EBID.

Average ET_oF, NDVI, and K_{cb} estimates for each image date are provided for each of the eight crops other than cotton in **Figure 6-8**. The average ET_oF values include evaporation and thus are generally greater than the K_{cb} values early in the crop season when evaporation occurs from the soil. Later in the season, when the soil is nearly, or in some cases, completely shaded the K_{cb} curve is much closer to the average ET_oF values.

Opinions

The K_{cb} curves are parameterized to represent average local conditions and stress levels across the entire population of fields in the Study Area. While these K_{cb} curves have the same general shape as published "book", or potential, K_{cb} curves for "pristine" crops, it is important to note that many individual fields have ET rates that vary from the "book" K_{cb}. These K_{cb} curves reflect influences of incidental in water stress, wetness of exposed soil, and the resulting transpiration and evaporation rates. These curves better represent local conditions than "book" K_{cb} curves.

Basal crop coefficients can be developed from METRIC-derived crop coefficients and NDVI values that are based on standard procedures and that are reflective of the level of ET of applied water obtained through local irrigation and crop management practices. These basal crop coefficients can be used with a calibrated ET Demands root zone model to estimate ET of applied water. These basal crop coefficients used together with a calibrated ET Demands model and climate data result in reliable full supply ET_c and ET_{aw} estimates for all year types including years with less than full supply, even though, the actual ET_c and ET_{aw} may be less than the full supply ET_c and ET_{aw} for years with less than a full water supply. That reduction is made in the farm water budget model.

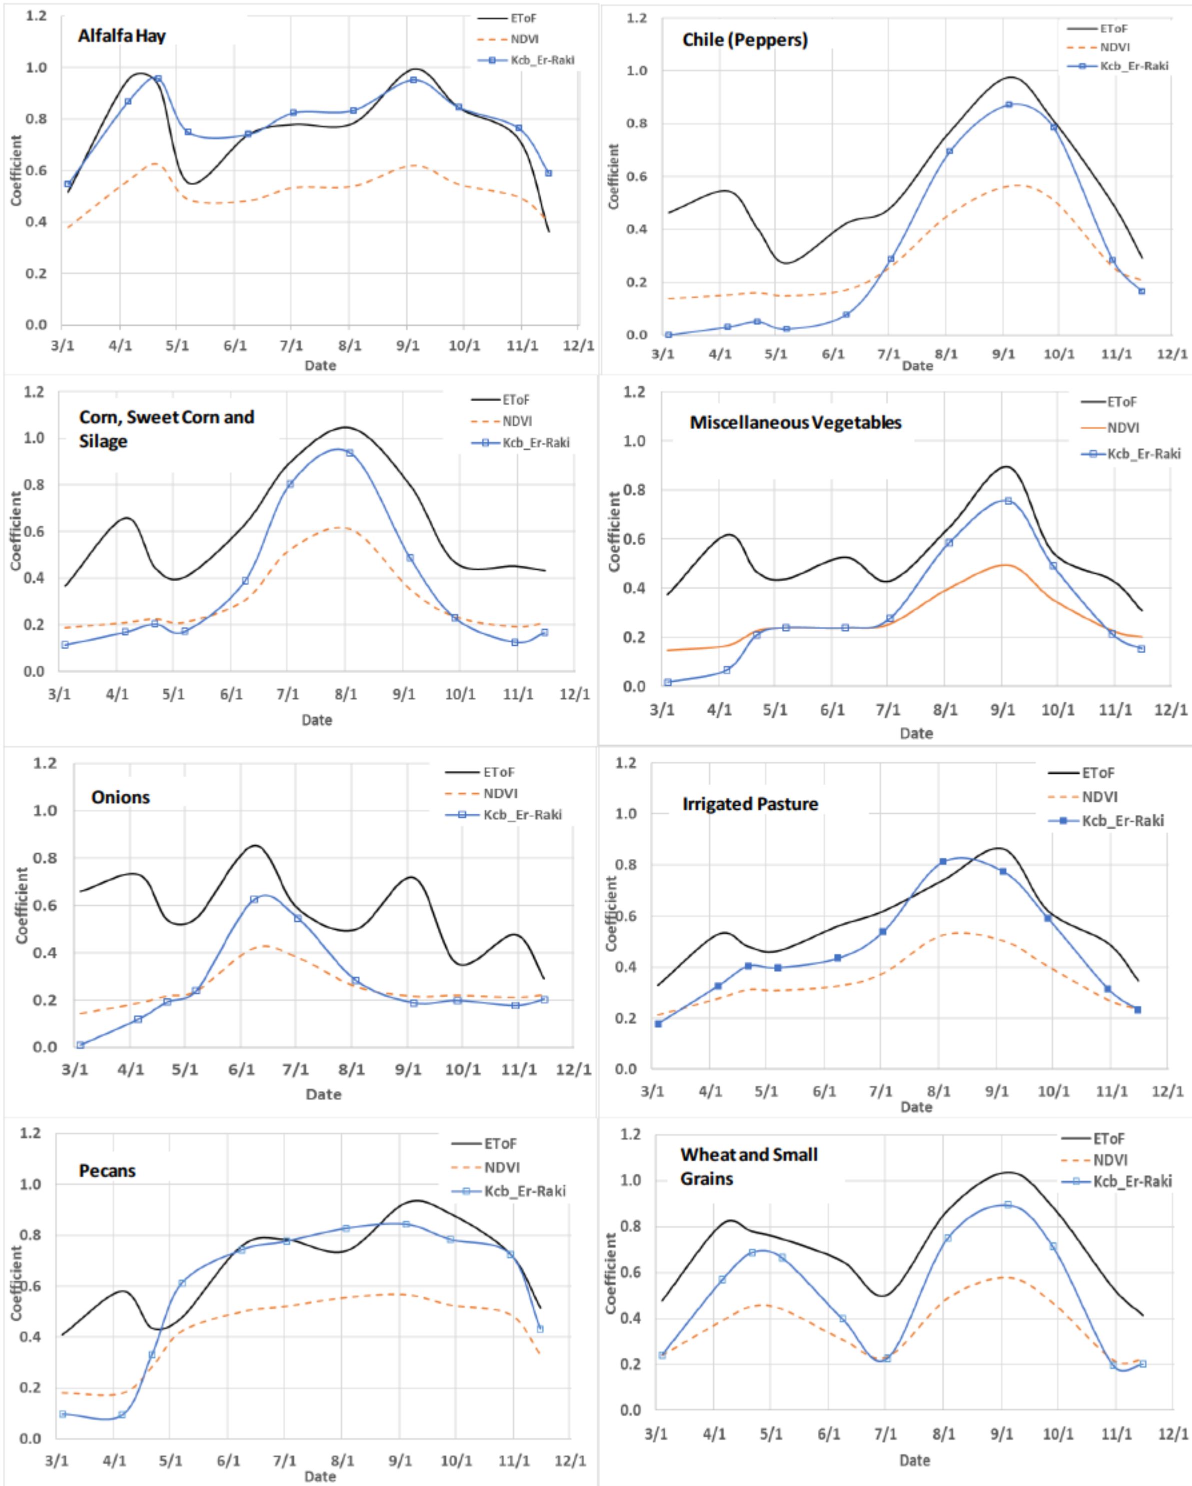

Figure 6-8. Average NDVI, ET_oF, and Basal Crop Coefficients for EBID Crops, 2008.

VII. ET Demands Local Calibration and Results

Purpose

The purpose of this section is to describe the local calibration of the daily root zone water balance model, ET Demands, and results for actual crop evapotranspiration (ET_c) and ET of applied water (ET_{aw}) for the irrigated lands in the Study Area. This section describes the ET Demands calibration methodology, results, and findings.

Methodology

Local calibration of basal crop coefficients comprises the second, third, and fourth steps in a four-step process (**Figure 7-1**) to calibrate ET Demands results to remotely sensed surface energy balance ET estimates. The objective of the calibration process is to develop crop season ET estimates in the ET Demands model that are reliable and within 10 percent of the energy balance ET estimates for six subareas of the Study Area (defined later). The first step in the calibration process involves developing basal crop coefficients from remotely sensed ET results and is described in Section 6 of this report.

As described previously, in the second, third, and fourth calibration steps, crop consumptive use characteristics were first provided as inputs to the ET Demands model based on the 2008 METRIC analysis. Then, the resulting ET estimates from the ET Demands model were compared back to METRIC ET estimates from 2008, 2013, and 2002. These years were selected as 2008 and 2002 represented approximately full supply conditions in the Study Area, the conditions considered in this report. The third year, 2013 was selected to validate during a limited supply year. At each step, if the ET Demands estimates were not within 10 percent of the METRIC ET estimates, the crop inputs to the ET Demands model were revised and the calibration step was repeated again. At the conclusion of this calibration process, ET Demands estimates were within 10 percent of METRIC ET estimates across the overall Study Area during 2008 and 2002.

This section includes a short description of the surface energy balance ET_c estimates, ET Demands model, methods used in ET Demands calibration, and the methods for comparing ET Demands model ET_c estimates to METRIC ET_c estimates from 2008, 2013 and 2002.

Surface Energy Balance ET_c Estimates

As described previously, the METRIC surface energy balance model was used to develop locally accurate ET estimates for the Study Area and served as a reference for ET Demands during the calibration process. An important advantage of the energy balance methodology used by METRIC is that it inherently accounts for factors that cause ET_c under commercial growing conditions to be less than ET_c under ideal conditions (sometimes referred to as potential ET). METRIC utilizes spectral raster images from the visible, near infrared, and thermal infrared energy spectrum to compute the energy balance resulting in estimates of ET_c on a pixel-by-pixel[7] basis. General accuracy of ET_c estimated by METRIC has been shown to be ±5 to ±15% when applied by expert users (Allen et al., 2011). The 2008 growing season METRIC ET_c results for EBID were used to develop crop coefficients and results from 2002, 2008 and 2013 growing seasons were used to calibrate the ET Demands model to local conditions within the Study Area.

[7] A single raster element in a computer image that has a constant value across its domain. In Landsat images, a pixel has dimensions of 30 m x 30 m.

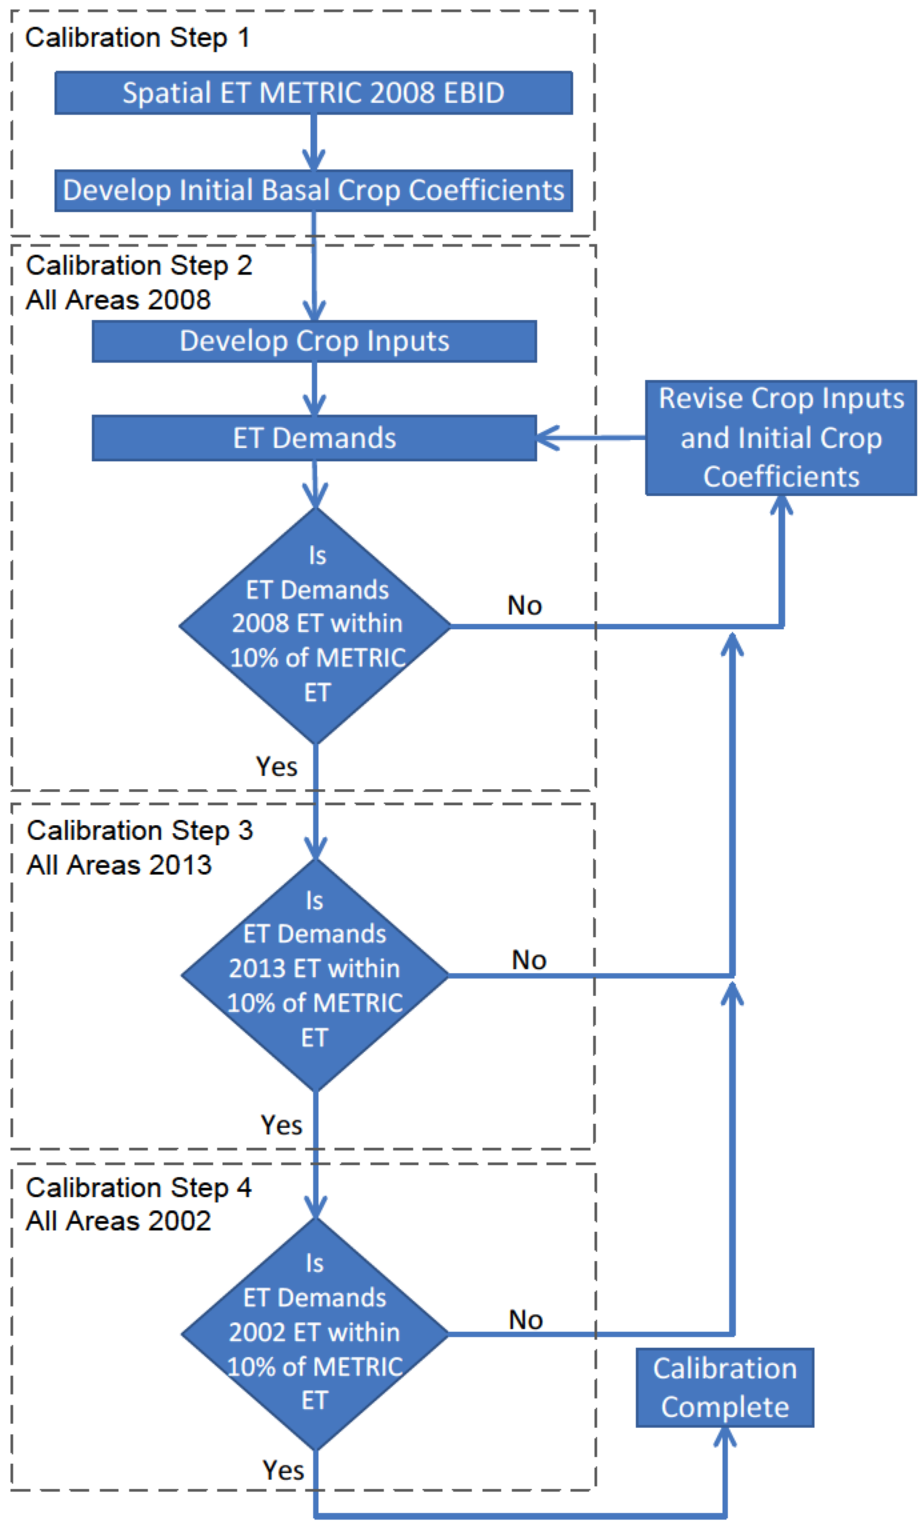

Figure 7-1. Schematic Describing Calibration of the ET Demands Model

ET Demands Model

The ET Demands model utilizes weather, crop and soil information to calculate a daily root zone water balance (**Figure 7-2**). Inflows to the root zone include rain, applied irrigation water and capillary rise; outflows include evapotranspiration (ET_c), runoff, and deep percolation. Rainfall and runoff are modeled in ET Demands based on precipitation data, irrigation frequency assumptions, and crop-soil surface characteristics, including slope, vegetation coverage, and soil type. Capillary rise (the flux of groundwater toward the soil surface) and deep percolation (the infiltration of water into the groundwater system) are both modeled based on soil characteristics as well as rainfall and irrigation events at the soil surface.

Weather inputs to the model include daily rainfall, reference evapotranspiration (ET_o) and temperature. Crop inputs include crop coefficients, maximum root depths, and planting and harvest dates. Soil inputs include available water holding capacity and hydrologic group.

On a daily time step, ET_o is multiplied by the dual crop coefficients, one to quantify crop transpiration and the other to quantify evaporation of water from wet soil surfaces following rainfall and modeled irrigation events (Allen and Robison, 2009). Daily crop transpiration and evaporation are then summed to obtain daily ET_c. This approach accounts separately for evaporation and transpiration, thereby accounting for the influence of the timing and magnitude of rainfall and irrigation events on evaporation. The daily calculation is performed continuously, both during and outside the growing season, to quantify ET_c, ET_{pr} and ultimately ET_{aw}.

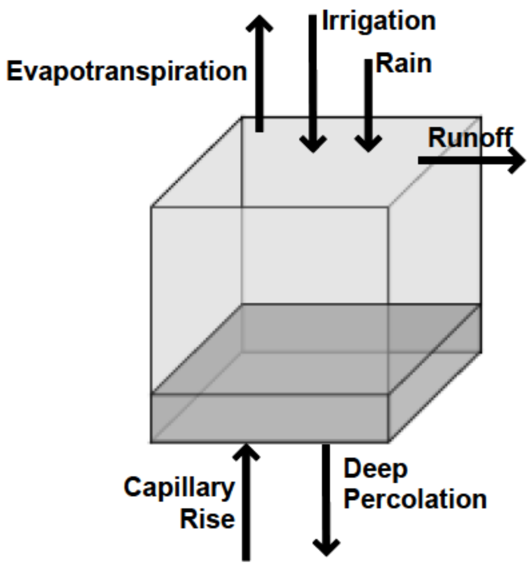

Figure 7-2. ET Demands Model Root Zone Water Balance Following FAO-56 Root Zone Water Balance. Modified from Allen et al. (1998).

The ET Demands model also generates daily estimates of applied irrigation water, surface runoff of rainfall and deep percolation (the drainage of soil water by gravity below the effective depth of the root zone). Capillary rise was assumed to be negligible because irrigation water was applied by the model before the root zone dried to the point where significant capillary rise would occur. These estimates are used along with daily ET_c estimates to calculate a daily root zone water balance for each crop and soil type combination, thereby accounting for consumptive water use in the entire Study Area. The following sections describe the weather, crop, and soil information required for computing ET_o, ET_c, and ET_{aw} in the ET Demands model.

Weather Inputs

Reference ET is calculated using the standardized short (0.12 m tall) grass reference ET equation (ASCE-EWRI 2005, ASCE 2016). The weather data used for calculating ET_o, including the weather stations reviewed and selected, and the data review and quality control procedures applied, as previously addressed. The Leyendecker Automatic Weather Station (AWS) was selected to represent the Rincon and Mesilla Valleys, and Art Ivey AWS was selected to represent the El Paso and Juarez Valleys. As previously described in detail in the weather data section, weather data, including rainfall records, were reviewed and accepted practices (EWRI ASCE, 2005 and ASCE, 2016) applied to fill data gaps and address other data anomalies. The result from this process was two daily time series of ET_o, temperature and rainfall for 1938 through 2018 for input to the ET Demands model.

Crop Inputs

Crop inputs include basal crop coefficient parameters (see Section 6), crop planting and harvest dates, crop root depths and crop irrigation parameters. For most crops, the start date and duration of growing season were determined uniquely for each year to account for weather variability from one year to the next. The basal crop coefficient (K_{cb}) curves were expressed on relative time scales or relative thermal unit scales (ASCE, 2016), so that the curves reflect differences in crop growing conditions from year-to-year. The end of each growing season was based on the maturation of the crop as predicted by cumulative growing degree days (CGDDs), local observed maturation dates, or by the occurrence of a killing frost. Beginnings of growing seasons were generally estimated using a 30-day running average mean air temperature ending on the start date. One of four methods can be selected in ET Demands to express the daily changes to the K_{cb} curve as the season progresses: 1) percent time from planting to harvest; 2) percent time from planting to effective full cover, with this ratio extended until termination; 3) percent time from planting to effective full cover and then days after full-cover; and 4) percent CGDDs from planting to effective full cover, with this ratio extended until termination. The method chosen can vary depending on the crop and the method chosen for each crop is described in the results subsection.

For this analysis, daily changes to the K_{cb} curves progressed according to CGDDs and their relationship to local growth stage lengths. The initial basis for the crop coefficient curve and other crop-inputs were adopted from Allen (2009) and adjusted during the calibration process to fit the METRIC ET_c results and local observations from the literature and personal observations.

ET demands uses the FAO-56 method (Allen, et al. 1998) for estimating evaporation from and computing a daily water balance for the top 10 cm of soil (the soil surface) following rainfall and irrigation events. The evaporation rate is reduced as the soil surface dries. Water stored between the soil surface and the bottom of the root zone is available for uptake and transpiration by the crop. Irrigations are scheduled in ET Demands when the daily water balance indicates that the water remaining in the root zone has reached a management allowed depletion[8] (MAD). Rooting depth and MAD values are defined by crop type and crop development stage (**Figure 7-2**). Irrigations are simulated in the model in the manner that is typically used for surface irrigation, as described in the following sentences. When the soil moisture within the root zone is reduced to the MAD, irrigation is triggered, with the applied water equal to the depth required to fill the root zone to field capacity, the soil moisture level above which water drains

[8] The management allowed depletion (*MAD*) is defined as the management planned percentage of the available soil water (between field capacity and the lower limit of extractable water) that is depleted between irrigations (ASCE, 2016).

from the root zone due to gravity, plus 10 percent. The additional 10 percent is a factor of safety often added to ensure that the crop is fully irrigated and that it does not increase the calculated crop ET.

Soil Inputs

Available Waterholding Capacities (AWC) and permeabilities (K_{sat}) were determined based on a GIS analysis of information from the National SSURGO soils database covering the Study Area (SSURGO, 2014). This analysis is described in Section 2. About 85 percent of the soils within each area were found to have AWC and K_{sat} in relatively narrow ranges, thus, single weighted average values were selected to represent all soils occurring within each Valley, except for the El Paso Valley which was divided into areas for EPCWID and Hudspeth. Runoff of rainfall was estimated using the widely used USDA-NRCS Curve Number method (ASCE, 2016), with antecedent moisture determined from the daily soil surface water balance in the ET Demands model. Evaporation occurring during the nongrowing periods for each crop group was calculated by assigning one of the following three soil surface conditions that provide different degrees of regulation of potential evaporation rates: (1) bare soil, (2) mulched soil (wheat and small grains) or (3) dormant sod (pasture).

ET Demands Calibration

The initial development of basal crop coefficients (k_{cb}) from METRIC ET results for 2008 is described in detail in a separate report. (This is illustrated as Calibration Step 1 in **Figure 7-1**.) The next three steps to calibrate ET Demands (Calibration Steps 2 through 4 in **Figure 7-1**) involve an iterative process of setting crop parameters in ET Demands, and then comparing the ET Demands crop ET results to the METRIC ET results for years 2008, 2013 and 2002. By computing ET from the energy consumed by evaporation of water from soil and plant surfaces, the surface energy balance of METRIC inherently accounts for the effects of salinity, deficit irrigation, disease, poor plant stands, and other field conditions that typically cause ET_{act} to be less than potential (ET_{pot}) on a field, farm, or district scale. Thus, ET generated from satellite-based surface balances represents local management practices and water availability. METRIC ET_{act} estimates have been validated extensively in irrigated agriculture environments (Allen, et al., 2007a,Singh and Senay, 2016, French, et al., 2015, He et al., 2017 and Madugundu et al., 2017). Sections describing pre-season evaporation coefficient estimates and maximum crop coefficient estimates follow.

Pre-Season Evaporation Coefficient Estimates

The ET Demands model triggers irrigation events when available soil moisture has been depleted by crop use to certain user-specified levels referred to as the MAD. In actual practice, growers often irrigate bare fields prior to planting certain crops. These irrigations are referred to as pre-irrigations and are used for a variety of purposes, including leaching salts from the root zone, conditioning soil for bed forming operations, establishing conditions favorable for seed germination, and establishing deep soil moisture. For crops known to typically have pre-irrigations, such as cotton, pre-season evaporation coefficients were estimated to match observed average crop coefficient values from METRIC during pre-season periods. For each crop, the pre-season evaporation coefficient was initially set equal to the average observed METRIC ET_oF[9] value for the image dates starting with March and before planting. Then, the initial evaporation coefficients were iteratively adjusted until a pre-irrigation was triggered in ET Demands at approximately the time that typical pre-irrigations are actually observed and the ET Demands monthly ET was approximately equal to the monthly METRIC ET.

[9] Grass reference ET fraction, synonymous with K_{cm} and generally refers to K_{cm} values from METRIC results.

Maximum Crop Coefficient Estimates

ET Demands requires the setting of a maximum limit on the crop coefficient value (k_{cmaxo}) for each crop to prevent overestimation of k_e and the ET Demands simulated crop coefficient following rainfall and simulated irrigation events. The k_{cmaxo} ensures that the dual crop coefficient does not result in transpiration and evaporation values that exceed the available energy (ASCE, 2016). For each crop, values for k_{cmaxo} were iteratively adjusted (always downward) until crop ET calculated by ET Demands approximately equaled crop ET from METRIC. The k_{cmaxo} values determined through this calibration and used in the ET Demands model are not the same as the maximum k_c values observed in the METRIC data and are not the same as the k_{cmaxo} described in ASCE (2016). Rather, the adjusted k_{cmaxo} as used here is used to calibrate modeled conditions representing a hypothetical field with crop ET equal to the average ET obtained from METRIC for each crop. It is recognized that fields having higher and lower ET rates and volumes exist in the population of fields planted to each crop, but are represented, on average, by the average field.

Initial k_{cmaxo} values were estimated as the maximum of the average crop coefficient value for a given crop from all METRIC image dates. These values were adjusted iteratively for each crop until the 2008 growing season ET_c from the ET Demands model agreed with 2008 METRIC ET_c within approximately ten percent. The resulting values were used in ET Demands and the ET_c results compared to the METRIC ET_c results as described in the results section.

ET Demands to METRIC ET Comparisons

Three years were chosen for METRIC remote sensing analyses to provide a basis for developing and calibrating crop coefficients for the Study Area for use with the ET Demands root zone water balance model. The initial calibration used the 2008 year because of the availability of the NMOSE ground survey in EBID to identify crops in fields and because it was a "full supply" project year. Next, the water short year 2013 was selected to confirm that crop coefficients developed from the full supply year (2008) would result in ET Demands actual ET_c estimates equal to or greater than the METRIC actual ET_c for 2013. Finally, a second full supply year, 2002, was chosen to confirm that the crop coefficients developed from one full supply year (2008) would result in ET_c estimates equal to or greater than the METRIC actual ET_c for a different full supply year (2002).

METRIC ET_c results were aggregated to produce an average depth of ET_c over all irrigated areas and are described as METRIC total ET_c. Similarly, ET Demands results were aggregated and reported as the average depth of ET_c over all irrigated areas and are described as ET Demands total ET_c. Delineation of irrigated areas was based on a Normalized Difference Vegetation Index (NDVI) analysis completed by Intera in April 2016 (Intera, 2018), which identifies irrigated fields in 2002, 2008 and 2013 throughout the Study Area. Fields classified as "Irrigated Agriculture" or "Possible Irrigated Agriculture" were considered to be irrigated areas.

Monthly METRIC ET_c results were extracted for the area remaining after applying a buffer (Clark, et al., 2007) to account for field edge effects. Using the monthly METRIC results, the average depth of ET_c was calculated for all irrigated fields as identified by the NDVI analysis. The ET Demands total ET_c was calculated by multiplying the ET Demands ET_c for each crop by the irrigated area of that crop. Irrigated areas by crop for each of the six areas described below are provided in the crop distribution report. The METRIC total ET_c estimates and the ET Demands total ET_c estimates were compared for 2008, 2013 and 2002 for the following six separate areas of the Study Area:

1. EBID irrigated lands with access to both surface water and groundwater (combined water source),
2. Irrigated lands with access to only groundwater (groundwater only water source) in New Mexico (about 60 percent this area is in close proximity to, but outside of, the EBID boundary, and the remaining 40 percent is within the EBID boundaries),
3. Subset of EPCWID irrigated lands with access to surface water in the Mesilla Valley,
4. Subset of EPCWID irrigated lands with access to surface water in the El Paso Valley,
5. Hudspeth irrigated lands with access to surface water in the El Paso Valley, and
6. Juarez irrigated lands with access to surface water in the Juarez Valley with ET Demands results.

For each annual comparison, when the ET Demands total ET_c was within ten percent of the METRIC total ET_c, individual crop ET values were reviewed to identify the crop(s) requiring crop input data adjustments. Input parameters were adjusted to achieve ET demands model ET_c agreement with METRIC ET_c results for the identified crops using consistent and standard model calibration methods. Selection of input parameters to adjust was based on review of monthly ET_c data for identified crops and determination of the parameters that most impacted deviations from monthly METRIC results. The objective of calibration is to develop ET Demands total ET_c results as the upper limit of ET_c under full water supply conditions. This requires that ET Demands total ET_c results be, on average, equal to the METRIC total ET_c in the Study Area for full water supply years and equal to, or greater than, METRIC total ET_c for less than full water supply years. Thus, when the ET Demands total ET_c for all six areas for all three years was either greater than the METRIC total ET_c or within ten percent less than the METRIC total ET_c, the goal of local calibration was considered to have been accomplished. The farm budget model, described in a separate report compares the surface water supply to ET Demands results and if the surface water supply is insufficient, the consumptive use estimates are reduced by the farm budget model. Finally, all ET Demands and METRIC ET results were reviewed for all individual crop groups for years 2008 and 2013 (the years with crop locations known) to ensure that the ET Demands estimates for each individual crop were also within 10 percent of METRIC ET results. This was done to ensure that any large shifts in crop areas did not reduce the overall ET estimation accuracy.

Results

The final crop inputs and maximum crop coefficient estimates arrived at through calibration for each crop, and used in the ET Demands model, are discussed in the first two of the three subsections in this section. The last subsection describes the ET Demands and METRIC ET comparison for the ending calibration for 2008, 2013 and 2002 for each of the six areas of the Study Area described above. Crop by crop comparisons are provided in **Appendix 7A** for 2008 and 2013, the years where spatial crop information is available.

Crop Inputs

The crop inputs resulting from the calibration of the ET Demands total ET_c results to the METRIC total ET_c results are summarized in **Tables 7-1 and 7-2**. The initial crop inputs were obtained from the literature, corroborated by personal observations during field trips. The calibrated crop inputs were within the ranges noted in the literature and also corroborated by personal observations during field trips to the area. The curve type and value used to estimate when the crop coefficient starts, effective cover is reached and when the crop is harvested together with the dates in 2008 when the development stage of the crop coefficient began and the harvest date for each of the nine crops are provided in **Table 7-1**.

Table 7-1. Crop Coefficient Types Used in ET Demands and Values Used to Specify Growth Stages in Crop Coefficient Curves.

Crop	Curve Type	Crop Coefficient Curve Value (K_c)		
		Initiation	Effective Cover	Termination
Alfalfa Hay	CGDD*	370	850	900 **
Chile (Peppers)	CGDD	110	1990	2780
Corn, Sweet Corn, and Silage	CGDD	230	1240	2550

Maximum Crop Coefficients

For each crop, the k_{cmaxo} establishes an upper limit during the estimation of k_e following rainfall and simulated irrigation events, thus, ensuring that the dual crop coefficient does not result in transpiration plus evaporation values that exceed the available energy (ASCE, 2016). Values for k_{cmaxo} were set during calibration and were adjusted iteratively until the 2008 growing season ET Demands ET_c results for each crop for agreed with METRIC ET_c results within approximately ten percent. The resulting values were used in ET Demands and the ET_c results compared to the METRIC ET_c results. Because 2002 ET Demands ET was less than the METRIC ET_c in the 2002 for EPCWID and Hudspeth, the k_{cmaxo} values for cotton and alfalfa, the two main crops in those areas, were adjusted upward from 1.15 to 1.20 to allow the ET Demands ET to increase. The adjusted values were used in ET Demands and the results were again compared to the METRIC ET_c results with the ET Demands ET results three percent lower than the METRIC ET with the new calibration for these two crops. Calibrated k_{cmaxo} values by crop are summarized in **Table 7-3**.

Table 7-3. Estimated $k_{c,maxo}$ Values for Each Crop in ET Demands.

Crop Group	ET Demands $k_{c,maxo}$
Alfalfa	1.2
Chile (Peppers)	1.1
Corn	1.2
Cotton	1.2
Miscellaneous Vegetables	1.5
Onion	1.2
Pasture and Hay	1.1
Pecans	0.9
Wheat and Other Small Grains	1.2

Comparison of Calibrated ET Demands to METRIC Results

This section describes the comparison of METRIC total ET_c to the ET Demands calibrated model total ET_c for 2002, 2008 and 2013. Comparisons are made for each of the six geographic areas described in the Methodology section. As described in the methodology section, 2002 and 2008 were full supply years and 2013 was a water short (less than full supply) year. Although both 2002 and 2008 were full supply years, the total supply in 2002 was somewhat greater than in 2008. Additionally, 2002 was the last year of 23 consecutive full supply years, whereas 2008 was preceded by five years with less than full supply.

In 2002, the calibrated ET Demands total ET_c for all areas, except the area in New Mexico with access to only groundwater, were within five percent of the METRIC total ET_c (**Table 7-4**). The ET Demands total ET_c in 2002 was greater than the 2002 METRIC total ET_c for four of the six areas considered (**Table 7-4**). In the remaining two areas – the EPCWID Irrigated Lands in the El Paso Valley and the Hudspeth area – the ET Demands total ET_c was three percent less than the METRIC total ET_c. The close agreement between the calibrated ET Demands total ET_c and METRIC total ET_c suggests that the calibrated basal crop coefficients and related crop inputs derived during the calibration are representative of the Study Area as a whole. From this, it can be deduced that the influences of drought, salinity and other stress factors on ET_c are similar between EBID, for which the basal crop coefficients were developed, and the other parts of the Study Area, except for the area in New Mexico having access to only groundwater.

Table 7-4. Comparison of Total ET_c (Total of ET_{aw} and ET_{pr}) from METRIC and ET Demands for the 2002 March through October Irrigation Season.

Area	Total Irrigated Area (acres)	METRIC Total ET_c (inches)	ET Demands Total ET_c (inches)	% Difference*
EBID Irrigated Lands with Access to SW and GW	79,164	38.0	38.2	1%
Irrigated Lands in New Mexico with Access to Only GW	5,556	30.5	39.4	29%
EPCWID Irrigated Lands in the Mesilla Valley	4,746	35.4	36.1	2%
EPCWID Irrigated Lands in the El Paso Valley	36,295	37.6	36.4	-3%
Hudspeth Irrigated Lands in the El Paso Valley	15,220	33.4	32.5	-3%
Juarez Irrigated Lands in the Juarez Valley	36,323	37.6	38.8	3%
Total, All	177,304	37.1	37.4	1%
Total, New Mexico	84,720	37.5	38.3	2%
Total, Texas	56,261	36.3	35.3	-3%
Total, Mexico	36,323	37.6	38.8	3%

*(ET Demands - METRIC)/(METRIC)

**Irrigated area using groundwater only that is in close proximity to EBID, but mostly outside the district

The ET Demands total ET_c in 2008 was greater than the 2008 METRIC total ET_c for all areas except for the EPCWID area in the El Paso Valley, which was three percent less than the METRIC total ET_c results (**Table 7-5**). For three of the six areas, the ET Demands total ET_c was more than ten percent greater than the METRIC total ET_c. As for 2002, the area in New Mexico with access to only groundwater had the greatest difference, with the ET Demands total ET_c being 31 percent higher than the METRIC total ET_c. Hudspeth had the next largest difference with the ET Demands total ET_c being about 27 percent higher than the METRIC total ET_c. As the METRIC total ET_c represents the best available science to calculate actual ET_c from satellite imagery, the lower value of METRIC total ET_c indicates that a full water supply for the irrigated area was either not available to Hudspeth in 2008, or that a full water supply was not effectively distributed within Hudspeth to supply potential crop water needs. Published "book," or potential, crop coefficients would overestimate ET_c in years having less than full supply, since they generally exceed the METRIC-derived crop coefficients calibrated for the ET Demands model applications.

In both 2002 and 2008, average METRIC total ET_c for EPCWID irrigated lands in the El Paso Valley were within one inch of the METRIC total ET_c for EBID irrigated lands with access to both surface water and groundwater. The close correspondence between METRIC total ET_c estimates and the ET Demands results across the Study Area as a whole helps to support the validity of this methodology in consistently and accurately representing crop consumptive use in full supply years.

In 2013, a year with less than full supply, the ET Demands total ET_c was greater than the METRIC total ET_c for all areas and more than 10 percent greater for four of the six areas (**Table 7-6**). As in 2002 and 2008, the area in New Mexico having access to only groundwater had the greatest difference with the ET Demands total ET_c 39 percent higher than the METRIC results. Again, as in 2008, Hudspeth had the next largest difference with the ET Demands total ET_c 31 percent higher than the METRIC total ET_cWhile the differences between the ET Demands results and METRIC results for 2013, a less than full water supply year, are slightly greater than those found in 2002 and 2008, they are well within 10 percent accuracy across the Study Area as a whole. Thus, the comparisons with METRIC results demonstrate that the ET_c estimates developed using ET Demands and these calibrated crop coefficients are accurate and can be relied on for further analyses.

Table 7-5. Comparison of Total ET_c (Total of ET_{aw} and ET_{pr}) from METRIC and ET Demands for the 2008 March through October Irrigation Season.

Area	Total Irrigated Area (acres)	METRIC Total ET_c (inches)	ET Demands Total ET_c (inches)	% Difference*

Total, Mexico	32,235	35.6	37.0	4%

*% Difference = (ET Demands - METRIC)/(METRIC)

Irrigated Lands in New Mexico with Access to Only Groundwater

The ET Demands total ET_c for irrigated lands in New Mexico with access to only groundwater ranged from 29 to 39 percent higher than the METRIC ET_c. This is because total ET_c is less from the irrigated lands in New Mexico with access to only groundwater than it is for the irrigated areas with access to both surface water and groundwater. ET Demands and METRIC analyses were carefully reviewed and these analyses were found to be correct. Although this area represents less than four percent of the Study Area, additional analyses were conducted to confirm lower ET from the irrigated areas having access to groundwater only and to understand why the METRIC ET_c was lower for this area. Initially, a detailed review of the METRIC analysis by crop, soil and within each field was completed. Also, NDVI, a related indicator of ET, was reviewed for this area and compared to the other areas. These comparisons supported the METRIC ET_c results of lower ET_c from the irrigated lands in New Mexico with access to only groundwater, but did not provide insight into why the crops from this area had, on average, lower ET_c. In August 2017, a field trip was organized to visit selected groundwater-only irrigated lands to visually confirm lower ET_c on fields. Approximately 31 irrigated fields were selected for visual inspection based on professional judgement. These fields represented a cross section of the crops, soils and locations of the irrigated fields with access only to groundwater in the study area.

LRG Water Master Ryan Serrano put together a package for 23 fields that included a map of the field, the water rights summary, and the meter pumping summary sheet. The fields were inspected for factors that have been found to impact ET_c: proximity of irrigated land to groundwater well, the effort/diligence expended (i.e. commercial farming v. hobby farm), irrigation infrastructure and proximity to other fields with surface water supplies. Eighteen fields were inspected over two days. The inspection was continued until the number of fields was determined adequate to accomplish the purpose of confirming that many fields had low ET_c. The field inspection determined that the aforementioned average 33 percent difference appears to be a combination of farming effort, sparse stands, poor crop health and stressed crops, depending on the field. Each field had a unique factor or combination of factors contributing to reduced ET_c and some fields had full ET_c.

Lumping all the irrigated lands in New Mexico together results in ET Demands ET_c results greater than the METRIC ET_c results by two, five and seven percent in 2002, 2008 and 2013, respectively. These are all within the ten percent calibration goal. Thus, although the ET Demands ET_c results are slightly greater than the METRIC ET_c results in New Mexico, separate crop coefficients were not developed, and the result is slightly greater actual ET_c than if the irrigated lands with access to groundwater had separate crop coefficients.

ET_{aw} Results

Because METRIC results provide the total ET_c that is derived from both precipitation and applied water, the total ET_c results from the calibrated model are compared to METRIC during the calibration process. Ultimately, the objective of the calibrated ET Demands model is to estimate ET of applied water, ET_{aw}, under "full supply" conditions (when water supplies are not limiting). To do so, the ET Demands model first estimates ET_c, which has been calibrated to the METRIC results, and then apportions ET_c between ET_{pr} and ET_{aw} for the Study Area. This section describes the ET_{aw} results for the three years and six areas used in the calibration process.

ET_{aw} in 2002 (**Table 7-7**) ranged from 25.5 to 34.1 inches for Hudspeth and irrigated lands in New Mexico having access to only groundwater, respectively. ET_{pr} in the EBID irrigated area and the EPCWID irrigated lands in the Mesilla Valley ranged from 5.1 to 5.3 inches. In the El Paso and Juarez Valleys, ET_{pr} ranged from 7.0 to 7.1 inches.

Table 7-7. Average ET_c, ET_{aw} and ET_{pr} for 2002

Area	Total Irrigated Area (acres)	ET Demands Total ET_c (inches)	ET Demands Total ET_{aw} (inches)	ET Demands Total ET_{pr} (inches)
EBID Irrigated Lands with Access to SW and GW	79,164	38.2	32.9	5.3
Irrigated Lands in New Mexico with Access to Only GW	5,556	39.4	34.1	5.3
EPCWID Irrigated Lands in the Mesilla Valley	4,746	36.1	30.9	5.1
EPCWID Irrigated Lands in the El Paso Valley	36,295	36.4	29.3	7.0
Hudspeth Irrigated Lands in the El Paso Valley	15,220	32.5	25.5	7.0
Juarez Irrigated Lands in the Juarez Valley	36,323	38.8	31.7	7.1

ET_{aw} in 2008 (**Table 7-8**) ranged from 23.0 to 32.4 inches for Hudspeth and irrigated lands in New Mexico with access to only groundwater, respectively. ET_{pr} in the EBID irrigated area and the EPCWID irrigated lands in the Mesilla Valley ranged from 7.0 to 8.0 inches. In the El Paso and Juarez Valleys, ET_{pr} ranged from 10.9 to 13.0 inches.

Table 7-8. Average ET_c, ET_{aw} and ET_{pr} for 2008

Area	Total Irrigated Area (acres)	ET Demands Total ET_c (inches)	ET Demands Total ET_{aw} (inches)	ET Demands Total ET_{pr} (inches)
EBID Irrigated Lands with Access to SW and GW	77,730	39.7	31.9	7.9
Irrigated Lands in New Mexico with Access to Only GW	4,898	40.4	32.4	8.0
EPCWID Irrigated Lands in the Mesilla Valley	3,940	37.9	30.9	7.0
EPCWID Irrigated Lands in the El Paso Valley	36,967	37.0	26.1	10.9
Hudspeth Irrigated Lands in the El Paso Valley	13,632	36.0	23.0	13.0
Juarez Irrigated Lands in the Juarez Valley	35,463	38.4	26.4	11.9

ET_{aw} within the Study Area in 2013 is provided in **Table 7-9** below.

Table 7-9. Average ET_c, ET_{aw} and ET_{pr} for 2013

Area	Total Irrigated Area (acres)	ET Demands Total ET_c (inches)	ET Demands Total ET_{aw} (inches)	ET Demands Total ET_{pr} (inches)
EBID Irrigated Lands with Access to SW and GW	73,684	38.6	33.2	5.4
Irrigated Lands in New Mexico with Access to Only GW	5,066	39.3	33.7	5.5
EPCWID Irrigated Lands in the Mesilla Valley	3,536	37.4	32.1	5.2
EPCWID Irrigated Lands in the El Paso Valley	26,451	37.7	31.3	6.4
Hudspeth Irrigated Lands in the El Paso Valley	6,160	34.7	27.0	7.7
Juarez Irrigated Lands in the Juarez Valley	32,235	37.0	29.9	7.2

In all three years, the lowest ET Demands ET_{aw} was in Hudspeth and the highest was in the irrigated lands in New Mexico having access only to groundwater.

Opinions

When used in the ET Demands root zone water balance model, locally calibrated basal crop coefficients based on 2008 METRIC actual ET for EBID yield reasonable and expected estimates of Study Area ET_c and ET_{aw} under "full supply" conditions.

Over the entire Study Area, ET Demands ET_c estimates are one, four and eight percent higher than the METRIC ET_c results in 2002, 2008 and 2013, respectively. All years are within the 10 percent calibration objective with the limited supply year of 2013 having the greatest difference.

Five of the six subareas had ET Demands total ET_c estimates within plus or minus three percent of the METRIC total ET_c estimates in 2002, the 24th consecutive full supply year. The one area (irrigated lands in New Mexico with access to groundwater only) that was not within three percent had higher ET Demands total ET_c compared to METRIC ET_c, which was found to be related to less intensive agricultural management practiced in this area. Overall, the ET Demands total ET_c estimates (representing ET_c under full supply) are higher than the METRIC total ET_c estimates (representing actual ET_c) in all areas in 2013 (a limited supply year), reflecting the expected changes in consumptive use with changes in water supply. ET Demands ET_c estimates are slightly higher in all but one area in 2008 and in all but two areas in 2002, which were full supply years. The ET Demands estimates were within three percent of the METRIC ET estimates in all areas and years having ET Demands total ET_c estimates lower than the METRIC total ET_c estimates.

In New Mexico, the actual ET_c estimated for full supply conditions varied in its comparison o METRIC-derived estimates of actual ET_c depending on the water sources available. ET Demands estimates total ET_c for EBID irrigated lands having access to surface water and groundwater to average 3.3 percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013. For the irrigated lands in New Mexico having access to groundwater only, the ET Demands total ET_c averaged 33 percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013. Reasons for the departure between ET demands ETc and METRIC actual ETc are apparently due to suboptimal agricultural and irrigation practices in the groundwater only area.

The ET Demands total ET_c for the EPCWID irrigated lands in the Mesilla Valley averaged nine percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013. The ET Demands total ET_c for the EPCWID irrigated lands in the El Paso Valley averaged 1.7 percent more than the METRIC total actual ET_c estimates for 2002, 2008, and 2013.

In Hudspeth, the ET Demands total ET_c for the irrigated lands averaged 18.3 percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013.

In Juarez, the ET Demands total ET_c for irrigated lands averaged 3.7 percent higher than the METRIC total actual ET_c estimates for 2002, 2008 and 2013.

The crop coefficients used to calculate ET_c in the ET Demands model have been developed based on best practices using locally-derived calibration to the 2008 METRIC results. When the crop coefficients are used to estimate ET_c representing full water supply for 2002 and 2013, the differences between the ET Demands results and METRIC results are slightly greater than those found in 2008, but are well within generally accepted ET modeling results. Thus, the comparisons with METRIC results demonstrate that the full supply ET_c estimates developed using ET Demands and locally calibrated crop coefficients are reproducible and can be relied upon for conducting water balance and consumptive use analyses.

VIII. Historical Consumptive Use Estimates

Overview

ET Demands model results for the consumptive use of irrigation water from irrigated lands under full water supply (full supply) conditions have been calibrated to local conditions using surface energy balance results for 2002, 2008 and 2013. The ET Demands calibrated inputs have been used to estimate consumptive use of irrigation water under “full supply conditions” for 1938 through 2013. “Full supply conditions” is generally understood to mean that available water supplies are sufficient to fully satisfy irrigation water demands for all lands irrigated.

Crop varieties, cultivation practices and irrigation management has changed over the 1938 to 2018 study period. The Rio Grande Project Histories, historical photographs and agricultural extension and research publications are important sources of information about the crop and irrigation management practices during this time period. These information sources were reviewed to assess the differences in agricultural practices that potentially affect ET_{aw} that are likely to have occurred under “full supply” conditions during the 1938 to 1970-time period as compared to the more recent time period. The time period 1938 through 1970 (early period) was chosen because after this time the crop mix began to diversify, moderating the dominant planting of cotton and alfalfa. This section compares and contrasts important agricultural practices and yield with those of the more recent 1970 to 2013-time period (recent period), and describes the adjustments applied to ET_{aw}.

Historical Consumptive Use Estimates

The Rio Grande Joint Investigation (RGJI) defines consumptive use (or evapotranspiration) as “the sum of the volumes of water used by the vegetative growth of a given area in transpiration or building of plant tissue and that evaporated from adjacent soil, snow, or intercepted precipitation on the area in any specified time” (RGJI, 1938). This definition includes evapotranspiration of precipitation (ET_{pr}). The values reported by the RGJI below were estimated based on the “...so-called integration method; that is, based on all available experience and judgment, unit values of consumption (acre-feet per acre) are assigned to the various classes of vegetative and other cover, taking into account the location of the latter within the basin with respect to altitude and latitude.” The depletions from the METRIC-calibrated ET demands root zone model differ only slightly from RGJI results for the Rincon, Mesilla and El Paso Valleys. The ET Demands results for 1936 are 0.3 acre-feet per acre, or 14 percent, higher than the RGJI estimates for cotton (**Table 8-1**). For alfalfa hay, the ET Demands results for 1936 are 0.1 acre-feet per acre, or 4 percent, lower than the RGJI estimates.

Table 8-1. Comparison of Joint Investigation Consumptive Use Estimates to ET Demands ET_{aw} Results (all values are in acre-feet per acre).

Location	Cotton		Alfalfa	
	Rio Grande Joint Investigation (1936)	ET Demands	Rio Grande Joint Investigation (1936)	ET Demands
Rincon Valley (in Sierra and Dona Ana Counties)	2.5	2.8	4.0	3.9
Mesilla Valley in New Mexico and Texas	2.5	2.8	4.0	3.9
El Paso division, Rio Grande project	2.5	2.7	4.2	3.9
Hudspeth County Conservation and Reclamation District No. 1	2.5	2.7	4.2	3.9

NA = Not Available

Historical Agricultural Practices and Yields

Between 1938 and 1970 cotton was grown on more than 60 percent of the area irrigated in the Rio Grande Project (Reclamation Crop Reports, 1938-1970). Alfalfa and cotton together during this period accounted for between 80 and 90 percent of the crops irrigated in Elephant Butte Irrigation District (EBID), El Paso County Water Improvement District #1 (EPCWID), Hudspeth County Conservation & Reclamation District #1 (Hudspeth) and Juarez Valley Irrigation District (Juarez) (**Figures 8-1, 8-2, 8-3 and 8-4**). The reduction in irrigated areas beginning approximately in 1953, and shown in all four major geographic areas in **Figures 8-1 through 8-4**, was due to a drought that reduced water supplies in the Rio Grande Project. Given the dominance of cotton and alfalfa as the primary crops during this period, first cotton and then alfalfa will be discussed in the following sections.

Cotton

Over 40 historical agricultural extension and research reports that included information on cotton agricultural practices were reviewed. The reports reviewed are listed and illustrative photos are provided in **Appendix 8A**. Although most of these reports focused on the Mesilla Valley, New Mexico, eight of the reports reported on research trials in the El Paso Valley, Texas. The agricultural practices documented in these reports from the El Paso Valley were generally consistent with the practices in the nearby Mesilla Valley, so review results were summarized into one combined table (**Table 8-2**). Reported seed rates ranged from 12 to 40 pounds per acre in the 1920 through 1970-time period compared to 25 pounds per acre now. The research publications reported more irrigations applying smaller amounts with each irrigation compared to the present era. Although lower seed rates could indicate lower ET, the thinning practices and final stand density are more important to the ET_{aw}. In general, agricultural practices are very similar during the two-time periods. With regards to fertilizer practices, the historical trials showed little response to fertilizer other than manure. Contrast this with the current recommended extension practice to apply 120 pounds of Nitrogen and 50 pounds of P_2O_5 fertilizer per acre. This is likely due to current, improved cotton varieties having improved ability to respond to higher nutrient availabilities and to be less prone to become rank under water and fertilizer abundant conditions.

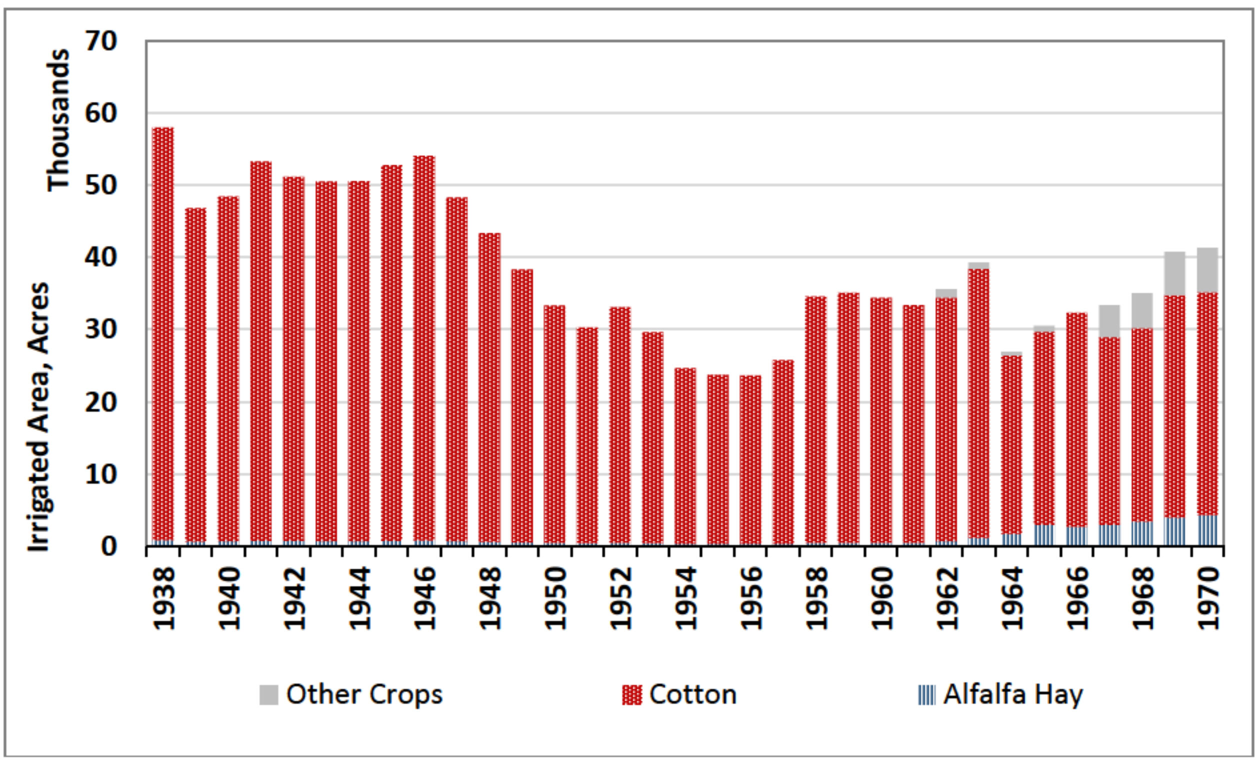

Figure 8-4. Juarez major crops 1938 through 1970.

Table 8-2. Summary of Reported Cotton Agricultural Practices in Mesilla Valley, New Mexico and El Paso Valley, Texas.

Cultural Practice	Historical Practices Early Period (1920* through 1970)		Current Practices**
	Minimum	Maximum	
Planting Dates	4/14	5/28	April 15-30
Row Spacing, inches	36	42	40
Seed Rate, lbs/acre	12	40	25
Plant Spacing, inches	3	20	
Pre-irrigation	A pre-irrigation late March/early April is standard practice.		Late March or Early April
No. of irrigations	3	8	4
Irrigation applied, inches***	15	35	33
Fertilizer	Most trials show little response to fertilizer other than manure.		120 lbs N, 50 lbs P_2O_5

*Some historical reports available beginning in 1920.
**Current practices from personal observation, Zhang (2015) and Cost and Return Study Dona Ana County (2003).
***Irrigation applied amounts obtained from research trials.

Reclamation reports crop areas and yields for upland and long staple (Pima) cotton for lint, in bales per acre, and for seed in tons per acre. This information is collected from water users each year by Reclamation staff on Form 7-332 and compiled on Form 7-316 (Reclamation, 1917). These crop reports indicate that cotton yields increased from the 1920s through the 1960s (**Figure 8-5**). The yields began decreasing again in the late 1960s back to the yield levels of the 1930s. Similar statewide cotton yield trends during the late 1960s were reported by Lansford, et al. (1987). Yield data from the National Agricultural Statistics Service (NASS) shows that yield began increasing again in the 1980s. Lansford, et al. (1987) attribute the yield increase to improved crop varieties, the decline that followed in the early 1960s to climatic factors (primarily lower temperatures during the growing season) and the subsequent rebound due to improved varieties.

Alfalfa Hay

Over 20 historical agricultural extension and research reports that included information on alfalfa agricultural practices were reviewed. The reports reviewed are listed and illustrative photos provided in **Appendix 8B**. Although most of these reports focused on the Mesilla Valley, one report reported on research trials in the El Paso Valley. The agricultural practices documented in these reports from the El Paso Valley were generally consistent with the practices in the nearby Mesilla Valley, so review results were summarized into one combined table (**Table 8-3**). With the exception of fertilizer practices, noted in the bottom row, the practices are fairly consistent throughout that time period and with current practices. The historical trials showed little response to fertilizer. Contrast this with the current recommended extension practice, which is to apply 35 pounds of Nitrogen and 90 pounds of Phosphorous fertilizer per acre. This is likely due to current, improved varieties having improved ability to respond to higher nutrient availabilities.

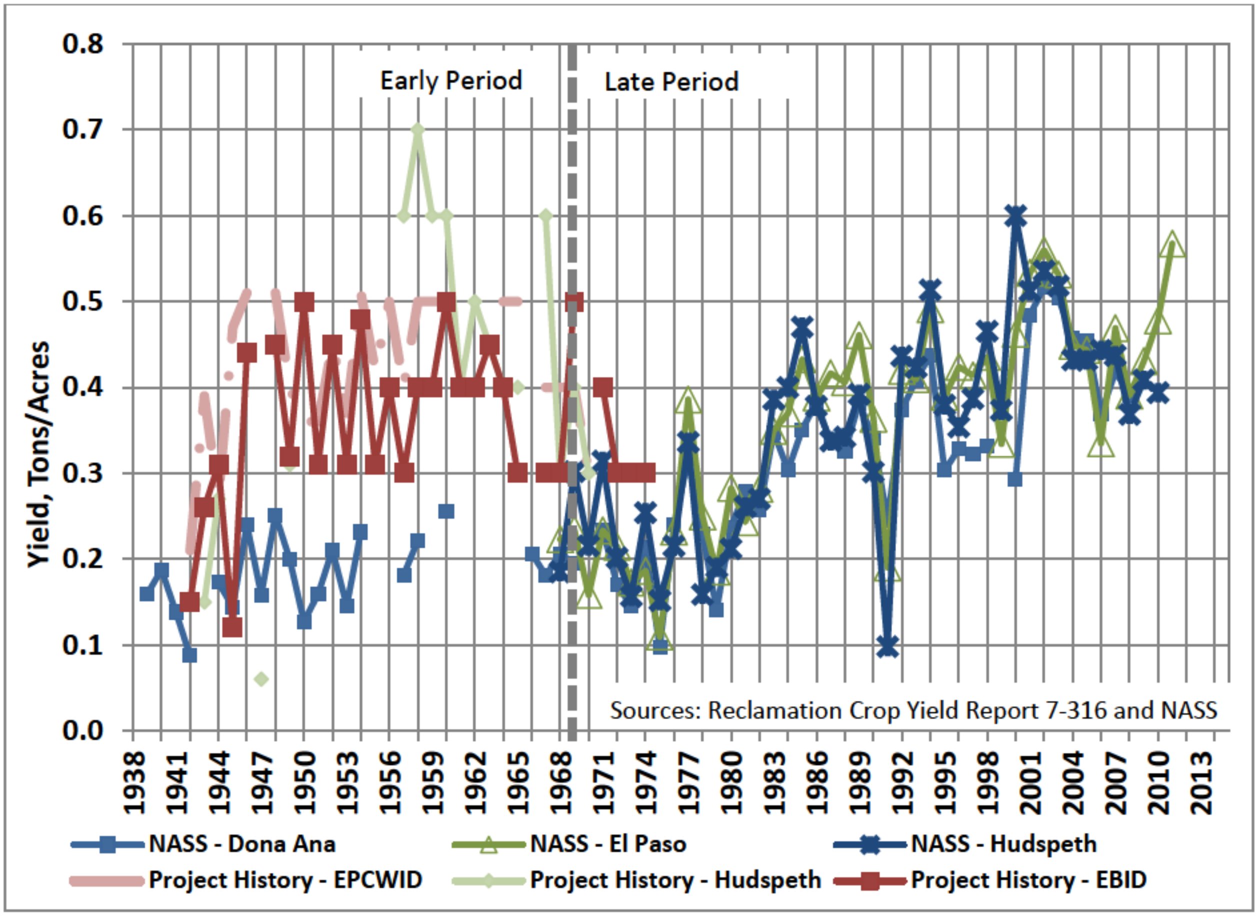

Figure 8-5. Average cotton yields in the project 1938 through 2013

Table 8-3. Summary of Reported Alfalfa Agricultural Practices in Mesilla Valley, New Mexico and El Paso Valley, Texas.

Cultural Practice	Based on Extension Bulletins Published in 1923, 1931, 1940 and 1943. Min	Max	Current Practices*
Number of cuttings	4	6	5
First Cutting Date	10-Apr	7-Jun	1-May
Second Cutting Date	20-May	17-Jul	
Third Cutting Date	15-Jul	9-Sep	
Fourth Cutting Date	18-Aug	18-Oct	
Fifth Cutting Date	10-Oct	16-Oct	1-Oct
No. of irrigations	9	14	10
Irrigation applied, inches	46	52	60
Fertilizer	Vary	Vary	35 lbs N, 90 lbs P
Yield Data (tons/acre)	5.5	7.6	6.5 to 8.0

*Current practices from personal observation, and Cost and Return Study Dona Ana County (2003).

Reclamation crop reports for the project indicate that alfalfa yields ranged from about 3.5 to 4.5 tons per acre from the 1930s through the late 1950s (**Figure 8-6**). In the late 1950s through the early 1960s, alfalfa yields increased to about 5 tons per acre, staying at about that level through the early 1970s. In the early 1970s, yields increased again to about 6 to 6.5 tons per acre by the early 1980s. These trends are similar to statewide yield trends reported in Lansford, et al. (1987), but the actual yields are higher, as would be expected from an irrigated area and somewhat longer growing season compared to other parts of the state reported in Lansford, et al. (1987). Yield data from the NASS shows that average yields in Dona Ana, El Paso and Hudspeth County remain between 6.5 and 7.5 tons per acre with a few years above 8 tons per acre between 2000 and 2015. Lansford, et al. (1987) attribute the yield increases in the late 1950s and early 1970s to improved varieties.

Summary of Key Differences between Early and Late Periods

Available historical photos, agricultural practices and yield were reviewed for the early period, 1938 through 1970, for cotton and alfalfa to consider the need to adjust ET_{aw} during this time period.

Cotton

Historical photos

- Photos are mostly from research publications and are generally of poor quality (**Appendix 8A**)
- Cotton density looks similar to modern densities

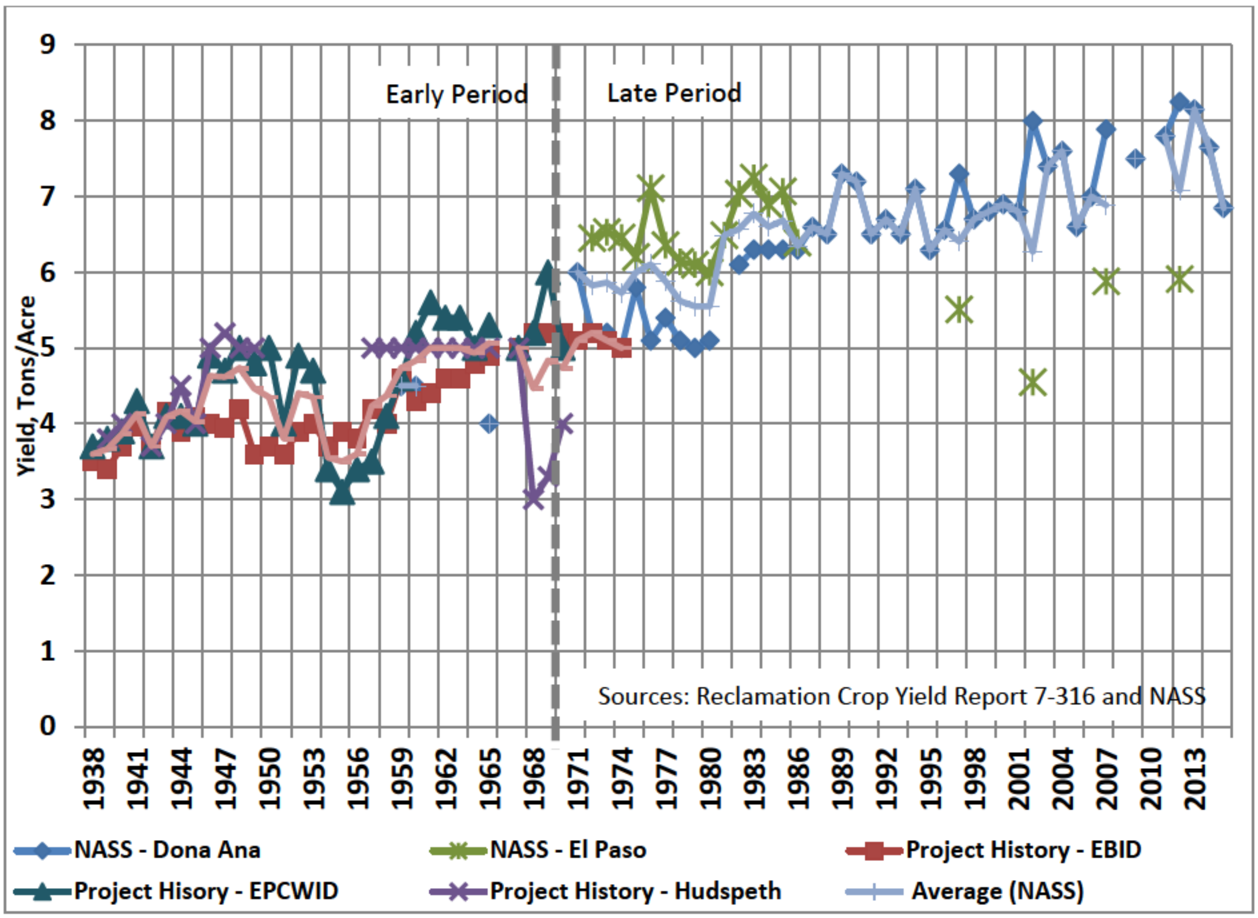

Figure 8-6. Average alfalfa yields in the project 1938 through 2013.

Agricultural Practices

- Modern seed rate is 25 pounds per acre compared to 15 to 20 pounds in the earlier time period
- **Table 8-4** summarizes agricultural practices that impact the plant population in the field and the volume of water available to the cotton plant. Comparing the 1938 to 1970 to the 1971 to 2013-time period, relevant agricultural practices for the 1938 to 1970 period were slightly lower compared to the recent period.

Table 8-4. Summary of Changed Agricultural Practices That Impact Crop ET and Estimates of Cotton ET.

Cultural Practice/ET_c Estimate	Early Period (1938 to 1970)	Recent Period (1981-2013)	Early Period Relative to Recent Period
Row Spacing, inches	40	40	Same
Seed Rate, lbs/acre	18	25	Lower
Irrigation applied, inches	25	33	Lower

Yield

- Cotton yield has varied over this time period primarily due to variety changes and cool summers (Lansford, et al., 1981).

Alfalfa

Historical photos

- Photos are mostly from research publications and are generally of poor quality (**Appendix 8B**)
- Alfalfa density looks similar to modern densities

Agricultural Practices

- Modern seed rate is 20 pounds per acre compared to 18 to 20 pounds in the earlier time period
- Most growers take 6 cuttings now with some growers taking 7 cuttings compared to an average of 5 cuttings in the earlier time period. Many growers cut sooner now compared to the earlier period to increase the protein in the hay. This is especially desirable for hay fed to dairy cows.
- **Table 8-5** summarizes agricultural practices that impact the water consumption of the alfalfa hay crop. Comparing the 1938 to 1970 to the 1971 to 2013-time period, relevant agricultural practices for the 1938 to 1970 period were slightly lower compared to the recent period.

Yield

- Alfalfa yield has generally increased with average yields ranging between six and seven tons per acre from 1980 to 2015 compared to average yields ranging from 3.5 to 5 tons per acre for the 1938 to 1970-time period. Because alfalfa yield is primarily dry matter, the yield is strongly related to the crop ET.

Table 8-5. Summary of Changed Agricultural Practices That Impact Crop ET and Estimates of Alfalfa ET.

Cultural Practice/ET_c Estimate	Early Period (1938 to 1970)	Recent Period (1971-2013)	Early Period Relative to Recent Period
Number of Cuttings	5	6	Lower
Yield, tons per acre	5.5	7.6	Lower
Irrigation applied, inches	46 to 52	60	Lower

Opinions

A reduction of five percent applied to the alfalfa and cotton ET_{aw} for the 1938 to 1953 period, reducing linearly from 1954 to zero reduction in 1970 is reasonable to accurately account for historical improvements in agricultural practices that include plant density and yield, and that have impacted ET_{aw}. ET_{aw} from 1970 through 2018 does not require adjustment.

IX. Irrigation Consumptive Use Coefficient

Purpose

The purpose of this section is to estimate the Irrigation Consumptive Use Coefficient (ICUC) under conditions of limited surface water supply, which is used to determine groundwater pumping before records became available. Burt, et al. (1997) defined the ICUC as the ratio of volume of irrigation water consumptively used to the quantity of the total volume of irrigation water applied minus the change in storage of irrigation water, both in a specified period of time and expressed as a percentage. Under conditions of limited surface water supply, the total volume of applied water (both surface water and groundwater) can be estimated as the evapotranspiration of applied water (ET_{aw}), often referred to as consumptive use of applied water, divided by the ICUC. Given the volume of surface water applied in a defined area, the groundwater pumping required to meet irrigation requirements can be calculated as the total volume of applied water minus the surface water applied.

Methodology

This section describes the methodology for estimating ICUC in each district for 1938 through 2018. First, irrigation performance measures are discussed and explanation is given for the selection of ICUC to estimate groundwater pumping under limited water supply conditions. The methodology used to calculate district-wide ICUC under conditions of limited surface water supply is then described for EBID. This is followed by description of the methodology used to extrapolate the ICUC values to the other districts and then the methodology to extrapolate the ICUC values to past years.

Irrigation Performance Measures

Many definitions have been proposed for Irrigation Efficiency (IE) and other irrigation performance measures. In 1997, Burt et al. (1997) reported on the results of the American Society of Civil Engineers (ASCE) Task Committee on Defining Irrigation Efficiency and Uniformity. This report, presented as a peer-reviewed technical article in the Journal of Irrigation and Drainage Engineering, describes seven irrigation performance indicators. Four indicators are used to characterize single irrigation event performance, while three – including ICUC and IE – are used to characterize overall project management over some time interval, such as an irrigation season or on an annual basis. More fundamentally, the report describes a peer-reviewed and widely accepted scientific and technical framework and approach to determine the appropriate irrigation performance indicator for a defined purpose.

In addition to ICUC, three of the most commonly used efficiency terms are IE, application efficiency (AE) and distribution uniformity (DU). AE and DU are used to evaluate efficiency for a single field, or sometimes smaller unit, and for a single irrigation event. Because a district-wide efficiency term is needed to estimate district-wide groundwater pumping volumes, only the ICUC and IE indicators, which can be applied to a field, farm, district, project, or basin are appropriate in this investigation.

Burt, et al. (1997) defined IE as the percentage of volume of irrigation water *beneficially* used relative to the total volume of irrigation water applied (**Equation 9-1**). The total volume of irrigation water applied is equal to the volume of irrigation water applied minus the change in storage of irrigation water. Irrigation water beneficially used can be either consumed or not consumed. For example, water used to leach salts from the root zone is beneficially used, but is not consumed; rather, it percolates below the root zone. Thus, IE requires quantification of all beneficial uses and an estimate of the change in storage of irrigation water to calculate the volume of irrigation water applied (**Equation 9-2**). However, the total volume of irrigation water beneficially used is not always quantified or easily estimated across an area as extensive as the Study Area.

$$IE = \frac{volume\ of\ irrigation\ water\ beneficially\ used}{volume\ of\ irrigation\ water\ applied - change\ in\ storage\ of\ irrigation\ water} \cdot 100$$ (**Eq. 9-1**)

$$volume\ of\ irrigation\ water\ applied = \frac{volume\ of\ irrigation\ water\ beneficially\ used}{IE} \cdot 100 + change\ in\ storage\ of\ irrigation\ water$$ (**Eq. 9-2**)

The ICUC, first described by Jensen (1993), is an alternative efficiency term that quantifies the percentage of irrigation water *consumed* relative to the total volume of irrigation water applied. This performance indicator is used to characterize overall project management and is calculated for a selected area and time interval, commonly for a complete irrigation season (**Equation 9-3**). Compared to irrigation water beneficially used, the volume of irrigation water consumptively used (ET_{aw}) is more readily quantified and estimated over large areas and extended time periods based on reference evapotranspiration derived from local weather and climate data and locally-calibrated crop coefficients. Thus, ICUC is a more appropriate term to use in this basin-scale study over an extended period of time.

$$ICUC = \frac{volume\ of\ irrigation\ water\ consumptively\ used}{volume\ of\ irrigation\ water\ applied - change\ in\ storage\ of\ irrigation\ water} \cdot 100$$ (**Eq. 9-3**)

Because the ICUC performance indicator quantifies *consumed* water as a percentage of irrigation water applied (applied water), the total volume of applied water can be determined by dividing ET_{aw} by the ICUC, multiplying by 100 and adding the change in storage of irrigation water (**Equation 9-4**).

$$volume\ of\ irrigation\ water\ applied = \frac{ETaw}{ICUC} \cdot 100 + change\ in\ storage\ of\ irrigation\ water$$ (**Eq. 9-4**)

When calculated for an entire irrigation season, the change in storage of irrigation water is often assumed to be zero. The volume of irrigation water stored in the root zone is generally low at both the beginning and end of the irrigation season. At the end, growers stop irrigating prior to harvest so that the fields and crops will be dry for harvest. At the beginning, storage of irrigation water is also low because no irrigation water has been applied since the end of the preceding irrigation season. For the Study Area, Hulsman (1983) concludes that the change in storage in the root zone over the irrigation season is near zero. Thus, the total volume of applied water can be calculated simply as the ETaw divided by the ICUC and multiplied by 100 (**Equation 9-5**).

$$volume\ of\ irrigation\ water\ applied = \frac{ETaw}{ICUC} \cdot 100$$ (**Eq. 9-5**)

Once the total volume of applied water is determined, the volume of groundwater pumped can be determined by subtracting the volume of surface water applied from the total volume of applied water (Equation 9-6).

$$volume\ of\ groundwater = volume\ of\ irrigation\ water\ applied - volume\ of\ surface\ water$$ (**Eq. 9-6**)

Likewise, ICUC for an entire irrigation season can be calculated from the total volume of applied water and ET_{aw} when values of both are available (**Equation 9-7**).

$$ICUC = \frac{ETaw}{volume\ of\ irrigation\ water\ applied} \cdot 100 \qquad \textbf{(Eq. 9-7)}$$

ICUC Calculations

To calculate ICUC (**Equation 9-7**), the volume of irrigation water consumptively used by crops (also referred to as ET_{aw}) and the volume of irrigation water applied over the time period selected must be known. These volumes must be specific to the area and time period considered. These data are only available for EBID and nearby irrigated lands with access only to groundwater during the period 2009 through 2016, when Reclamation Crop and Data Forms 7-316 and 7-2045 are available and contain sufficient information regarding applied irrigation water. Additionally, ICUC changes between years depending on water availability and related irrigation practices. Thus, to use ICUC to estimate groundwater pumping in years with limited surface water supply, the ICUC must be calculated during years with limited surface water supply. Data sources and calculations related to these considerations are described below.

ET_{aw}

ET_{aw} is based on crop coefficients developed from remotely sensed energy balance ET analyses for 2008 and calibrated through review of 2002 and 2013 METRIC results. The crop coefficients and resulting ET_{aw} volumes from the METRIC analysis and ET Demands root zone model were developed to represent full water supply conditions. Development of these values is described in detail in the Consumptive Use of Applied Water in the Rincon, Mesilla, El Paso and Juarez Valleys of the Rio Grande Report.

Volume of Irrigation Water Applied

The volume of irrigation water applied is based on EBID reports of total annual farm delivery volume provided to Reclamation. Beginning in 2008, the state of New Mexico required growers to measure and report the volume of groundwater pumped. The first full year with measurements of groundwater pumped was 2009. Thus, the years 2009 through 2016 include the best and most complete measurements of farm deliveries including groundwater pumping and estimates of the ET_{aw} demand for use in a district-wide annual ICUC analysis.

Limited Surface Water Supply

Growers generally prefer surface water when it is available because it is less expensive than groundwater because of pumping costs. When surface supplies are limited, growers implement additional management actions that, within limits, result in an increase in the ICUC. Thus, the ICUC used to calculate groundwater pumping is calculated for years with limited surface water supplies. Limited surface water supplies within the Study Area are generally defined as years having less than three acre-feet per acre of surface water available. For years that meet these criteria, the ICUC was calculated for EBID and nearby irrigated lands with access to only groundwater as the ET_{aw} divided by the total volume of water applied (equal to measured farm head gate deliveries plus measured groundwater pumped).

Extrapolate EBID ICUC Values to other Districts

The EBID ICUC values calculated for the period 2009 through 2016 were then extrapolated for all other districts in the Study Area having insufficient data to calculate separate district-specific ICUC values. Similarities and differences between EBID, EPCWID, Hudspeth and Juarez were evaluated with regards to factors affecting on-farm surface irrigation efficiencies. When districts were found to be dissimilar to EBID, the findings of these analyses were used to develop an adjustment factor for the ICUC calculated for EBID to account for differences in the physical and management situations in the other districts. Methodologies used to evaluate these similarities and differences are described for irrigation methods, field slopes, soils, field size, and water ordering and delivery flexibility in the following paragraphs.

Irrigation Methods

Irrigation methods are an important factor affecting ICUC values. In the US Districts, irrigation methods were identified from crop survey data. Crop survey data were unavailable in Juarez, so irrigation methods were assumed to be similar to methods in EPCWID and Hudspeth based on the similarity in terrain, soils, and cropping between these districts.

In 2008, the New Mexico Office of the State Engineer (NMOSE) conducted a ground crop survey by mapping and visual inspection to identify crops and irrigation methods in all irrigated fields in EBID (Longworth, 2011). A second crop survey[10] in 2016 identified crops and irrigation methods in a random sample of fields in EBID, EPCWID and Hudspeth. The random sample included 822 fields in EBID (covering 23 percent of the irrigated area), 279 fields in EPCWID (covering 14 percent of the irrigated area), and 112 fields in Hudspeth (covering 36 percent of the irrigated area). These surveys found that most fields in the Study Area are irrigated by surface irrigation methods. The three main surface irrigation methods observed – border, furrow and basin – are summarized below:

1. Border, or border strip, irrigation consists of a sloping strip of land that is level widthwise across the strip and bounded by borders so as to prevent water from spreading laterally (Burt et al, 2000). Water is released into the upper end of the strip and spreads longitudinally by gravity downslope along the strip. Border irrigation is generally used to irrigate alfalfa, pasture, grain and pecans in the Rio Grande Project area.
2. Furrow irrigation consists of a small, sloping channel in the soil between the crop rows (Burt et al, 2000). Water is released at the upper end of the furrow and flows downslope to the end of the field. Furrow irrigation is used to irrigate row crops, such as corn, cotton and miscellaneous vegetables.
3. Basin irrigation consists of a level, or nearly level, area of land bounded by dikes (Burt et al, 2000). Water is released into the basin and remains ponded until all the water infiltrates into the soil. Basin irrigation is generally used to irrigate alfalfa, pasture, grain and pecans in the Rio Grande Project area.

A few fields in the Study Area are irrigated by drip/micro irrigation. Drip/micro irrigation refers to irrigation methods in which water is delivered directly to small areas adjacent to plants through applicators, often simply small holes spaced along a pipe or tube delivering water (Burt et al, 2000).

Field Slopes

In the US Districts, ArcMap's 'Slope' tool was used to convert elevations from digital elevation model (DEM) datasets obtained from the National Map Viewer (USGS, 2017) to slopes. First, the DEM data were mosaicked to cover all the US Districts. DEM data for the Juarez area in Mexico were not available. Therefore slopes in Juarez were assumed to be similar to slopes in the US Districts based on their similarity in terrain. Next, the DEM data were resampled to a spatial resolution of 30 square meters using the cubic convolution method and reprojected in the NAD_1983_UTM_Zone_13N projection system[11]. After using the 'Slope' tool to convert the DEM elevation data to slopes, the slope data were extracted by field using ArcMap's 'Zonal Statistics as Table' tool with the Intera (2017) fields coverage.

---

[10] The survey methodology and results are described in detail in the Consumptive Use of Applied Water in the Rincon, Mesilla, El Paso and Juarez Valleys of the Rio Grande Report.

[11] Spatial coordinate projection systems are used to project locations on the Earth's surface to a two-dimensional Cartesian coordinate system. Each projection system relies on a spheroid to represent the approximately spherical

Soils

The Soil Survey Geographic Database (SSURGO) contains information about soil in the United States collected by the National Cooperative Soil Survey (NCSS). The NCSS is a nationwide partnership of federal, regional, state, and local agencies and private entities and institutions that cooperatively investigates, inventories, documents, classifies, interprets, disseminates, and publishes information about soils. The United States Department of Agriculture-Natural Resources Conservation Service (USDA-NRCS), formerly known as the Soil Conservation Service (SCS), organizes the NCSS and publishes scientifically sound and accepted standards for conducting soil surveys and classifying soils.

The SSURGO database is available on the internet and contains scientifically accepted and technically sound information on soils that was formerly provided in printed soil survey publications (SSURGO, 2014). Soils information is available for most areas in the United States, including New Mexico and Texas. The information in the database was gathered by observing the land and soil and collecting and analyzing soil samples (SSURGO, 2014). Soil maps in the database are commonly used in natural resource planning and management activities nationwide. Information available from the database includes soil infiltration characteristics, available waterholding capacity (AWC), and other data necessary for plant consumptive use analyses and other water resource engineering applications.

To characterize soils within the Study Area, the United States Department of Agriculture (USDA) textural classes were determined based on the percentage of sand and clay observed in the SSURGO database soil maps. The saturated hydraulic conductivity (K_{sat}) and AWC values were also obtained from SSURGO to characterize soil infiltration and AWC parameters, respectively, for each soil texture class. The procedures used to estimate these soil parameters are described in more detail in the Soils section of the Consumptive Use of Applied Water in the Rincon, Mesilla, El Paso and Juarez Valleys of the Rio Grande Report. Soil data for the portion of the Study Area in Mexico were not available in the SSURGO database, but were assumed to be similar to soils in the US Districts based on the similarity in soils on the west and east side of the Rio Grande in the Mesilla Valley.

Field Size and Head Ditch Lining

Field sizes were reviewed based on the most recent available field boundaries developed in GIS by Intera (2017) from aerial photographs. A head ditch is an irrigation ditch in a farm field from which irrigation water is diverted into furrows or border strips. Head ditches are often lined with concrete to reduce seepage into the ground. Information on head ditch lining was obtained from the Rio Grande Project Histories.

Water Ordering and Delivery Flexibility

Customer water ordering procedures and flexibility in the flow rate, duration, and timing of water deliveries together dictate the ability of irrigators to match water deliveries to individual fields' water needs and physical characteristics. To achieve high ICUC values, a district's flexibility in providing accurately timed water deliveries of requested flow rates and durations is important. Recent publications describing the districts' water ordering and delivery procedures were reviewed to assess similarities and differences among districts' abilities to support high ICUC values.

Extrapolate ICUC Values to Past Years

The calculated EBID ICUC values and the estimated ICUC values for all other districts were extrapolated to past years before 2009 and after 2016, when sufficient data were not available to calculate ICUC. The

---

surface of the Earth. For additional information, see http://resources.esri.com/help/9.3/arcgisengine/dotnet/89b720a5-7339-44b0-8b58-0f5bf2843393.htm.

ICUC values were extrapolated to years beyond 2009 to 2016 by adjusting for changes in the two main factors affecting ICUC values that have changed over time: irrigation methods and on farm irrigation system improvements. Historical information regarding each factor was extracted from the Rio Grande Project Histories and early research publications' descriptions of the Study Area. The Rio Grande Histories include annual reports by Reclamation summarizing Rio Grande Project operations for the years 1912 through 1988.

Results

The following sections present the results of the ICUC calculation for the EBID area; the evaluations of irrigation methods, field slopes, soils, field sizes, water ordering, and delivery flexibility used to extrapolate the EBID ICUC values to other districts; and the review of historical documents used to extrapolate the ICUC estimates to earlier years.

EBID ICUC Calculations

ICUC was calculated for EBID for 2009 through 2016. All eight years were considered to have limited surface water supplies, because the farm deliveries per irrigated area with access to surface water was less than three acre-feet per acre in all years, varying from 0.30 to 2.64 acre-feet per acre (**Table 9-1**). When the farm deliveries are combined with the available pumping data and the irrigated area with access to only groundwater are included, the total applied water increased to 3.68 acre-feet per acre or more in all eight years, exceeding limited supply conditions. Thus, it is reasonable to assume that groundwater pumping supplied enough water to meet the full ET demand of crops in EBID. The ICUC was calculated to range from 69 to 87 percent with an average of 76 percent (**Table 9-2**). The highest ICUC of 87 percent occurred in 2011, the year with the maximum reference ET in the 1936 to 2018 time period. The minimum ICUC of 69 occurred in 2015, a year of relatively low reference ET and irrigated area.

Extrapolate ICUC Estimates to other Districts

Similarities and differences between EBID, EPCWID, Hudspeth and Juarez were evaluated with regards to factors affecting on-farm surface irrigation efficiencies. These evaluations were used, if needed, to develop an adjustment factor for the EBID ICUC to reflect differences in the physical and management situations in the other districts. Results of the methodologies used to evaluate similarities and differences in irrigation methods, field slopes, soils, field sizes, and water ordering and delivery flexibility are described in the following paragraphs.

Table 9-1. Annual Surface Water Deliveries and Groundwater Pumping for EBID for years with GW Pumping Measurements.

Year	Farm Deliveries (Surface Water), acre-feet*	Groundwater Pumping, acre-feet	EBID SW Irrigated Area, Acres	GW Only NM Irrigated Area, Acres	Farm Deliveries (Surface Water) per acre, feet	Total Applied Water per acre, feet
2009	187,694	131,000	71,210	4,397	2.64	4.22
2010	155,416	138,000	74,875	4,794	2.08	3.68
2011	24,149	279,000	71,592	4,411	0.34	3.99
2012	53,756	265,000	68,110	4,415	0.79	4.40
2013	21,817	286,000	72,494	4,706	0.30	3.99
2014	39,999	252,000	72,124	4,646	0.55	3.80
2015	70,416	219,000	69,057	4,559	1.02	3.93

*2012-2014 estimated based on 2011 delivery efficiency and 2016 estimated based on 2015 delivery efficiency

Irrigation Methods

The 2008 ground survey of crops and irrigation methods in EBID completed by NMOSE staff (Longworth, 2011) found that combined border and basin irrigation (recorded as "flood" in the database) was the most prevalent irrigation method used on 78 percent of the fields. Furrow irrigation was the next most prevalent method used on 19 percent of the fields, while sprinkler and drip irrigation together were used on just under three percent of the fields. The 2016 survey[12] visited a random sample of 822 fields in EBID covering 23 percent of the irrigated area and found 75 percent of the sampled fields used the border or basin irrigation method (often referred to locally as flood irrigation). The furrow irrigation method was used on 22 percent of the sampled fields and drip or sprinkler irrigation was used on four percent of the sampled fields. This survey also observed and identified irrigation methods on a random sample of 279 and 112 fields in EPCWID and Hudspeth, respectively covering 14 and 36 percent of the irrigated area. In EPCWID, the survey found 50 percent of the sampled fields using border or basin and

[12] The survey methodology and results are described in detail in the Consumptive Use of Applied Water in the Rincon, Mesilla, El Paso and Juarez Valleys of the Rio Grande report.

50 percent of the sampled fields using furrow irrigation methods. In Hudspeth, the survey found 35 percent of the sampled fields using border or basin and 65 percent of the fields using furrow irrigation methods. The greater percentage of furrow irrigation found in EPCWID and Hudspeth is consistent with the greater percentage of irrigated cotton acreage found in EPCWID and Hudspeth compared to EBID. No drip or sprinkler irrigation was observed in EPCWID or Hudspeth. Based on the similarity in terrain, soils and cropping in Juarez, the irrigation methods are assumed to be similar to those in EPCWID and Hudspeth. Given the similarity in irrigation methods across the districts, an ICUC adjustment factor for irrigation method differences across districts is not needed.

Field Slopes

Irrigated areas in the Study Area are generally located on the valley lowlands with gentle slopes next to the Rio Grande. Additionally, nearly all the fields in the US Districts have been laser leveled to uniform and precise slopes. As part of a 1980 to 1982 study on irrigation efficiency, Hulsman (1983) measured slopes on 16 irrigated fields in EBID with nine different crops and all fields had slopes less than 0.2 percent. The DEM analysis described earlier also found that 70, 59, and 65 percent of the fields in EBID, EPCWID and Hudspeth, respectively, had slopes equal to or less than 0.5 percent. The topography in the US Districts and Juarez is similar, thus field slopes in Juarez are likely similar to those observed in the US Districts. Given the similarity in field slopes across all districts, an ICUC adjustment factor for field slope differences is not needed.

Soils

Soil textures within fields have important effects on irrigation performance. A soils analysis was completed using the SSURGO database compiled by NCSS (SSURGO, 2014) and is documented in a Soils section of the Consumptive Use of Applied Water in the Rincon, Mesilla, El Paso and Juarez Valleys of the Rio Grande Report. Sample results of that analysis are briefly summarized in Table 3 below. Soil textures in the three districts are generally similar and comprised of loamy Soils. Five textures – clay loam, loam, sandy loam, sandy clay loam, and silt loam – together comprise 88, 85, and 100 percent of the area cropped in EBID, EPCWID and Hudspeth, respectively. Detailed soil texture data are not available for the Juarez District in Mexico, but are assumed to be similar to the US Districts based on the similarity in soils on the west and east side of the Rio Grande in the Mesilla Valley.

As indicated in **Table 9-3**, the K_{sat} values in EBID and Hudspeth are greater compared to those measured in EPCWID and estimated for Juarez, but the soils are predominantly loamy in all districts with similar AWC values. Given the similarity in soil texture and AWC values across the districts, an ICUC adjustment factor for soil differences is not needed.

Table 9-3. K_{sat}, and AWC Values for the Study Area.

District	Ksat (in/hr)	AWC (in/ft)
EBID	5.69	1.65
EPCWID*	1.98	1.75
Hudspeth	6.09	1.79
Juarez	2.14	1.77

*In general loamy soils in the El Paso Valley portion of EPCWID contain higher percentages of clay than those in the Mesilla and Rincon Valleys resulting in lower K_{sat} values. This value is a weighted average that includes both the portion of EPCWID in the Mesilla Valley and the portion in the El Paso Valley.

Field Size and Head Ditch Lining

Field sizes are predominately in the 20 to 50-acre category in all districts, with 44, 48 and 49 percent of the fields in EBID, EPCWID and Hudspeth, respectively, falling within this range based on the Intera (2016) field boundaries. Field sizes tend to be slightly smaller in EBID, where the average field size is 19.0 acres compared to 24.1 and 25.7 acres in EPCWID and Hudspeth, respectively. Field sizes in Juarez are similar to those in the US Districts. Per the Rio Grande Project Histories, nearly all field ditches have been concrete lined since the 1950s in all Districts. The field sizes in the three US Districts and Juarez are similar and an adjustment factor related to field size is not needed. Since nearly all field ditches were lined over a two to three-year period during the drought in the early 1950s, an ICUC adjustment factor for differences in field ditch lining is also not needed.

Water Ordering and Delivery Flexibility

EBID typically delivers water within three days of an order being placed by a grower (DeMouche, 2004). EPCWID typically delivers water within three or sometimes four days of an order being made (EPCWID, 2017). Information on water ordering and delivery procedures for Hudspeth and Juarez was not found, but they are assumed to be similar to EBID and EPCWID practices based on similarity in regional agricultural practices, irrigation methods, and cropping. As the water ordering and delivery constraints in the districts are considered similar, an ICUC adjustment factor for water ordering and delivery flexibility differences is not needed.

Summary

As discussed above, the factors that affect ICUC in the Study Area are similar between all the Districts. As such, the ICUC is not expected to be different between the US Districts and Juarez due to these factors. Thus, the ICUC calculated for EBID does not require adjustment, and use of the EBID ICUC value for all districts is reasonable.

Extrapolate ICUC Estimates to Other Years

The calculated EBID ICUC values used for all districts during 2009 through 2018, as described above, were finally extrapolated to past years before 2009 when sufficient data were not available to calculate ICUC directly. These values were adjusted for changes in irrigation methods and on farm irrigation system improvements, as identified from historical documents.

The Rio Grande Project Histories (annual reports by Reclamation summarizing Rio Grande Project operations for the years 1912 through 1988) describe the main irrigation methods in use and improvements that occurred in the Study Area. With respect to the surface irrigation methods that are most common in the Study Area, the two practices described in the histories that have the greatest effect on ICUC values are improved land leveling with “bulldozers and carryalls” in the 1940s and 1950s, and the lining of field ditches in the 1950s. Additionally, with the advent of laser leveling practices in the 1970s and 1980s, fields in the project were leveled with increased uniformity and precision of field grades. Most fields receive touch up leveling every year or two.

Laser leveling has been estimated to increase on-farm efficiency by about five to ten percent (Daubert and Ayer, 1982) and was quickly adopted by most growers in the Study Area in the early 1980s. The average EBID ICUC value of 76 percent from 2009 through 2016 is therefore recommended for calculating total water deliveries and corresponding groundwater pumping in years with limited surface water supply between 1984 and 2018 (**Table 9-4**). Common use of laser leveling practices began in about 1980 and by 1984 laser leveling was used by most fields in the Study Area. This improvement led to an estimated increase in efficiency of five percent. Between 1955 and 1979, prior to the use of laser leveling, the calculated ICUC is estimated to be reduced five percent from 76 to 71 percent (Table 4). During the transition period between 1980 and 1983, the district-wide ICUC is estimated to increase by one percent each year, from 72 to 74 percent.

The other significant change in surface irrigation practices was triggered by the drought in the early 1950s (Reclamation, 1951). Due to the limited surface water supply, head ditches were lined throughout the Study Area and improved land leveling practices using bulldozers and carryalls were adopted. Together, these improvements are estimated to have increased the district-wide ICUC by five percent. Prior to 1950, the district-wide ICUC is estimated to be reduced five percent from 71 to 66 percent (**Table 9-4**). During the assumed five-year transition period when the improvements were taking place (1951 to 1954), the district-wide ICUC is assumed to increase by one percent each year from 67 to 70 percent.

Table 9A-1 provides a full summary of the annual ICUC values by district between 1938 and 2018. These values were ultimately used to estimate groundwater pumping before records became available.

Opinions

The ICUC estimates developed here and listed in **Table 9-4** and **Table 9A-1** are district-wide, annual values expressing consumption of irrigation water given irrigation performance when surface water supply is limiting. These average values reflect a large variability across the many fields of the Study Area. Notably, under conditions of limited surface water supply, growers apply additional management actions that may increase on-farm efficiencies that are reflected in increased ICUC values. Thus, in years having sufficient water supplies, the actual district-wide ICUC is less than the ICUC estimates described in this report. In addition, ICUC has changed over time with changes in on-farm practices. The main changes noted in the Study Area have been improved land leveling technologies and lining of head ditches. These on-farm improvements are reflected in the adjustments to ICUC estimates for earlier years.

Table 9-4. ICUC Values for Each Irrigation Unit for 1938 through 2018.

Years	EBID, EPCWID and Hudspeth	Comment
1984 to 2018	76%	Calculation of ICUC based on METRIC and ET Demands results and reported farm deliveries and groundwater pumping in EBID
1983	75%	One percent per year increase in ICUC as fields are laser leveled over a five-year period
1982	74%	
1981	73%	
1980	72%	
1955 to 1979	71%	Calculated ICUC minus five percent (laser leveling improvement has not occurred during this period, leveling has been improved and farm ditches lined compared to 1938 through 1950)
1954	70%	One percent per year increase in ICUC due to improved leveling and farm ditch lining over a five-year period
1953	69%	
1952	68%	
1951	67%	
1938 to 1950	66%	Calculated ICUC minus ten percent (five percent for improved leveling and lined farm ditches from 1951 through 1954 and five percent for laser leveling from 1980 through 1983

X. Bare Ground Evaporation from Groundwater

Purpose

The purpose of this section is to describe the development of the parameters used to calculate bare ground evaporation in the groundwater models encompassing the Rio Grande Valley from below Caballo Reservoir, New Mexico, to Fort Quitman, Texas. Groundwater in the Study Area is simulated by two groundwater models, the Rincon/Mesilla and Hueco groundwater models, that generally cover the New Mexico and Texas model areas, respectively.

Evaporation from bare ground is a necessary element of consumptive use of water in a groundwater model. Water that evaporates from bare ground can come from precipitation or from shallow groundwater that is made available at the ground surface through capillary rise. This process is limited by the depth to groundwater. Maddock, et al. (2005) describes a methodology used by a groundwater model to estimate evaporation of groundwater from bare ground that requires potential evaporation from groundwater, the rate of capillary rise as a function of depth to groundwater (called the transpiration flux curve for vegetation and referred to as the evaporation flux curve in this document) and an extinction depth. This section briefly describes an accepted scientific method to determine the potential bare ground evaporation from groundwater, the evaporation flux curve, and the extinction depth that accurately simulates bare ground evaporation in the Study Area.

Methodology

The following sections describe the methodology used to determine the potential bare ground evaporation from groundwater, the evaporation flux curve and the extinction depth.

Potential Bare Ground Evaporation from Groundwater

Potential evaporation is defined as "the rate of evaporation from a surface when all surface interfaces are wet or from a free water surface, so that there is no surface restriction on the rate" (ASCE, 2016). Potential evaporation from groundwater is calculated as the potential evaporation (assuming a continuously wet soil surface with water supplied by precipitation and groundwater) minus the evaporation from precipitation. This calculation accounts for evaporation from precipitation when available, so that the remaining water that is evaporated represents the potential groundwater that could be evaporated if the water table is at, or near, the ground surface and supplies water for evaporation through capillary rise. This potential evaporation from groundwater is limited by the availability of groundwater as defined by the evaporation flux curve in the next section.

An accepted method to determine total evaporation and the evaporation from precipitation is to use a daily root zone water balance model that uses the Food and Agricultural Organization 56 (FAO 56) model to estimate evaporation from a bare ground surface (FAO, 1998 and ASCE, 2016). Mutziger, et al (2006) evaluated the FAO 56 model using seven data sets from the literature. Their root zone water balance results suggested a model accuracy of about +/-15 percent.

For this study, the ET Demands Root Zone model (referred to as the ET Demands model) was selected because it has been widely applied to compute consumptive water use and to study the potential effects of climate change on agricultural water demands (Allen and Robison, 2009 and Allen and Huntington, 2010, Allen and Huntington, 2015, and Reclamation, 2015). ET Demands utilizes the FAO 56 method for estimating evaporation from bare, wet ground and follows a dual crop coefficient approach, using basal crop coefficients to more accurately account for evaporation resulting from rainfall and local irrigation practices.

The reference ET (ET_o) and precipitation data developed for the analysis were based primarily on the Leyendecker and Art Ivey weather stations in the New Mexico and Texas model areas simulated by the Rincon/Mesilla and Hueco groundwater models, respectively.

Following the ASCE (2016) methodology for determining bare ground evaporation, the potential bare ground evaporation is calculated by multiplying the ET_o by an evaporation coefficient, K_e, equal to 1.2, as recommended by technical publications (ASCE, 2016). Each month will have a different potential bare ground evaporation depending on ET_o for that month. To estimate bare ground evaporation from precipitation, an ET Demands model run was completed for bare ground with precipitation as the only water source (i.e. with no irrigation water or groundwater available for evaporation). The potential bare ground evaporation from groundwater was calculated as the potential bare ground evaporation minus the bare ground evaporation from precipitation.

Evaporation Flux Curve

The transpiration flux curve provides information on how the transpiration flux changes as the depth to groundwater changes (Maddock, 2005). For bare ground, this curve can be called an evaporation flux curve. Groundwater can contribute to evaporation from bare ground when the water table is at, or near, the land surface. As water is consumed by bare ground evaporation, groundwater from the water table can rise through capillary action into the effective evaporation layer of soil, from which evaporation occurs. This process is referred to as "capillary rise." The rate of capillary rise depends on the soil texture, the depth to the water table, and the soil water content of the upper soil profile (ASCE, 2016). The following sections describe the methodology for determining the soil textures underlying the bare ground in the two model areas, the regression equations describing capillary rise in each soil texture, and the use of those equations to estimate the evaporation flux curve.

Soils

Bare ground soil textures in the Rincon/Mesilla model area were determined based on the riparian sub-areas defined as 'bare' ground in the groundwater model and the soil textures found in these sub-areas in the Soil Survey Geographic (SSURGO, 2014) database.

Inputs to the Rincon-Mesilla groundwater model delineate the riparian corridor and subdivide it into discrete sub-areas with attributes quantifying the percent of bare ground and vegetation in each. The 2004 snapshot of the riparian corridor totals 13,099 acres, of which 10,036 acres are bare ground. The Rio Grande River located in the riparian corridor (which is identified as 'bare ground') was excluded from this analysis by applying a 50-meter buffer from approximately the centerline of the river. Only those sub-areas having at least 80 percent 'bare' ground and outside of the 50-buffer from the Rio Grande centerline, totaling 6,500 acres, were included when identifying primary soil textures in areas of bare ground. The soils in this snapshot are generally representative of the soils in the 'bare' ground model areas through time.

Bare ground soil textures in the Hueco model were also determined based on the sub-areas defined as 'bare' ground in the groundwater model and the Soil Survey Geographic (SSURGO) database. The SSURGO database contains information about soil in the United States collected by the National Cooperative Soil Survey (NCSS). The NCSS is a nationwide partnership of federal, regional, state, and local agencies and private entities and institutions that cooperatively investigates, inventories, documents, classifies, interprets, disseminates, and publishes information about soils. The United States Department of Agriculture-Natural Resources Conservation Service (USDA-NRCS), formerly known as the Soil Conservation Service (SCS), organizes the NCSS and publishes scientifically sound and accepted standards for conducting soil surveys and classifying soils.

The SSURGO database is available on the internet and contains scientifically accepted and technically sound information on soils that was formerly provided in printed soil survey publications (SSURGO, 2014). Soils information is available for most areas in the United States, including New Mexico and Texas. The information in the database was gathered by observing the land and soil and collecting and analyzing soil samples (SSURGO, 2014). Soil maps in the database are commonly used in natural resource planning and management activities nationwide. Information available from the database includes soil infiltration characteristics, available waterholding capacity (AWC), and other data necessary for plant consumptive use analyses and other water resource engineering applications.

The soil survey only covers the portion of the Hueco model within the United States (north of the Rio Grande). Similar to the Rincon/Mesilla model, the Hueco model specifies the percent 'bare' ground within each 10-acre sub-area. There are 13,323 acres (excluding Juarez) of 'bare' ground identified in the portion of the alluvial corridor of the Hueco model north of the Rio Grande. Only those 10-acre areas containing at least 80 percent 'bare' ground and located within the United States were included in the analysis to identify primary soil textures in areas of bare ground.

Capillary Rise Equations

Regression equations (**Eq. 10-1**) are available to estimate capillary rise based on depth to groundwater for each soil texture. These equations are based on simulations using UPFLOW (Raes and deProost, 2003 and Raes 2004), a software tool that estimates capillary rise using an analytical technique based on Brutsaert (1982).

$$CR = a_f * d_w \hat{} b_f \quad \text{(Eq. 10-1)}$$

In these equations, CR is capillary rise in millimeters per day (mm/day), d_w is the depth to groundwater from the ground surface in meters (m), and a_f and b_f are regression parameters (unitless) (**Table 10-1**). The resulting capillary rise is converted to inches per day. The effective evaporation surface layer was assumed to be dry and have a depth of four inches, per accepted methods given the Study Area climate and soil conditions (ASCE 2016).

Table 10-1. Regression Parameters for Capillary Rise (millimeters per day) in Dry Soil to the Soil Surface for Evaporation (Reproduced from ASCE 2016) for the Three Most Common Bare Ground Soil Textures.

Groundwater Model	Soil	a_f	b_f	R^2*
Rincon/Mesilla	Sandy Loam	0.94	-3.02	0.99
Rincon/Mesilla	Loamy Sand	1.89	-2.85	0.99
Rincon/Mesilla	Sand	1.44	-2.98	1.00
Hueco	Loam	4.32	-2.45	0.99
Hueco	Sand	1.44	-2.98	1.00
Hueco	Clay Loam	0.27	-1.54	0.99

*Regression coefficient of determination for the associated regression parameters.

Evaporation Flux Curve

The evaporation flux curve is developed from the capillary rise equation discussed in the previous section in two steps. First, the depth to groundwater (d_w) is plotted on the y-axis and the evaporation flux, or capillary rise (CR), is plotted on the x-axis. Second, at the groundwater depths where the evaporation flux is greater than the potential bare ground evaporation from groundwater calculated above, the evaporation flux is set equal to the potential bare ground evaporation from groundwater.

Results

The following sections describe the results of the methodologies above for the potential bare ground evaporation from groundwater, the evaporation flux curve, and the extinction depths in the Rincon/Mesilla and Hueco model areas.

Potential Bare Ground Evaporation from Groundwater

Sample monthly values for ET_o, potential bare ground evaporation, precipitation, bare ground evaporation from precipitation, and potential bare ground evaporation from groundwater are presented in **Table 10-2** for the 2008 Rincon/Mesilla groundwater model year. Daily ET Demands model results are summed by month for presentation in the table. **Appendices 10A and 10B** provide monthly values for 1938 through 2018 for the Rincon/Mesilla and Hueco groundwater model areas, respectively.

Evaporation Flux Curve

The following sections describe the soil textures found to underlie bare ground in the two model areas, as well as the capillary rise and evaporation flux curves developed for these soils.

Soils

Sandy loam, loamy sand, and sand together underlie 89 percent of bare ground in the Rincon/Mesilla model area (**Table 10-3**) based on soil textures underlying the riparian corridor sub-areas that are at least 80% bare ground and outside a 50-meter buffer of the Rio Grande centerline.

Table 10-2. Potential* Bare Ground Evaporation from Groundwater for the Rincon/Mesilla Model for 2008, all Values are in Inches.

Month	Leyendecker ET_o, in	Potential Bare Ground Evaporation, in	Precipitation, in	Bare Ground Evaporation from Precipitation, in	Potential Bare Ground Evaporation from Groundwater, in**
1	2.7	3.3	0.0	0.0	3.3
2	3.9	4.6	0.2	0.2	4.5
3	5.8	7.0	0.0	0.0	7.0
4	7.0	8.3	0.0	0.0	8.3
5	8.0	9.6	0.0	0.0	9.6

8	6.3	7.5	2.5	2.1	5.4
9	5.0	6.1	0.8	0.8	5.3
10	3.9	4.7	0.3	0.3	4.4
11	2.7	3.3	0.4	0.4	2.9
12	2.3	2.8	0.1	0.1	2.7
Totals	63.1	75.8	9.3	5.9	69.8

*Assumes groundwater remains near the ground surface so a water supply is continuously available for evaporation.

**Results for Potential Bare Ground Evaporation from Groundwater differ from the calculation of Potential Bare Ground Evaporation minus Bare Ground Evaporation from Precipitation by 0.1 inch in February and July due to rounding.

Table 10-3. Soil Textures in Riparian Sub-Areas that are at Least 80% Bare Ground within the Rincon/Mesilla Model Area.

Texture	Area*, Acres	Percent of Sample, %
sandy loam	2,689	41%
loamy sand	1,565	24%
sand	1,544	24%
Subtotal	5,798	89%
loam	506	8%
silt loam	91	1%
clay loam	59	1%
sandy clay loam	47	1%
clay	0	0%
Total	6,500	100%

***includes areas from riparian corridor outside 50-meter buffer of Rio Grande centerline with 80% or greater bare ground.**

Loam, sand, and clay loam together underlie 83 percent of bare ground in the Hueco model north of the Rio Grande (**Table 10-4**) based on soil textures underlying the 10-acre sub-areas that are at least 80% bare ground.

Table 10-4. Soil Textures in Sub-Areas that are at Least 80% Bare Ground within the Hueco Model Area.

Texture	Area*, Acres	Percent of Sample, %
loam	2,124	33%
sand	1,918	30%
clay loam	1,255	20%
Subtotal	5,297	83%
loamy sand	324	5%
sandy loam	285	4%
silt loam	214	3%
clay	147	2%
silty clay loam	72	1%
sandy clay loam	1	0%
Total	6,340	100%

*Includes the area of all 10-acre sub-areas from the Texas alluvial corridor with at least 80% bare ground and within the United States.

Capillary Rise Equations in Bare Ground Evaporation

The rate of capillary rise, or evaporation flux, from groundwater to the ground surface was calculated as a function of depth to the groundwater table using the regression equation identified in **Eq. 1** and the regression parameters identified in **Table 10-1**. Curves were developed to calculate evaporation flux for dry conditions and the three most common soil textures underlying bare ground in the riparian sub-areas along the Rio Grande in the Rincon/Mesilla and Hueco model areas. **Table 10-5** shows an example of the evaporation flux (in inches per day, in/day) from groundwater calculated for increasing depth to the groundwater table (in feet, ft) in June 2008. For the Hueco groundwater model, soils data from Mexico were not available, so soils were assumed to be similar to the soils on the Texas side of the Rio Grande.

Fluxes to the evaporation layer for the three main soil textures in the Rincon/Mesilla model area are similar (**Figure 10-1**). The three main soil textures in the Hueco model area have a wide range in fluxes to the evaporation layer, but the average flux is similar to the average flux from the soils in the Rincon/Mesilla model area (**Figure 10-2**).

Evaporation Flux Curve

Figure 10-3 shows the evaporation flux curve for bare ground in the Rincon/Mesilla model area during June 2008, showing a potential bare ground evaporation from groundwater rate of up to 0.337 inches per day that corresponds to 10.1 inches of total potential evaporation during that month (**Table 10-2**). Below the point of intersection of the potential bare ground evaporation from groundwater with the evaporation flux curve, bare ground evaporation from groundwater is limited by the depth to the groundwater table. **Table 10-5** provides the evaporation flux to the surface as the depth to groundwater increases by increments of 0.5 feet in June 2008.

Table 10-5. Evaporation Flux from Groundwater to the Surface Evaporation Layer for a Bare Ground and Dry Soil Condition as a Function of the Soil Texture and Depth to Groundwater for the Rincon/Mesilla and Hueco Models in June 2008.

Depth to Groundwater, ft	Evaporation Flux, in/day				Evaporation Flux, in/day

*Maximum depth to groundwater at which evaporation flux equals the potential bare ground evaporation from groundwater in the Hueco model.
**Maximum depth to groundwater at which evaporation flux equals the potential bare ground evaporation from groundwater in the Rincon-Mesilla model.

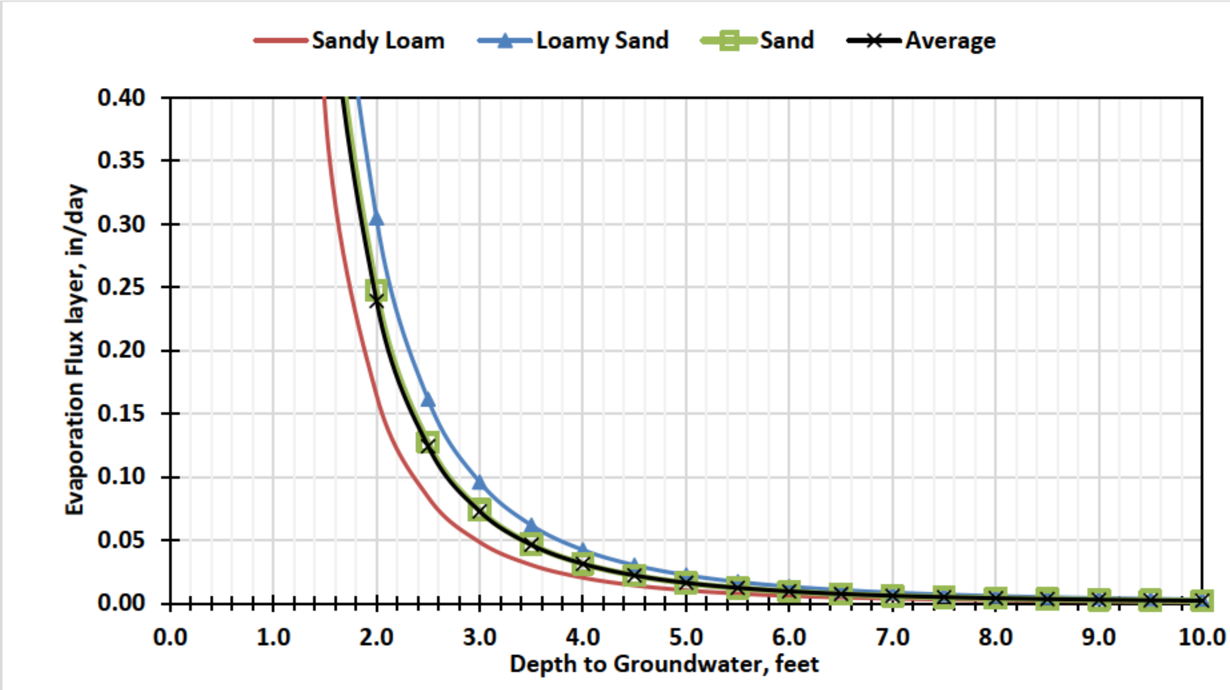

Figure 10-1. Capillary Rise, or Evaporation Flux, from Groundwater to the Surface Evaporation Layer for a Bare Ground and Dry Soil Condition as a Function of the Soil Texture and Depth to Groundwater in the Rincon/Mesilla Model Area.

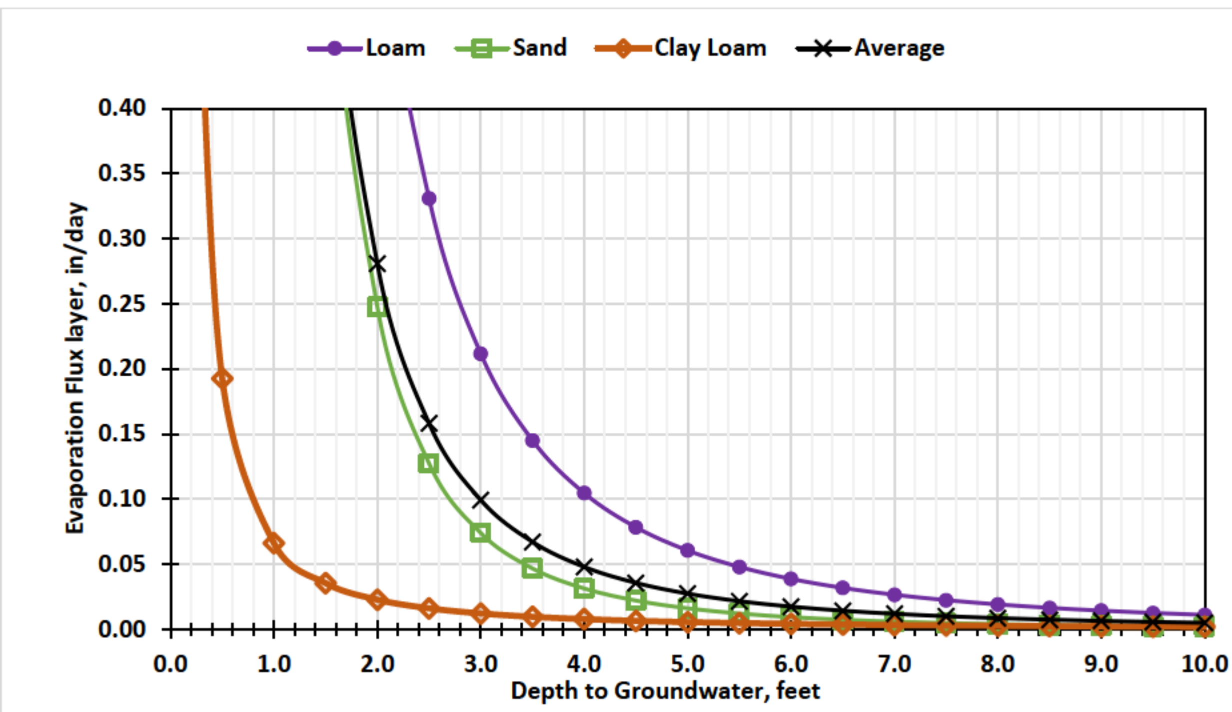

Figure 10-2. Capillary Rise, or Evaporation Flux, from Groundwater to the Surface Evaporation Layer for a Bare Ground and Dry Soil Condition as a Function of the Soil Texture and Depth to Groundwater in the Hueco Model Area.

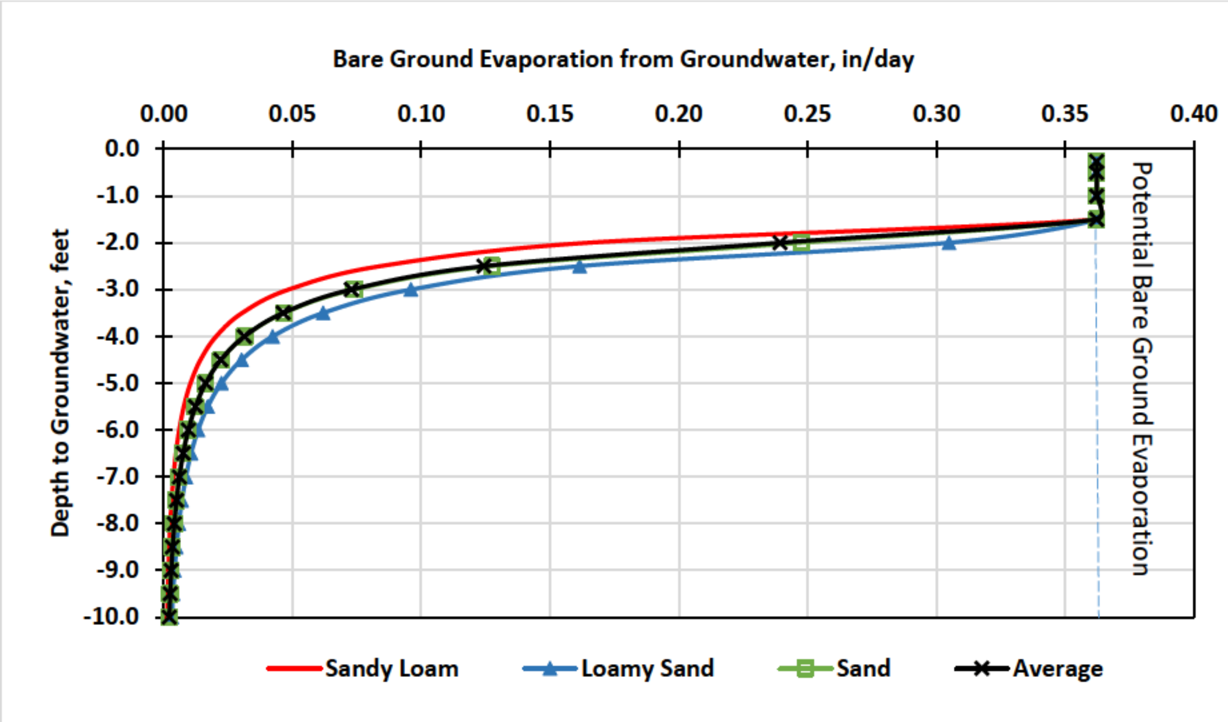

Figure 10-3. The Evaporation Flux from Bare Ground as a Function of the Soil Texture and Depth to Groundwater in the Rincon/Mesilla Groundwater Model Area for June 2008.

As described above, the potential bare ground evaporation from groundwater in a given month varies depending on ET_o and precipitation, thus the point at which the curve becomes vertical is different in each month. Monthly values are provided in Appendices 10A and 10B for the Rincon/Mesilla and Hueco model areas, respectively.

Extinction Depth

For all soil textures, the flux to the effective surface evaporation layer becomes increasingly closer to zero at 7 and 9 feet below the surface for the Rincon/Mesilla and Hueco models, respectively. The point where the flux begins to change by 0.001 inch per day for each 0.5 feet of decrease in depth to the groundwater is approximately the point at which the capillary rise is two percent of the potential evaporation. Thus, 7 and 9 feet below the surface is recommended for the extinction depth for the Rincon/Mesilla and Hueco models, respectively. The recommended extinction depths are summarized in **Table 10-6**.

Table 10-6. Recommended Extinction Depths by Region for Bare Ground Evaporation.

Region	Land cover	Extinction Depth, ft
Rincon/Mesilla	Bare Soil	7
Hueco	Bare Soil	9

Opinions

Bare ground evaporation from groundwater is an important outflow from the groundwater system and depends primarily on climatic demand and depth to groundwater. Evaporation flux curves have been developed to estimate bare ground evaporation from groundwater for groundwater modeling. These curves have a maximum evaporative flux, termed the potential bare ground evaporation from groundwater, that represents the maximum potential bare ground evaporation from groundwater that can occur when groundwater levels are close to the ground surface. The rate and depth to groundwater at which this occurs varies based on climatic demand, precipitation, and soil texture. When the depth to groundwater is below this level, the bare ground evaporation is limited by the capillary rise from the groundwater table to the evaporative layer.

XI. Technical Rebuttal of Expert Reports

Introduction

The purpose of this report is to provide a rebuttal to the following expert reports disclosed by Texas:

- Expert report of Dr. Joel E. Kimmelshue of Land IQ, LLC, titled *Land use Classification and Consumptive Use estimates for the Rincon, Mesilla, and El Paso Valley from 1936 to 2018* (henceforth referred to as the *Land IQ Report*).
- Expert report of Mr. Staffan W. Schorr and Dr. Colin P. Kikuchi of Montgomery & Associates, Inc., titled *Water Budget Estimates in Support of Groundwater Model Development: Rincon and Mesilla Basins, New Mexico, Texas, and Northern Mexico, 1938 through 2016* (henceforth referred to as the *Montgomery & Associates Report*).

The rebuttal of each report is presented in the order given above. Each rebuttal is organized by topic to summarize and critique major elements of each report. Each section includes a technical evaluation with supporting information to support the rebuttal opinions, followed by a statement of the New Mexico technical experts' opinions.

In summary, the use of potential crop coefficients rather than average, actual crop coefficients, as recommended by standard, recommended procedures (ASCE, 2016 and ITRC, 2019) for historical water balance analyses, leads to an overestimation of crop consumptive use by Land IQ. This overestimate, compounded by use of non-standard procedures for the soil water budget by Montgomery & Associates leads to a gross overestimation of the pumping necessary to meet consumptive use requirements.

Technical Rebuttal of Land IQ Report

This rebuttal centers on technical critiques of the methodologies to support land use classification and consumptive use estimation in the *Land IQ Report,* as well as the lack of clarity and detail provided therein. The report lacks sufficient documentation or data to support the opinions tendered by Dr. Kimmelshue.

Each of these critiques and objections is identified below under the applicable sections, by topic. Each section begins with a technical evaluation with supporting information to support the rebuttal opinions and concludes with a summary of the New Mexico technical experts' opinions.

Agricultural Land Use

In general, the *Land IQ Report* lacks sufficient detail to thoroughly explain how the land use classification analysis was completed. The level of detail provided in the disclosed report does not allow for replication or evaluation of each step within the procedure, and does not support the opinions tendered by Dr. Kimmelshue. Additionally, the time step of data used to define annual land use acreage (approximately one year per decade for agricultural land) is inadequate to accurately represent annual land use changes and does not fully utilize the abundance of data available in other years, such as annual reports from the U.S. Bureau of Reclamation, aerial photography, and remote sensing-based land use information.

Annual Land Use Analyses

Technical Evaluation

The technical experts for Texas state that they developed a spatial land use database for the period 1936-2018 based on image analyses (maps, aerial photos, and/or satellite imagery) and annual crop reports. Agricultural land use maps were developed approximately once per decade between 1936-2018 (more frequently since 2006), and riparian land use maps were developed for four years (Exhibit 45 lists 1955, 2005, 2014 and 2016). These generated maps were used with annual crop reports and field survey data to interpolate to annual land use datasets.

The agricultural land use maps identify spatial crop distribution. Prior to 1986, field-level crop classification was estimated from aerial photos and crop reports (1955, 1966, 1975) and from Rio Grande Joint Investigative Report maps and survey tables (1936). At minimum, these data sources were used to determine whether or not fields were irrigated. Beginning in 1986, a random forest classification algorithm was used to classify crop types from imagery (1986, 1996, 2006, 2011, 2014, 2016, 2018).

Depending on available data sources, between 5 and 34 individual crops and land use classes were identified in each of the years above. The annual land use analysis methodologies described in the report provide only high-level information on image sources and incomplete descriptions of classification algorithm procedures.

Opinion

The *Land IQ Report* lacks clear and sufficient information necessary to confirm the accuracy of the land use classification procedures, which are central to estimating consumptive use:

- **Classification accuracy of the crop classification algorithm**: Classification algorithms require training data. In random forest algorithms, such as those used in the *Land IQ Report*, error is closely related to the size of training/test data sets, the number of variables and categories used, and the tunable parameters that govern the random forest's development (Breiman, 2001; Tang, Garreau, and von Luxburg, 2018). Additionally, standard methodologies require training data to be from the year of analysis and indicate that observed field data from the same year produces the best accuracy. LandIQ had only field data available for training in 2014 and in 2018. In 2016, the LandIQ report states that the 2014 field data were used. Using field data from an earlier year is reasonable for a crop like pecans that can be expected to be the same two years later. However, it is not clear what LandIQ did for annual crops that may be different in 2016. For earlier years, the LandIQ report states that photo interpretation was used to crops for training sites. Reduced accuracies can be expected in the years when observed field data from that year are not available. While the Texas technical expert mentions using a random forest algorithm and preparing an "accuracy assessment," no details or results, such as the "accuracy assessment matrix," are given to evaluate the methodology's fitness except to say that "accuracies…are consistently in the mid-90s percentage or higher." (*Land IQ Report*, p. 9). This is not supported by any of the exhibits provided in the *Land IQ Report*. In a supplemental disclosure, accuracy assessments for 2014 and 2018 were provided.
    - *"After the random forest classification was completed, an accuracy assessment was performed with the independent validation sites. The resultant accuracy assessment matrix provides information on the overall accuracy as well as the accuracy of individual crop types."* (*Land IQ Report*, p. 15, 19, 24)

- **Criteria used to evaluate the classification accuracy**: As with the classification "accuracy assessment" described above, the Texas technical experts mention evaluating fields with "low probability values" and correcting these with photo-interpretation. No quantitative metrics are given to identify the source of these values or how these values were defined.
    - *"Fields with low probability values were inspected and evaluated against the imagery. When a low probability was identified, based on expert photo-interpretation, the class label was corrected*." (*Land IQ Report*, p. 15, 19, 25)
- **Photo-interpretation techniques and corrections**: The Texas technical experts state that they corrected crop classification of fields with "low probability" through "expert photo-interpretation," but no detail is given for the number of corrections necessary and no description is provided of the corrections that were made. The methodology applied to correct erroneous data and/or add data to incomplete datasets was not described, nor was the prevalence of fields that required further inspection or the "textural cues" (beyond "row structure" and "some plant structures") that were used to make these corrections.
    - *"The high resolution of the aerial imagery provided textural cues that were correlated to crop type. Row structures and even some plant structures could be discerned, allowing for a high level of discrimination between crop types during the review/editing phase."* (*Land IQ Report*, p. 15, 19, 25)
- **Specific image dates evaluated** (**Table 11-1**): This detail is foundational to interpreting the validity of the crop distribution maps. Specific dates correspond only to specific times during the growing season (specific stages of crop development) and to specific weather conditions, which can each impact the classification algorithm. Ideally, images are evaluated throughout the growing season to confirm crop coverage and consistency in image dates from year to year is highly desirable for consistency in classification.

Table 11-1. Sample Data Sources Table, 2018 Land Use Analysis (*Land IQ Report*, page 14).

	Imagery	Date	Resolution	Color
Rincon	Planet Labs Landsat 8 Google Earth	Multiple dates Multiple dates Multiple dates	5 m 30 m Various	Natural Color Multispectral Natural Color
Mesilla	Planet Labs Landsat 8 Google Earth	Multiple dates Multiple dates Multiple dates	5 m 30 m Various	Natural Color Multispectral Natural Color

- **Time step of land use data evaluated:** Land use changes from year to year as different areas are irrigated, different crops are cultivated, and riparian corridors grow or shrink. The *Land IQ Report* identifies 11 years (about one per decade between 1936-2018) in which agricultural land use maps were developed using available spatial data and crop reports. In the remaining years without spatial data, agricultural land use was linearly interpolated from these maps. In the riparian corridor, the *Land IQ Report* identifies only ten total years in which riparian land use was mapped by Land IQ or the Papadopulos Report (2008). Riparian land use in other years was assumed to be equal to a neighboring mapped year. These time steps are deemed inadequate to accurately capture the changeability in land use.

Validation of Procedures with Field Surveys (Ground-truthing)

Technical Evaluation

The technical experts for Texas state that in 2018 and 2014, field data were collected to serve as the basis for crop land use classification. These field data ("ground truth data") were used as training data for classification efforts. When ground truthing was conducted, the *Land IQ Report* states that "nearly a week each time was spent collecting anywhere from 3,200 to nearly 4,000 individual field data points depending on the year and season" (*Land IQ Report*, p. 9).

In August 2018, ground truth data were collected for summer crops in all three valleys. These data were stratified by crop type and divided into training and validation data for classification efforts to support development of the 2018 agricultural land use map (*Land IQ Report*, p. 15).

In June 2014, ground truth data were collected for summer crops in all three valleys. These data were also stratified by crop type and divided into training and validation data for classification efforts to support development of the 2016 and 2014 agricultural land use maps (*Land IQ Report*, p. 19, 24). Additional ground-truth data were collected for fall annuals during September 2014, and were similarly used to support development of just the 2014 agricultural land use map (*Land IQ Report*, p. 24).

Opinion

The field survey sampling design, sampling procedures, and other necessary information to elucidate how the field data were collected were not provided. Specific dates when data were collected, and information on which fields were sampled were not provided. Additionally, no clear description is given to state how these field data were used in crop classification, or to show how the proportional land use areas determined from the field study compare to the spatial land use database.

Field surveys play a primary role in confirming the reliability of crop classification methodologies under current field conditions. Field surveys and ground-truthing exercises should explicitly follow steps recommended for sample-based field verification studies (such as those described by Gilbert (1987)) and evaluate a statistically representative selection of a stratified, random sample of fields pre-determined following standard protocols (such as those described by Stehman and Milliken (2007)).

Specifically, a description of the field survey should outline the objectives, area of interest, physical environment, information to be collected, quality assurance protocols, field sampling designs, and planned statistical analyses. This information is not provided with the *Land IQ Report*.

El Paso Valley Irrigated Area Review

The irrigated area data received from Land IQ was found in the acreage tab of six Excel spreadsheets with consumptive use analyses by region. The Excel files contain cropped acreages, various factors applied to CUP+ crop ET and crop ET estimates. Below is a list of the Excel files provided by region/subregion:

1. Excel files
    a. ElPaso_ConsumptiveUse.xlsx Acreage tab labeled as showing areas for "El Paso Valley, Tx"
        i. EPCWID1_ConsumptiveUse.xlsx Acreage tab labeled as showing areas for "EPCWID1"

    ii. Hudspeth_ConsumptiveUse.xlsx Acreage tab labeled as showing areas for "Hudspeth"

b. MesillaAndRincon_ConsumptiveUse.xlsx Acreage tab labeled as showing areas for "Mesilla and Rincon Valleys"
    i. Mesilla_ConsumptiveUse.xlsx Acreage tab labeled as showing areas for "Mesilla"
    ii. Rincon_ConsumptiveUse.xlsx Acreage tab labeled as showing areas for "Rincon"

Technical Evaluation

Based on the comparisons described in the remainder of this section, it appears that Land IQ also included the portion of EPCWID within Mesilla Valley in the El Paso Valley irrigated areas in some years; thereby, incorrectly increasing the irrigated area of EPCWID lands in the El Paso Valley. Land IQ provided Excel files summarizing irrigated area and crop ET by region and subregion. Based on the use of "EPCWID1" in the spreadsheet name and the title in row one of the acreage tab, one would expect that the irrigated areas in this spreadsheet are for all of EPCWID including the areas in the Mesilla Valley. **Figure 11-1** shows that the irrigated area determined by Intera closely matches the irrigated area determined by Land IQ when the Intera irrigated areas include the portion of EPCWID that is in the Mesilla Valley. **Figure 11-2** shows that the irrigated area for Hudspeth, which is included in the El Paso Valley, determined by Intera closely matches the irrigated area determined by Land IQ. Based on the use of "ElPaso" in the spreadsheet name and the use of "El Paso Valley, Tx" in the title in row one of the acreage tab, one would expect that the irrigated areas in this spreadsheet are for only the EPCWID irrigated area in Texas plus the irrigated area in Hudspeth. However, the irrigated acres in the "ElPaso" spreadsheet are the sum of the irrigated area in the Excel files "EPCWID1" and "Hudspeth." Additionally, **Figure 11-3** shows that the irrigated areas determined by Intera and sent to (DE) closely match the irrigated areas determined by Land IQ when these irrigated areas include the portion of EPCWID that is in the Mesilla Valley. Correspondingly, the irrigated areas determined by Land IQ are greater than the irrigated areas determined by Intera when these irrigated areas do not include the portion of EPCWID that is in the Mesilla Valley.

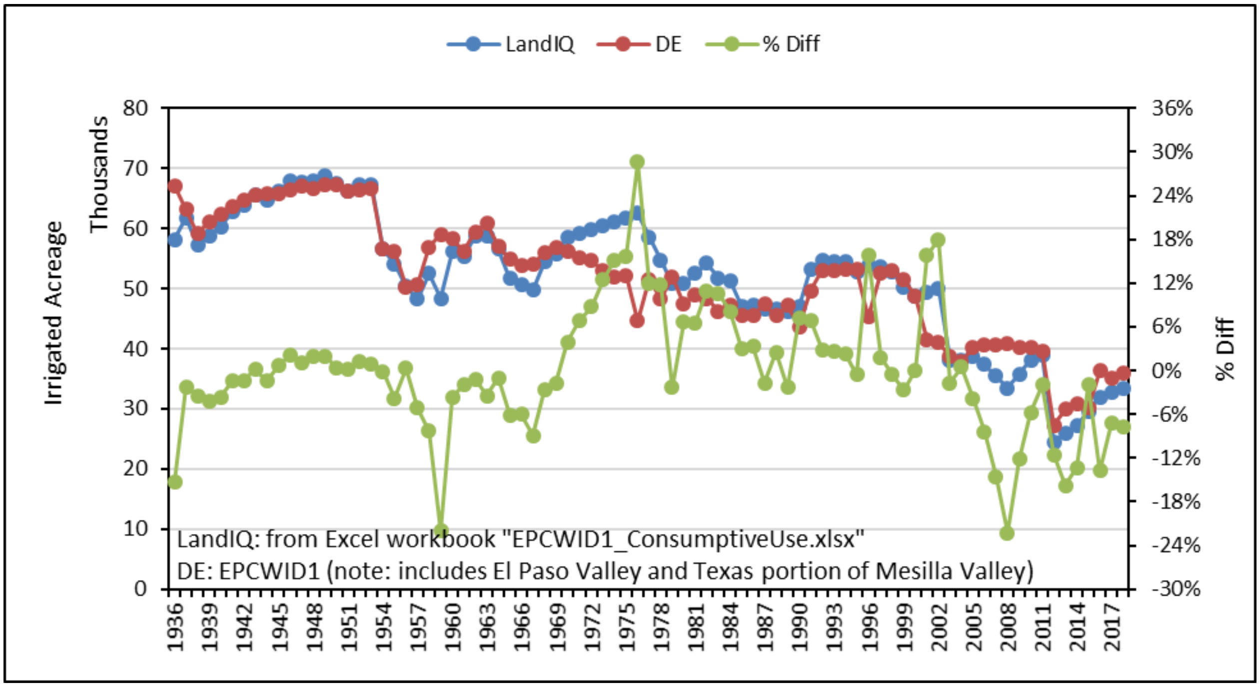

Figure 11-1. Irrigated Acreage for EPCWID1.

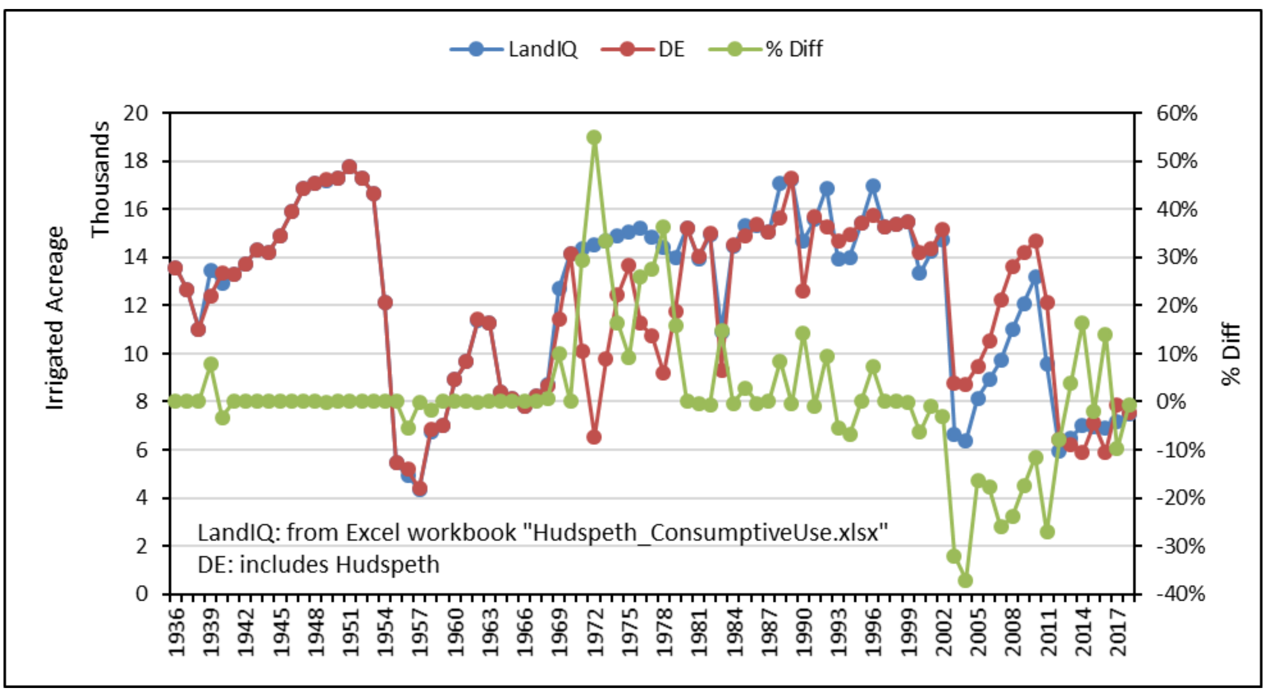

Figure 11-2. Irrigated Acreage for Hudspeth.

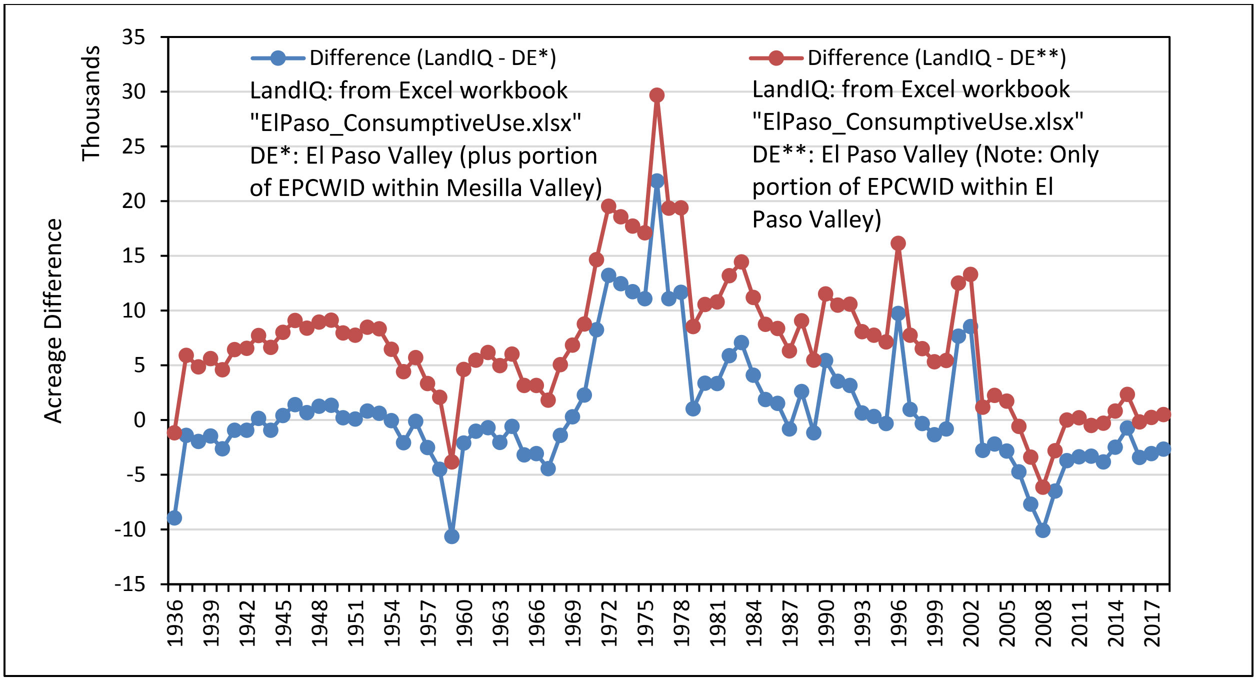

Figure 11-3. Irrigated Acreage for El Paso Valley, Tx.

Opinion

Exhibit 40 in the Land IQ Expert Report clearly indicates that the portion of EPCWID1 in Mesilla Valley was assigned to the Mesilla Valley as service areas 5, 6 and 13. The Land IQ Expert Report does not include a similar exhibit for the El Paso Valley. However, as described in the above technical evaluation, it appears that Land IQ included the portion of EPCWID1 within Mesilla Valley in the El Paso Valley irrigated areas.

Additionally, in the Land IQ Expert Report Agricultural Land Use opinions on page 11, three opinions on the irrigated areas of selected crops in the El Paso Valley have areas different than the areas in the ElPaso_consumptiveUse spreadsheet received as noted below:

- Alfalfa in the El Paso Valley has generally decreased from 16,649 **(17,409 acres in spreadsheet received)** acres in 1936 to 3,105 **(3,270 acres in spreadsheet received)** acres in 2018.
- Cotton in the El Paso Valley increased from 44,501 **(47,718 acres in spreadsheet received)** acres in 1936 to approximately 56,622 acres **(71,275 acres in spreadsheet received)** in 1951 and then decreased to 19,161 **(matched acres in spreadsheet received)** acres in 2018.
- Pecans in the El Paso Valley increased from essentially 0 **(446 acres in spreadsheet received)** acres in 1936 to 15,412 **(matched acres in spreadsheet received)** acres in 2018

Crop Area Review

Technical Evaluation

The spatial crop area data received from Land IQ was found to contain three columns of crop category information, one each for spring, summer and fall. When the crop areas were summed, if, for example, a field had alfalfa as the crop in the spring column and cotton as the crop in the summer column, the area for that field appears to have been counted both in the alfalfa and in the cotton areas. Although unlikely, it is possible that a field may have been alfalfa in the spring and converted to cotton in the summer. However, with the area in both alfalfa and cotton, the same field has consumptive use calculated for both alfalfa for March through December and for cotton for April through November.

Opinion

The methodology described above that LandIQ uses to include double cropped areas in the consumptive use totals double counts fields if the crop season defined for the two crops overlaps. A more correct way to account for double cropping is to count the field only once and to develop a crop coefficient that continues for the entire irrigation season and includes both crops sequentially.

Pecan Spacing and Age Analysis

Technical Evaluation

The stated purpose of the analysis is to determine whether orchards planted more recently have more trees per acre. The report states: "Especially in earlier years of an orchard (until the canopy closes in), it should be expected that more trees per acre will result in more consumptive use as compared to older, less dense orchards. This positive conclusion allows for the assumption of escalation of pecan consumptive use in more recent years." Although it seems reasonable that more trees per acre will result in more consumptive use, no studies are cited and no proof is offered to support this claim. Additionally, the report does not describe how the age of each pecan orchard was established even though this is the first step in the analysis.

The section focuses on the increased density of trees in recent years among the randomly selected orchards that were examined. However, the "Spacing Results" section describes the occurrence of some "alternately spaced orchards" between the 1980s and 1990s that were thinned from 30 foot spacing down to 60 foot spacing between trees in alternate rows. Exhibit 36 generally shows average tree density varying between 35 and 50 trees per acre for orchards planted between 1988 and 2006 (including alternately spaced orchards) while orchards planted after 2006 have an average tree density of just under 60 trees per acre. This section concludes by stating that: "Older orchards tend to have more widely spaced trees, while younger orchards tend to have tighter spacings."

The pecan age analysis results in Exhibit 38 generally show that the area of pecans planted in years between 1985 and 2018 varied from a few hundred to just over 2,000 acres.

Opinion

The *Land IQ Report* fails to support the conclusion that more trees per acre will result in more consumptive use. Furthermore, after making this conclusion, the supporting files provided by Land IQ fail to account for any differences in consumptive use between older and younger orchards.

The report states that this "allows for the assumption of escalation of pecan consumptive use in more recent years." However, the calculations in the spreadsheets provided by Land IQ use the same crop coefficient during the 1968 through 2018 time period to represent pecan consumptive use and use an irrigation and production adjustment of 1.00. Thus, the pecan consumptive use is not escalated in the analysis prepared by Land IQ due to the decreased spacing. More importantly, the pecan crop coefficient that was used is for mature trees and is NOT adjusted downward to account for the area of young trees. The pecan consumptive use is too high because it erroneously assumes that all of the pecan trees are mature.

Riparian Land Use and Classification

Technical Evaluation

During development of their spatial land use database, the Texas technical experts determined the relative cover of different riparian vegetation classes through analysis of images with geospatial techniques, and then calibrated these results to a historical study of vegetation cover change by Papadopulos (2008) that was informed by ground level survey data.

The Texas technical experts delineated riparian corridors (comprised of "riparian polygons") for 1955, 2005, and 2014 using digital mapping techniques and photo interpretation of images collected in June 1955, August 2005, June/July/August 2014, and May/June/August 2016.

The riparian corridor in 2014 (the "baseline") was assessed using NDVI-based classification to determine the relative cover of three land cover classes, or plant functional groups (PFGs) in each riparian polygon: riparian trees, riparian shrubs, and bare ground. In intervening years, the relative coverage of vegetation and bare ground in each polygon were adjusted in increments of 5% to account for differences in canopy cover of trees or shrubs determined from imagery in 2005 (and presumably 1955).

The accuracy of the riparian land use was evaluated by comparing the total extent of riparian area mapped by the Texas experts in 1955 and 2005 to the extent mapped by Papadopulos in 1955 and 2004, respectively, and by comparing the relative total vegetation and bare ground areas mapped by the Texas experts and Papadopulos in 2005 and 2004, respectively. Differences in the total vegetation area between these sources were used to calibrate the baseline coverage of vegetation in 2014.

Regarding the estimation of land cover using the vegetation index NDVI, on page 79 the report states: "This difference is expected and due to the common overestimation of Cover using NDVI values (pixel-based) compared with field survey data. The Papadopulos (2008) report had the benefit of field survey data to verify and measure riparian vegetation cover in 2004. Therefore, the tabular 2014 total vegetation cover values were reduced by 159% to calibrate the 2014 NDVI-based cover observations to 2004 field-based observations in the Papadopulos (2008) report."

No explanation is given regarding why the NDVI-based methods overestimated vegetation cover by 159%. The reason for the flaw caused by using NDVI is not described. It is noted in most modern literature[13] that NDVI generally has a close, nearly 1:1 correspondence with fraction of ground cover. Therefore, the 2.59 ratio of NDVI-estimated cover to actual cover is unexpected and surprising, and suggests a substantial flaw in the vegetation cover analysis. No documentation is provided to explain this large, unexpected departure between estimated and actual ground cover, or to explain why the NDVI-based procedure overestimates ground cover if it was initially calibrated to known data. In addition, no description is provided for how Papadopulos (2008) measured riparian vegetation cover in 2004.

---

[13] For example, Jiang, Z., Huete, A.R., Chen, J., Chen, Y., Li, J., Yan, G. and Zhang, X., 2006. Analysis of NDVI and scaled difference vegetation index retrievals of vegetation fraction. Remote sensing of environment, 101(3), pp.366-378; Verger, A., Martínez, B., Camacho-de Coca, F. and García-Haro, F.J., 2009. Accuracy assessment of fraction of vegetation cover and leaf area index estimates from pragmatic methods in a cropland area. International Journal of Remote Sensing, 30(10), pp.2685-2704; and Glenn, E.P., Huete, A.R., Nagler, P.L. and Nelson, S.G., 2008. Relationship between remotely-sensed vegetation indices, canopy attributes and plant physiological processes: What vegetation indices can and cannot tell us about the landscape. Sensors, 8(4), pp.2136-2160.

In exhibit 48 on p. 79, it is not explained why there was so much bare ground determined for riparian areas. The physical reason or cause is not provided. Riparian areas are typically defined as areas having close proximity to surface water or to shallow ground water. Under these conditions, vegetation usually prospers and extensive areas of bare soil are not found to occur. No explanation is given for why bare ground is considered to be riparian. Is it due to proximity to a stream or drain where water flow or human intervention discourages vegetative growth?

Opinion

To calibrate the riparian land use analysis, the *Land IQ Report* uses erroneous comparisons between land use analysis results from different years. Specifically, calibration is made by comparison between the Land IQ analysis for 2005 and the Papadopulos analysis for 2004. However, these years are not necessarily equivalent. Calibration based on comparisons between different years is difficult at best, requires information supporting the "equivalence" of the years, and likely resulted in inaccurate riparian land use classifications.

Riparian vegetation growth depends, in part, on river flows and changes depending on Rio Grande flows in the years and months prior to the analysis. For example, leading up to the Papadopulos analysis in 2004, flows along the Rio Grande upstream of the Study Area remained below 1,200 CFS most days between October 2000 and December 2004, with the exceptions of several days in May/June 2001 and April/May 2004[14]. Lower flows provide less water to support riparian vegetation, potentially explaining the higher bare ground coverage observed by Papadopulos in 2004. Between the Papadopulos analysis for 2004 and the Land IQ analysis for August 2005, Rio Grande flows at the same site exceeded 3,500 cubic feet per second nearly every day between mid-April and the end of June 2005. These higher flows could have several consequences, providing more water to support expanded vegetation growth or potentially washing away riparian vegetation. Either impact would affect vegetation areas in August 2005. It is likely that riparian vegetation coverages would have been different between 2004 and August 2005.

On p. 80, the *Land IQ Report* states: "Photo-interpretation of the 2005 and 2014 high-resolution aerials showed little to no detectable change in the relative PFG composition between 2005 and 2014 in the riparian areas." However, the report does not describe how the photo-interpretation was conducted to show little to no detectable change in PFG composition. No description is given regarding the assumptions and means for analyzing the 4-band aerial photo images.

Confidence in the accuracy of the Land IQ estimates of riparian vegetation coverage is substantially reduced by the large estimation bias in their NDVI-based method. This suggests that Land IQ should redevelop their NDVI-based method for estimating vegetation amount, and increase use of literature-based approaches and findings. In addition, for image pixels that may have had some open water intermixed with vegetation, no description is given pertaining to the impact of negative NDVI caused by open water on lowering the pixel-wide NDVI.

Page 76 of the *Land IQ Report* states that "Bare Ground**:** Includes areas that are bare year-round and areas that may have seasonal vegetation cover (dominated by annual grasses and other herbaceous vegetation (the life cycle of which is driven by rainfall events and not due to deeper rooted perennial

[14] Based on 15-minute discharge, in cubic feet per second (CFS), reported at USGS Station 08358400, Rio Grande Floodway at San Marcial, NM.

transpiration)." Evaporation of water from bare ground following rainfall is an important part of the water balance for these areas and this is not discussed in the *Land IQ Report*. It is not explained why areas that may have seasonal vegetation cover such as annual grasses was not classified as annual grasses, and an appropriate ET estimate assigned.

No documentation is provided, nor justification given, that "the Herbaceous Riparian PFG is both insignificant from a consumptive water use perspective given its limited extent and relatively shallow rooting morphology." (p. 76).

Consumptive Use Estimates

As with its documentation of the land use classification analyses, the *Land IQ Report* lacks sufficient detail to thoroughly explain how consumptive use estimates were developed. The level of detail provided in the disclosed report and accompanying materials does not allow for replication or evaluation of the steps to achieve the final consumptive use estimates. Furthermore, the ETo_adjustment tab in the spreadsheets provided for the Texas area applied Blaney-Criddle adjustment factors to the Hargreaves-Samani reference ET estimates output during years with limited data availability, which is incorrect usage.

Although Land IQ uses the crop coefficient-reference crop methodology, they do not reference the most recent and up-to-date description of the methodology found in the second edition of the American Society of Civil Engineers Practice Manual 70 (ASCE, 2016). Additionally, as described in the following sections, the weather station selection is poor for representing weather conditions over agricultural areas and weather data quality control is inadequate. In addition, the ET calculation procedure often does not use locally-based or calibrated crop coefficients. Based on the information presented in the *Land IQ Report*, the best available information and the best available science has not been used to quantify the consumptive use estimates. The following sections on preparing weather station data, crop irrigation season parameters, consumptive use estimates, and yield analyses describe specific areas where the best available information and the best available science were not used.

Weather Station Selection

Technical Evaluation

Producing accurate estimates of ET using the crop coefficient and reference crop ET methodology requires accurate and complete weather data from representative stations (ASCE, 2016). These data are necessary to calculate the consumptive use of water from cropland and riparian vegetation. The standardized Penman-Monteith (PM) methodology has been recognized as the preferred "gold standard" for ET estimation by the Food and Agricultural Organization (Allen et al., 1998), in the ASCE Task Committee Report on the Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005) and in ASCE Manual 70 (ASCE, 2016).

The PM methodology requires solar radiation, air temperature, vapor pressure and wind speed data. Importantly, the ASCE Task Committee Report and Manual 70 provide explicit recommendations regarding methodologies used to estimate the required inputs to the standardized equation when measured data are missing, incorrect, or generally unavailable. Ultimately, the weather data that are used to develop reference ET estimates for determining crop water requirements must be representative of irrigated agriculture under equivalent weather and climate conditions as compared to the Study Area (Allen et al., 1998). Stringent quality assessment and quality control (QA/QC) methods must be employed, as described in the ASCE 2005 report and ASCE Manual 70.

In presenting the factors used to evaluate all available weather stations in the vicinity of the Study Area, the Texas technical experts list several generally accepted parameters recommended for consideration by ASCE (2016), including “location/distance to agriculture fields, immediate surroundings (e.g. irrigated surface vs. vacant lot), measured values (preference for stations that have required data supporting the PM calculation for ET_o), and data reliability and consistency” (*Land IQ Report*, p. 86). However, in presenting the preferred weather stations chosen by Land IQ, no clear explanation or results are given to describe how these factors were compared and supported the ranking of preferred stations. Land IQ is basing calculation of ET_o upon weather stations that do not represent the best sites and upon data that have not been subject to stringent QA/QC methods.

Opinion

The weather stations selected by Land IQ and, thus, the weather data relied upon in calculating ET_o are not the most representative sites for the agricultural conditions in the area. In addition, the data that are used were not subject to stringent QA/QC methods. The use of weather data from sites that are not the most representative and that were not subject to QA/QC methods results in inaccurate calculations of ET_o and subsequently consumptive use by Texas.

The reasons for selecting the weather stations shown in Exhibit 52 are not provided in the report. Our review of weather stations in the Study Area indicates that many of the stations selected in the *Land IQ Report* are not the best stations for the reasons presented in **Table 11-2**.

Weather Data Quality Assurance and Quality Control (QAQC)

Technical Evaluation

As described above, the careful selection of an appropriately located and representative weather station is a crucial step in assuring the suitability of weather data for estimating consumptive use. To confirm the quality of the data from selected weather stations, several quality assurance (QA) and quality control (QC) measures are recommended in the ASCE Task Committee Report on the Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005) and in ASCE Manual 70 (ASCE, 2016).

Central to these QA and QC measures is the determination of inaccurate or missing data, and subsequent correction or estimation of these values. Neglecting this process can result in inaccurate or incomplete ET estimates.

For example, the year 2000 is the first year with complete weather data available to calculate the PM equation at the Fabian Garcia weather station. In that year, the annual reference ET rate reported and used by the Texas technical experts increased nearly half a foot over prior years (**Figure 11-4**). Review of the weather data from that station following standard, recommended procedures shows that the measured solar radiation data exceeded the clear sky solar radiation (the theoretical maximum solar radiation striking the earth's surface from a cloudless sky) in the winter/spring and fall/winter of that year (**Figure 11-5**), apparently due to sensor or data collection error. When these data are corrected following standard, recommended procedures, the solar radiation values are reduced to expected levels (**Figure 11-6**) and the reference ET decreases from 5.98 feet to 4.78 feet, a reduction of 20%.

Table 11-2. Summary of Weather Stations Selected in the *Land IQ Report* and the Reasons these Stations are not Representative.

Date Range	Valley	Station Selected as "Most Desirable" in *Land IQ Report* (Exhibit 52)	Reason Station Not Representative
2017-2018	EPCWID1/Hudspeth	*No station listed in Exhibit 52*	*No station listed in Exhibit 52*
2007-2011	EPCWID1/Hudspeth	Tirres	Environment less representative of reference conditions compared to Art Ivey based on an aridity assessment of the reported weather data
1962-1977	EPCWID1/Hudspeth	Fabens	Vegetated areas surrounding Ysleta are more representative of the agricultural area during this period.
1936-1950	EPCWID1/Hudspeth	Socorro	Vegetated areas surrounding Ysleta are more representative of the agricultural area during this period.
2015-2018	Rincon/Mesilla	*No station listed in Exhibit 52*	*No station listed in Exhibit 52*
2001-2014	Rincon/Mesilla	Fabian Garcia	Environment is less representative of reference conditions compared to Leyendecker PRSC II based on visual inspection of the two stations. The Fabian Garcia station is impacted by close-by trees, orchards and residential development that reduce wind speed.
1944-2000	Rincon/Mesilla	Las Cruces, NM	Environment less representative of reference conditions compared to Leyendecker and NMSU weather stations based on visual inspection of the two stations regarding fetch of transpiring vegetation within 200 m and openness regarding close-by orchards and buildings.

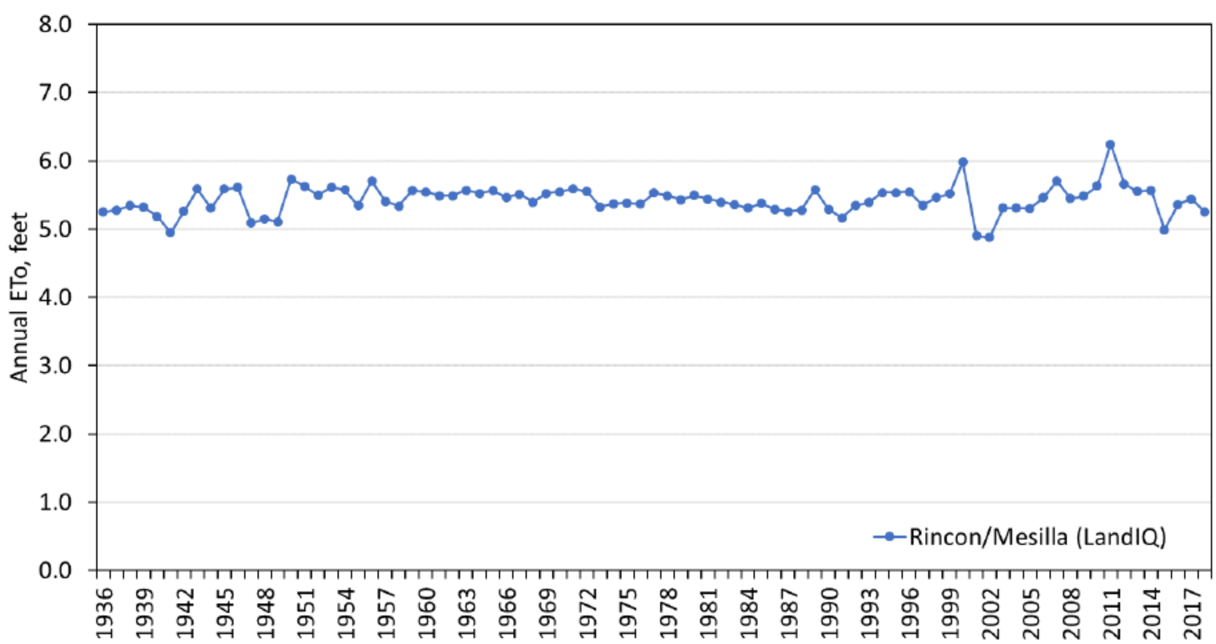

Figure 11-4. Land IQ Reference ET for the Rincon/Mesilla Valleys (note large increase in 2000).

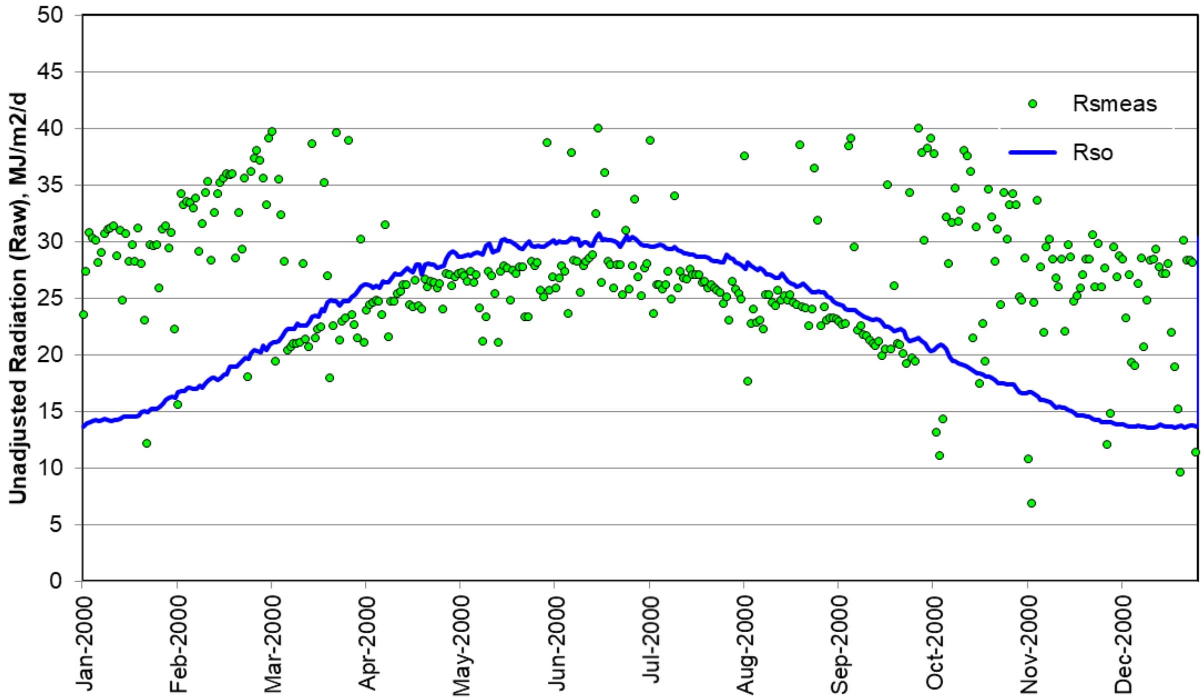

Figure 11-5. Fabian Garcia Weather Station Unadjusted (Raw) Solar Radiation Data, 2000, as utilized by Texas experts. The blue line (Rso) represents the theoretical maximum solar radiation expected under clear-sky (no clouds) conditions.

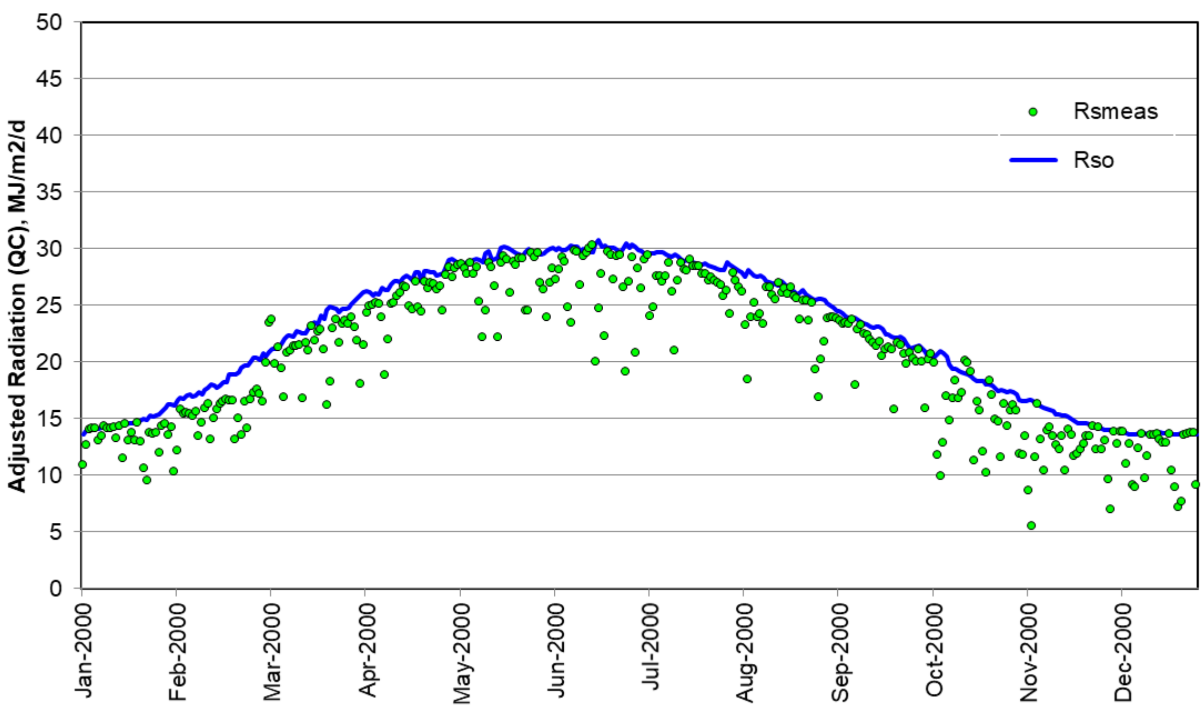

Figure 11-6. Fabian Garcia Weather Station Adjusted (QC) Solar Radiation Data Following Adjustment using Standard, Recommended Procedures of ASCE-EWRI (2005) and ASCE (2016).

Opinion

The *Land IQ Report* does not provide sufficient information on their weather data QA/QC measures to evaluate the quality of data that were used by the Texas team to develop the reference ET_o data used to compute crop consumptive use. Review of the weather input data described in the preceding section indicates that the QA/QC of the weather data did not follow standard, recommend procedures (ASCE-EWRI, 2005, and ASCE, 2016). Standard, recommended QA/QC analysis techniques (ASCE-EWRI, 2005, and ASCE, 2016) should always be utilized to ensure the accuracy and representativeness of solar radiation, air temperature, wind speed, and humidity data and all necessary corrections made to adjust inaccurate data.

Reference ET Equations

Technical Evaluation

Central to the *Land IQ Report's* estimates of consumptive use within the Study Area is the methodology used to estimate ET. ET encompasses all water that is consumptively used either through evaporation from the soil or crop surface or as transpiration through the plant tissue. ET rates vary between individual crops, soil surface coverage conditions, and surrounding weather and climate conditions. ET rates can also vary with the type of irrigation that is used due to the frequencies of irrigation and consequent soil evaporation events and the extent of surface wetted by the particular irrigation system.

When following standard procedures (ASCE, 2016), reference ET is calculated for a known reference surface using local weather data and is then adjusted to other individual crops based on specific crop coefficients that vary throughout the growing season. This is referred to as the "crop coefficient – reference crop ET" methodology.

At present, the PM method "is recommended as the sole standard method" for estimating reference ET, providing "strong likelihood of correctly predicting ET_o in a wide range of locations and climates [with] provision for application in data-short situations" (Allen et al., 1998). The aforementioned ASCE Task Committee report and the recently published second edition of ASCE Manual 70 (ASCE, 2016) also recommend the PM method in the form of the ASCE Standardized Penman-Monteith method. ASCE (2005 and 2016) recommend employment of the PM method with estimation of missing humidity, wind and solar radiation data when only air temperature data are available. The employment of the PM method under all conditions, including those when only air temperature data are available, is recommended by ASCE over the Hargreaves-Samani method and Blaney-Criddle methods.

The *Land IQ Report* utilizes the PM methodology when sufficient weather data are available for its application. However, when available data are insufficient for the PM, the *Land IQ Report* states that the "…Blaney-Criddle ET calculation method was used…" (page 88). However, notes on the ET_o adjustment tabs in the spreadsheets disclosed by the Texas technical experts indicate that prior to the years 2000 and 2004 in New Mexico and Texas, respectively, two separate methodologies are used to estimate reference ET for the New Mexico and Texas regions of the Study Area. For the Rincon and Mesilla Valleys (EBID and the small area of EPCWID in the Mesilla Valley), the Hargreaves-Samani methodology is used to estimate ET_o. For the El Paso Valley (Hudspeth and the area of EPCWID1 not in the Mesilla Valley), the note in row states: "Values used to Scale Blaney Criddle ETo prior to 2000 to Penman Monteith." This seems to indicate that the Blaney-Criddle method is used to estimate ET_o. However, the Blaney-Criddle method does not provide an ET_o estimate. Also, sufficient data to use the PM equation is not available until 2004 in the El Paso Valley, not 2000 as stated in the note. According to the spreadsheets, a monthly ET_o adjustment factor is applied to the ET_o calculated from the Hargreaves-Samani and Blaney-Criddle equations. The report states that: "In years that the Penman-Monteith data were available, however, both methods were calculated in order to compare methods and generate adjustment factors for earlier years where only Blaney-Criddle could be used." Presumably these adjustment factors are monthly averages from the years of overlap, however, no further description of the methodology was provided and the input data and results of the calculation have not been provided.

Notably, the Texas technical experts state that the CUP+ program released by the California Department of Water Resources (CDWR) was used to generate ET_o estimates, but the program documentation states that it calculates ET_o using the Hargreaves-Samani methodology when the data provided are not sufficient to calculate the PM ET_o.

Per an additional data request prior to the deposition, Land IQ provided additional information on the ET_o adjustment factors in the form of a spreadsheet with two tabs. One tab contained adjustment factors used in the Rincon, Mesilla and RinconandMesilla spreadsheets that appeared to be an exact copy of the ET_o adjustment tab included in those spreadsheets. However, in the other tab containing adjustment factors used by the EPCWID1, Hudspeth and El Paso Valley spreadsheets, the note at the top of the sheet was changed from the previous sheets to indicate that these adjustment factors were for the Hargreaves-Samani equation, but the adjustment factors were unchanged. Thus, it is not clear which methodology was used to calculate ET_o and the adjustment factors used in the EPCWID1, Hudspeth and El Paso Valley spreadsheets, and why the same adjustment factors apply equally to the Hargreaves-Samani and Blaney-Criddle methods in the El Paso Valley.

Opinion

Use of different reference ET equations to estimate reference ET during the years when all the parameters for the PM equation are not available leads to incongruencies between reference ET estimates for areas within New Mexico and areas within Texas.

ASCE Manual 70 (ASCE, 2016), Allen et al. (1998) and ASCE-EWRI (2005) recommend that for the time periods when sufficient weather data are not available, reference ET should be calculated by first using standard methodology to estimate the missing weather parameters, then employing the estimated weather parameters in the standardized PM equation. Standard methodologies are able to incorporate variation in regional wind speed over time based on regional wind speed data and variation in relative humidity over time in some proportion to reported air temperature. These variations drive ET_o estimates by the PM equation to increase accuracy of ET_o estimates from year to year as compared to Hargreaves-Samani and Blaney-Criddle equations that have no knowledge of year to year or month to month variation in regional wind speed or relative humidity and their impact on ET_o.

Crop Coefficient Values and Derivation

Technical Evaluation

Crop coefficients are foundational to calculating the consumptive use of water from agricultural land and riparian vegetation using the reference ET and crop coefficient methodology. Crop coefficients *must* be derived from, and calibrated to, local, observed crop growth characteristics within the Study Area to accurately account for crop consumptive water use in that area. Furthermore, the magnitudes of crop coefficients, when used for water balance estimates, must be derived from, or calibrated to, local measurements or estimates of actual (not potential) consumptive use.

In the section "Water Use of Mesilla Valley Crops" (*Land IQ Report*, p. 82-86), the *Land IQ Report* identifies some sources used as the basis for crop coefficients of chilis, onions, and lettuce crops in the

Mesilla Valley, and qualitatively describes “reasonable” crop coefficient adjustments to account for changes in crop ET in historical years (from 1936 to approximately 1985, with continued adjustment for a few crops into the 1990s).

The sources given for these crop coefficients include published crop coefficients from the New Mexico Climate Center and FAO Irrigation and Drainage Paper 56 (Allen et al., 1998). However, the crop coefficient curves are neither given nor described in the report. The sources of crop coefficients for other crops and other regions in the Study Area are also not clearly identified. Following the deposition, additional information was received that provided sources for the crop coefficients. Many of the crop coefficients provided were the default crop coefficients, in terms of magnitude, and were applied with default planting and harvest dates and with default growing season lengths that came with the CUP+ program released by the California Department of Water Resources (CDWR). California is a large state that spans over 1,000 miles from north to south. The crop coefficients, the planting and harvest dates, and the growing season durations developed for application in California can be substantially different from conditions of southern New Mexico and western Texas.

The *Land IQ Report* bases its historical crop coefficients and crop coefficient adjustments on a brief and inconclusive evaluation of literature on crop water use associated with differing irrigation methods and crop yields. The sources identified by the *Land IQ Report* for each crop are discussed below. Following this evaluation, the report repeatedly concludes that: “adjusting crop coefficient[s] downward going back in time in the study period is a reasonable approach to estimate consumptive use throughout the study period” (*Land IQ Report* pp. 83, 85, 86). However, the quantitative basis for this adjustment is not described and, more importantly, the basis for the unadjusted California crop coefficients used for recent history (about 1985 through 2018) is not established. The following sections briefly discuss the sources for the crop coefficients used by Land IQ (as indicated in *Kc_Values_and_Sources_20190924.xlsx*) given for each crop in approximate order from greatest to least irrigated area in 2018.

Pecans

Information provided by Land IQ indicates that the crop coefficients for pecans originate from “Evapotranspiration of flood-irrigated pecans” (Sammis, Mexal, and Miller, 2004) and the work of Samani et al. (2012).

The study by Sammis, Mexal, and Miller reports on daily ET measurements for 5.1 hectares of mature pecan orchards (21 year old stand) located in the Rio Grande floodplain in New Mexico near Las Cruces. ET was calculated from the net surface energy balance measured at a tower located in the middle of the orchard during 2001 and 2002. Notably, this work calculates grass reference evapotranspiration using Penman’s equation per the methodology specified in Sammis et al. (1985). This methodology differs from the standardized PM methodology, and consequently results in different ET_o values. Thus, the crop coefficients derived with the Penman ET_o equation must be adjusted prior to use with ET_o calculated with the standardized PM equation to account for differences between the two ET_o methods.

In reference to the work of Samani et al., Land IQ notes that the crop coefficients for pecans are “listed under stone fruit in FAO 56.” However, a separate analysis by Taylor et al. (2017) argues that “pecans should not be grouped under stone fruit” and that models such as the pecan monthly water use simulator developed by Samani et al. “may not always give acceptably accurate ET values outside of the area in which they were calibrated.” Suitable crop coefficients should be calculated based on the same ET_o methodology with which they will be used (i.e., the standardized PM methodology) and should be calibrated to local conditions. Additionally, the Sammis Kc was developed for well-managed mature trees and therefore not appropriate for application to immature trees or poorly managed trees.

Alfalfa

The crop coefficient used by Land IQ for alfalfa crops is estimated from FAO Irrigation and Drainage Paper 24 (FAO 24) and research from the University of California, as communicated through Dr. Richard Snyder at the University of California in Davis, CA (UC Davis).

The alfalfa crop coefficient is constant and equal to the mean K_c value given for alfalfa in a dry climate with light to moderate wind (FAO 24, p. 45). Notably, this reference describes crop coefficients that are used to calculate ideal, potential crop water requirements (FAO 24, p. 1: "Crop water requirements are defined here as 'the depth of water needed to meet the water loss through evapotranspiration…of a disease-free crop, growing in large fields under non-restricting soil conditions including soil water and fertility and achieving full production potential under the given growing environment'."). This definition describes ideal conditions, which are characterized by potential ET. Because some of the alfalfa crops are affected by water stress, disease, restrictive soil conditions, or other factors leading to reduced ET, these crop coefficient values overestimate the actual ET of the average alfalfa crop in the Rincon, Mesilla and El Paso Valleys.

Cotton

The crop coefficients used by Land IQ for cotton are adjusted from the K_c values given in FAO 56 according to the Kc values given in CUP+ and the consumptive use of cotton reported in a study by Ahadi, Samani, and Skaggs (2013).

The initial and end of season Kc values equal those of cotton as reported in FAO 56. For mid-season, Land IQ states that the peak Kc value is estimated to be "not as high as 1.15-1.20" (as in FAO 56), and "not as low as CUP+ (0.95)" (note in *Kc_Values_and_Sources_20190924.xlsx*). Neither FAO 56 nor CUP+ provide local information for southern New Mexico or western Texas conditions. The K_c values provided in FAO 56 are representative of ideal conditions for "non stressed, well-managed crops in subhumid climates" (FAO 56, Table 12), whereas the source of the default crop coefficients given in CUP+ is unclear. Presumably, they were developed for simulating crop water requirements across California.

Onions

The crop coefficients used by Land IQ for onions are taken from CUP+. The source of the default crop coefficients given in CUP+ is unclear, though presumably they were developed for simulating crop water requirements across California., a large state spanning diverse climate regions. The crop coefficients developed for application in California are likely different than what might be expected in southern New Mexico and western Texas due to likely differences in plant density, row spacing, watering practices and lengths of growing seasons.

Corn

The crop coefficients used by Land IQ for corn are taken from CUP+, with adjustment to match the end of season Kc value given in FAO 56. Neither FAO 56 nor CUP+ provide local information from southern New Mexico or western Texas. The K_c values provided in FAO 56 are representative of ideal conditions for "non stressed, well-managed crops in subhumid climates" (FAO 56, Table 12), whereas the source of the default crop coefficients given in CUP+ is unclear, though presumably they were developed for simulating crop water requirements across California.

Chilis

The crop coefficients used by Land IQ for chilis are taken from New Mexico crop information provided by the New Mexico Climate Center (NMSU, 1996), which is based on the work of Saddiq (1983). On p. 83, the *Land IQ Report* states that the crop coefficients from the New Mexico Climate Center were adjusted "for lower yields in historical crops." However, no documentation supporting the derivation of and application of the adjustments to ET "for lower yields" is provided. In addition, the basis for the "crop coefficients from the New Mexico Climate Center (1996)" is not provided beyond the source's reference to Saddiq (1983). If those coefficients applied were derived based on Penman's equation per the methodology specified in Sammis et al. (1985), they should be adjusted to the PM ET_o basis prior to use with PM ET_o developed by *Land IQ.*

Pasture

The crop coefficient used by Land IQ for irrigated pasture is taken from FAO 24 and communication with Dr. Richard Snyder at UC Davis.

The pasture crop coefficient is constant and equal to the mean K_c value given for "grass for hay" in a dry climate with light to moderate wind (FAO 24, p. 45). As described above, FAO 24 provides crop coefficients that are used to calculate ideal, potential crop water requirements (FAO 24, p. 1: "Crop water requirements are defined here as 'the depth of water needed to meet the water loss through evapotranspiration…of a disease-free crop, growing in large fields under non-restricting soil conditions including soil water and fertility and achieving full production potential under the given growing environment'."). This definition describes ideal conditions, which are characterized by potential ET. These crop coefficient values overestimate the actual ET of average crops because some crops are affected by water stress, disease, restrictive soil conditions, or other factors that reduce water use below the potential ET described by these crop coefficients.

Hay

The crop coefficient used by Land IQ for hay crops are estimated based on the crop coefficients for alfalfa reduced by a value of 0.1 throughout the growing season. As described above, the alfalfa crop coefficients represent ideal, potential ET conditions and overestimate the actual ET of crops that are affected by water stress, disease, restrictive soil conditions, etc. The same concerns with alfalfa crop coefficients apply to hay as well. Furthermore, the basis for the 0.1 K_c value reduction from the alfalfa crop coefficients is not given.

Cole/Leafy Greens

The crop coefficients used by Land IQ for cole and leafy greens were based on crop coefficients reported for lettuce through communication with Dr. Richard Snyder at UC Davis. The lettuce crop coefficient is constant and presumably developed for application in California, a large state spanning diverse climate regions. The crop coefficients developed for application in California are likely different than what might be expected in southern New Mexico and western Texas.

Grain, Grapes, Legumes, Melons/Squash, Root Crop, Tomatoes, and Turf

The crop coefficients used by Land IQ for grain, grapes, legumes, melons/squash, root crop, tomatoes, and turf are taken from CUP+. The default crop coefficients given in CUP+ were developed for simulating crop water requirements across California, a large state spanning diverse climate regions. The crop coefficients developed for application in California are likely different than what might be expected in southern New Mexico and western Texas.

Asparagus

The crop coefficients used by Land IQ for asparagus are taken from the K_c values given in FAO 56. The K_c values provided in FAO 56 are representative of ideal conditions for "non stressed, well-managed crops in subhumid climates" (FAO 56, Table 12). These conditions may not be representative of actual agricultural fields in southern New Mexico or western Texas.

Irrigated Annuals and Miscellaneous/Other

The crop coefficient used by Land IQ for irrigated annuals and other miscellaneous crops were estimated to be equal to the crop coefficients for chilis. Therefore, the same concerns with chili crop coefficients listed above applies for these crops as well.

Opinion

The *Land IQ Report* provides insufficient information to understand the basis for the crop coefficients used in the Study Area and to support their usage. For most crops and regions of the Study Area, this information is neither described nor provided in the Report. For the three crops (chilis, onions, lettuce) in the Mesilla Valley that the report does provide crop coefficient sources, these crop coefficients are gleaned from published literature, and are seemingly not calculated specifically for observed crop growth in the Study Area. This is confirmed by the documentation of crop coefficient sources provided by Land IQ since the initial disclosures.

To provide the most accurate estimates of consumptive use, crop coefficient curves should ideally represent average local conditions and crop water use across the entire population of fields in the Study Area (ASCE, 2016). Published crop coefficient curves from technical literature and manuals ("book" crop coefficient curves) generally represent growing conditions of idealized "well-managed" crops and do not reflect local differences in irrigation practices, soil conditions, and resulting transpiration and evaporation rates among fields. As described in the technical evaluation above, the Mesilla Valley crop coefficients referenced by the *Land IQ Report* (the *Land IQ Report* does not discuss the differences between potential and actual crop coefficients) represent potential water use rather than actual water use. It is important to note that individual fields often have ET rates that vary from the "book" crop coefficient curves (Tasumi et al. 2005, 2006 and Tasumi and Allen 2007, Singh and Irmak 2009). Locally derived and calibrated crop coefficient curves reflect local differences in water stress, wetness of exposed soil, and resulting transpiration and evaporation rates and are necessary to correctly calculate consumptive use (Allen et al., 1998; ASCE 2016). Land IQ used published crop coefficients developed to represent potential crop water use (as evident by their use of the term potential daily evapotranspiration (PET)), rather than locally derived and calibrated, actual crop coefficient curves as recommended for standard practice (ASCE, 2016).

The *Land IQ Report* only discusses total ET. The ET of applied water (ET_{aw}) and ET of precipitation (ET_{pr}) components of ET_c must be discussed, as the ET_{aw} is required to determine consumption of applied water.

Monthly Adjusted Agricultural Consumptive Use and Yield Analysis

Technical Evaluation

On page 88, the *Land IQ Report* states that PET was "adjusted for irrigation and production differences across time" using an adjustment factor that "takes into account improvements in irrigation efficiency, land leveling, and increased yields/biomass." This adjustment factor was "employed for many of the crop types (dominated by cotton and alfalfa) based on yield records and image analysis," including comparison between reported yield in the JIR and crop reports, and comparison between historical

(1955) and recent (2014) photographs (shown in Exhibit 53). No clear explanation is given to describe how these comparisons were used to arrive at a quantitative "Irrigation and Production Factor."

Similarly, on page 88 the report states: "This factor reduces the PET of crops in historical years because the overall yield, vigor, density and consistency of growth were proven (through historical yield records and image analysis) to be less in previous years. As a result, the consumptive use was correspondingly less. An adjustment factor was employed for many of the crop types (dominated by cotton and alfalfa) based on yield records and image analysis." No documentation is provided to support the notion that all increases in ET have come from an increase in yield, which implies that some increases in yield cannot have come from a larger harvestable yield/biomass ratio that is unrelated to factors that affect ET, such as leaf area or ground cover. Increases in harvestable yield and biomass ratio are common to nearly all modern crops, even with the same amount of ground cover and ET[15]. This is especially the case for cotton where harvestable yield has increased substantially over time.

With regards to chilis, page 83 of the *Land IQ Report* states: "the crop coefficient from 1996 represents relatively high yielding crops compared to today's crops." No documentation is provided to support this statement. Furthermore, page 83 states: "current crops are even higher yielding, but may also be more water efficient, and likely don't need more water." No documentation is provided to support this statement that current crops may be more water efficient. No indication is given as to what has changed with modern crops to cause this. Similar documentation and justification are needed for onion and lettuce crops also. The section on chilis concludes on page 83 by going on to state: "Therefore, adjusting the crop coefficient downward going back in time in the study period is a reasonable approach to estimate consumptive use throughout the study period."

The onion section concludes with very similar statement at the top of page 85. Again, documentation is not provided to support downward adjustment in time as a reasonable approach, and to support proportionality between crop yield and crop ET. The statement does not show congruency with the previous three bullets from that section on chilis.

Documentation is also needed for adjustment to other crops, including lettuce. The lettuce section, presumably discussing the "cole/leafy greens" crop coefficient, concludes with the following two bullets and the statement about adjusting crop coefficients:

- "the crop coefficients used to estimate lettuce and cabbage ET are likely applicable
- Current crops may be higher yielding, but likely don't use much more water than crops grown during the time period when crop coefficients were developed.

Therefore, adjusting the crop coefficient downward going back in time in the study period is a reasonable approach to estimate consumptive use throughout the study period."

---

[15] For example: Barbieri, P., Echarte, L., Della Maggiora, A., Sadras, V.O., Echeverria, H. and Andrade, F.H., 2012. Maize evapotranspiration and water-use efficiency in response to row spacing. Agronomy journal, 104(4), pp.939-944. and
Howell, T.A., 2001. Enhancing water use efficiency in irrigated agriculture. Agronomy journal, 93(2), pp.281-289. and for rainfed corn and soybeans:
Egli, D.B., 2008. Comparison of corn and soybean yields in the United States: Historical trends and future prospects. Agronomy journal, 100(Supplement_3), pp.S-79.

The second bullet and the concluding statement contradict with the bullet stating that “current crops may be higher yielding, but don’t use much more water…” and compared to a concluding statement that states that adjusting crop coefficients, and thus water use, going back in time is reasonable.

Opinion

The methodology used in the *Land IQ Report* does not provide any clear justification or metric for quantifying the proposed Irrigation and Production Factor. Little crop yield information is provided except for chilis, onions, and lettuce in the Mesilla Valley, and those values are provided in differing units that cannot be directly compared without additional information. No quantitative analysis is described in the report to support the proposed Irrigation and Production Factors. Following the deposition, spreadsheets were provided with yield data and graphs, but no description of how the reduction factor used relates to yield and consumptive use was provided.

The *Land IQ Report* states “Visual evidence of these crop growth differences can also be clearly seen when comparing image resources from different decades (Exhibit 53).” No quantitative analysis of the images is described to support the proposed Irrigation and Production Factors. Furthermore, there is no description of how the fields were selected and no analysis describing the number of fields with clear evidence of crop growth differences. It seems simply by chance that four fields with reduced growth in 1955 could be found and compared to 2014. Also, the subjective comparison of higher resolution color images from 2014 to black and white images from 1955 biases the comparison.

The comparison should be for a pre-determined random sample of fields to eliminate any of bias of the analyst in selecting fields that appear most different, and clear criteria should be used to consistently identify cropping and irrigation status, and to quantify parameters of crop growth characteristics that are used to compute a PET adjustment factor. Both images should be black and white (the minimum information available between the two pictures) to prevent subjective effects on the evaluation of consumptive use.

Growing Season Duration

Technical Evaluation

In the supporting spreadsheets accompanying the *Land IQ Report*, consumptive use is calculated for each crop during a growing season that begins on the same season start date for each crop and progresses to the harvest date (season end date) (**Table 11-3**).

Table 11-3. Summary of Growing Season for Predominant Crops in the Rincon and Mesilla Valleys (over 1,000 ac) from the *Land IQ Report* Supporting Files.

Crops (over 1,000 ac, per *Land IQ Report*)	Season Start Date	Season End Date
Alfalfa	3/1	12/1
Chile/ Peppers	4/1	10/1
Corn/ Silage	5/1	11/15
Cotton	4/15	11/30
Onions	11/1	6/1
Pasture	3/1	10/31
Pecans/ Other Trees	3/1	11/30

Source: *MesillaAndRincon_ConsumptiveUse* file, Land IQ, LLC Supporting Files and *Kc_Values_and_Sources_20190924.xlsx provided following the deposition*.

Opinion

No evidence is given to support the selection of the growing season start and end dates chosen for each crop. While the growing season can be defined based on local observed planting and crop maturation dates, the approaches applied are rigid and do not reflect year-to-year changes in weather and temperature. More generally accepted approaches (ASCE, 2016) base the beginning and progression of the growing season on air temperature or via cumulative growing degree days (CGDDs). The end of a growing season for annual perennial crops should be defined by air temperature, by CGDDs or by the occurrence of a killing frost. FAO-56 (Allen et al. 1998) strongly recommends basing starts and ends of growing periods on local observations.

Riparian Water Consumption

Technical Evaluation

Page 108 of the *Land IQ Report* states: "Evapotranspiration rates are available from literature resources and studies relevant to the study area for these three PFGs." The literature sources used to support this statement are not cited. Page 108 of the report goes on to state: "Evapotranspiration (ET) rates depend on several factors including the characteristics of the plant community (including species identity, height and age, vegetation health), stand densities, site conditions such as depth to groundwater and salinity, temperature and precipitation (Tamarisk Coalition 2009, Johns 1989)." However, documentation on how the factors in the statement were quantified in estimating ET for riparian vegetation is not provided.

Page 108 also states: "Using relative tree cover estimates from Papadopulos (2008) for those three tree groups for each of the years of analysis, an average riparian tree ET was developed." No documentation is provided describing how the average riparian tree ET was quantified using relative tree cover.

Page 110 of the *Land IQ Report* states: "Annual ET rates for the Cottonwood-Willow riparian vegetation community were selected by reviewing Allen et al. (2005), which calculated average annual ET (mm) for Cottonwood (1380 mm) and Willow (1283 mm) for a study area in the Middle Rio Grande River Basin, with 2002 Imagery and a satellite based energy balance calculation method using Landsat Imagery. The selected rate was 0.47 m/year." No description, evidence, nor documentation supporting the decision to estimate cottonwood-willow ET as 0.47 m/year as compared to the substantially larger 1331 mm (1.33 m/year) as found by Allen et al. (2005) is provided. The difference between these two values is 180 percent.

Page 110 also states: "An ET rate of 0.5 m/year was selected for Mesquite." The ET rate of 0.5 m/year for mesquite is opposed by values in Exhibit 64 of the *Land IQ Report* that are higher than this rate. No discussion supporting 0.5 m/year is provided.

Opinion

Little evidence or documentation is provided to support the selection of water consumption amounts for riparian systems. The approach is far from a mechanistic approach that considers influences of weather (evaporative demand), wetting frequency, vegetation density, and vegetation health. Rather, broad estimates of water consumption are put forward based on literature values obtained from different climates and different types of riparian conditions.

Nongrowing season water consumption

Technical Evaluation

As described above, the supporting fields accompanying the *Land IQ Report* calculate consumptive use for each crop during a growing season defined by the start and end dates in **Table 11-3**. Outside of this season, the apparent calculated monthly consumptive use is zero.

Opinion

Consumptive use, or evapotranspiration (ET), encompasses all water that is consumptively used either through evaporation from the soil or crop surface or transpiration through the plant tissue. Consumptive use includes the use of water from precipitation and from irrigation. Consumptive use rates vary between individual crops throughout the year based on soil surface coverage conditions and surrounding weather and climate conditions. Outside of the growing season, the consumptive use rates may be low, but they will not equal zero for crops that remain in the field (e.g. pecans and other trees), particularly during precipitation events. Additionally, pre-season irrigation of certain crops, such as cotton, is an important consumptive use of water outside the growing season. Excluding these elements of consumptive water use results in inaccurate results.

Summary

In summary, the methodologies provided in the *Land IQ Report* are generally not clear, are not well documented nor justified, and often do not adhere to standard and accepted procedures. Conclusions regarding crop coefficient adjustments are especially unfounded, as are the weather stations selected to develop weather data for calculating reference evapotranspiration. Additionally, as was demonstrated, weather data QA/QC did not follow standard, recommended quality control procedures as described in the second edition of ASCE Practice Manual 70 (ASCE, 2016) and other widely accepted reference materials. Most importantly, the use of potential crop coefficients rather than average, actual crop coefficients, as recommended by standard, recommended procedures (ASCE, 2016 and ITRC, 2019) for historical water balance analyses, leads to an overestimation of crop consumptive use. This overestimate, compounded by use of non-standard procedures for the soil water budget (as discussed later in this report), leads to a gross overestimation of the pumping necessary to meet consumptive use requirements.

Technical Rebuttal of Montgomery & Associates Report

This rebuttal centers on technical critiques of the methodologies used in the soil water balance and of the related opinions presented in the *Montgomery & Associates Report*. As described, these methodologies do not accurately reflect actual conditions observed on irrigated fields in the Study Area, nor do they adhere to standard and accepted soil water balance practices as described in the second edition of ASCE Practice Manual 70 (ASCE, 2016) and other widely accepted reference materials.

Each of these critiques and objections is identified below under the applicable sections, by topic. Each section concludes with a summary of the New Mexico technical experts' opinions and describes the key areas of disagreement with information to support the rebuttal opinions.

Montgomery & Associates Opinions

Technical Evaluation

On page 9 of the Montgomery & Associates Report, Dr. Kikuchi highlights that "Crop consumptive use simulated using the soil water balance model matches crop consumptive use reported in Dr.

Kimmelshue's report very closely, with average percent discrepancy less than 0.01%." Although this comparison is written in the opinion that it validates the soil water balance model results, later in the report it becomes clear that there is insufficient evidence and justification, as the Land IQ estimates were used as targets of calibration.

Opinion

Page 42 of the *Montgomery & Associates Report* specifies that the monthly model was calibrated using the adjusted crop evapotranspiration rates provided by Land IQ. Thus, the fact that the soil water balance results match the Land IQ results does not serve as a validation of the accuracy of the soil water balance compared to local conditions in the Study Area. Indeed, the same problems with the Land IQ ET estimates, such as the overestimation caused by using potential rather than average, actual crop coefficients for actual conditions observed in the Study Area (see above) apply to the soil water balance results as well.

Soil Water Balance Model

The documentation of the soil water balance model in the *Montgomery & Associates Report* reveals several key incongruities with standard and accepted soil water balance practices. The choices in methodologies likely impede the ability of the model to accurately simulate actual conditions observed in the Rincon and Mesilla Valleys.

The following sections describe the water balance time step and model calibration efforts used in the *Montgomery & Associates Report*. Each section highlights specific areas where the best available information and the *best available science* were not used.

Soil Water Balance Time Step

Technical Evaluation

The soil water balance model developed by Montgomery & Associates "tracks soil moisture within the maximum extent of irrigated agricultural lands of the Rincon and Mesilla basins on a monthly time step" (*Montgomery & Associates Report*, p. 19). Ultimately, the soil water balance is used to "estimate agricultural groundwater pumping and deep percolation" between 1938 and 2016 (p. 19). On page 25, the report describes using the water stress model developed by Allen, et al. (1998) that requires a daily time step, and then incorrectly applies the model on a monthly time step.

Opinion

Standard practices for developing a root zone soil water balance require a daily time step (Allen et al., 1998, ASCE 2016). The monthly time step used for developing the soil water balance is typically used for simulating larger-scale groundwater inflows and outflows, but a daily time step is necessary to accurately simulate the inflows, outflows, and change in storage within the root zone that impact crop water stress (ASCE 2016).

A daily time step aligns more closely with the time scale of events impacting soil moisture exchange and crop consumptive use, such as irrigation and precipitation events and daily crop development. Consequently, a daily model is capable of tracking soil moisture more realistically. Importantly, a monthly model cannot track soil moisture correctly because within the monthly time step irrigation water generally needs to be applied more than once and deep percolation fluxes vary daily and may last only five to ten days.

Monthly models do not capture all of these exchanges and can therefore misrepresent or understate or overstate changes in soil water storage and other flow paths (e.g. consumptive water use). For example, in the Montgomery & Associates soil water balance results, average monthly soil moisture drops below the permanent wilting point of some crops during some months and remains above field capacity (FC; the maximum amount of water that a well-drained soil can hold) in other months. Both scenarios are wholly unrealistic, i.e. physically impossible. Soil moisture exceeding FC can occur briefly (i.e., for a few days) in a typical field, but the excess water will drain through deep percolation soon after (Bauer and Vaccaro, 1987; Willis et al., 1997; Allen et al., 1998; Bethune et al. 2008).

Furthermore, the monthly time step does not clearly describe specific planting/harvest dates or irrigation dates (or volumes on those dates). These events are all critically important to estimating stages of crop development, water stress and consumptive water use in the beginning and ending months of the season.

Model Calibration

Technical Evaluation

As indicated on pg. 42 of the *Montgomery & Associates Report*, the monthly model "was calibrated to match available historic data as closely as possible" and "consisted of adjusting surface runoff of applied water" and "soil moisture uniformity parameters within reasonable ranges to simultaneously match historic data and conceptual trends." The data used to calibrate the monthly model include the adjusted crop evapotranspiration rates provided by Land IQ ("accounting for observed historical trends in crop yield"), metered groundwater pumping at registered irrigation wells, and estimates of on-farm irrigation efficiency.

Opinion

It is not clear that the calibration described above was sufficient to accurately represent observed conditions in the Rincon and Mesilla Valleys. Rather, the calibration suggests that the soil water balance results were effectively predetermined to target the Land IQ consumptive use estimates (which overestimate consumptive use for the Rincon and Mesilla Valleys, as stated in the opinions in the previous section).

As described, the calibration appears to be partly subjective (calibration "to simultaneously match historic data and conceptual trends") and does not use sufficient historic data to address all concerns with accuracy in a monthly model. The adjustment of surface runoff of applied water ("tailwater") to match ET and metered groundwater pumping effectively ignores potential changes in deep percolation, a significant flow path in the soil water balance.

Model Inputs and Methodologies

Several key inputs and methodologies used in the Montgomery & Associates soil water balance model do not reflect the soil characteristics, soil moisture conditions, or crop water stress characteristics observed in the Rincon and Mesilla Valleys.

The following sections describe the assumptions used by Montgomery & Associates to route precipitation inputs through the model and to select soil, irrigation, and water stress characteristics. Each section highlights specific areas where the best available information and the *best available science* were not used.

Soil Analysis

Technical Evaluation

Soil properties used in the soil water balance model are described in Section 2.1.3.4 of the *Montgomery & Associates Report*. The Soil Survey Geographic Database (SSURGO) is given as the source for determining the distribution of soil classes in the Rincon and Mesilla Valleys, which dominantly include clay loam, loam, and loamy sand soils (collectively 70% of the basins). However, following this analysis, "a loam soil was chosen as the representative soil type for the soil water balance analysis" (p. 38-39). Loam soil characteristics were used in the farm soil water balances in both the Rincon and Mesilla Valleys.

Opinion

The extent of the soil analysis is wholly inadequate to characterize the entirety of the Rincon and Mesilla Valleys. Despite the similarity in their expression as "loam" type soils, each of the soil types identified by the Texas technical experts refers to a classification that covers a spectrum of soils. The physical characteristics of clay loam, loam, and loamy sand soils can be quite varied depending on the precise relative composition of sand, clay, and organic matter in each. For example, in the work of Saxton and Rawls (2006) the saturated hydraulic conductivity of these soils can range from nearly 97 mm/hr for loamy sand soils to just 4.3 mm/hr for clay loam (assuming 2.5% organic matter by weight). Likewise, the soil moisture available to plants varies substantially, from 7% by volume in loamy sand to 14% by volume in clay loam. These differences matter, both to actual crops in the field, the flow and distribution of water in the soil, and to a model simulating the soil water balance to determine crop consumptive use.

Lumping all soils into one "loam" category does not accurately reflect the distribution of soils across agricultural land in the Rincon and Mesilla Valleys and the hydraulic behavior of those soils. A more accurate approach for defining soil characteristic inputs for the model would be to conduct a more extensive analysis of the SSURGO data, which is readily available in the public domain, to identify the distribution and percent composition of soil types in each region and then calculating area-weighted soil characteristics to represent each of these soils. It is not clear why this approach was not used in the *Montgomery & Associates Report*. The use of a single soil type and characteristics invalidates the representativeness of parameters determined for the Montgomery & Associates soil water balance model.

Precipitation Routing

Technical Evaluation

As described on page 31 of the *Montgomery & Associates Report*, the monthly soil water balance model simulates surface runoff of precipitation using the Soil Conservation Service (SCS) curve number method. The same curve number value of 85 is used to simulate all agricultural land (cropped and non-cropped) in both the Rincon and Mesilla Valleys. This value is based on curve number values for hydrologic soil group C, corresponding to the loam soil chosen as the representative soil type for both valleys in the soil water balance analysis.

Effective precipitation in the soil water balance model was calculated "using empirical equations adopted by the U.S. Bureau of Reclamation (USBR) […that are] recommended for arid and semi-arid regions" (p. 32).

Opinion

The methodology used by the Texas technical experts to simulate surface runoff of precipitation does not follow best practices for several reasons. First, the standardized approach for estimating surface runoff of precipitation, as recommended by the American Society of Civil Engineers (ASCE), is to use a daily root zone water budget model (ASCE, 2016). As described previously, the monthly soil water balance is unable to accurately simulate daily changes in soil moisture and precipitation that are central to accurately estimating surface runoff. Second, curve number values are to be selected to specifically simulate soil surface characteristics influenced by the soil type and by the crops that are grown in the soil. The Texas technical experts' application of the same curve number to simulate the entirety of both the Rincon and Mesilla Valleys is unlikely to accurately capture the runoff characteristics of different soils and crops across both valleys. A more structured and analytical approach to calculate area-weighted soil parameters and curve numbers using SSURGO data is a more standard and recommended approach.

The reason for selecting the empirical USBR method to calculate effective precipitation is unclear. As with the simulation of surface runoff of precipitation, a daily root zone water budget model is recommended for estimating effective precipitation to account for changes in soil water content, precipitation amounts and ET demands that all vary daily (ASCE, 2016).

Field Irrigation and Non-Uniform Moisture Distribution

Technical Evaluation

In the soil water balance model described in the *Montgomery & Associates Report*, surface irrigation is simulated assuming non-uniform moisture distribution along the lengths of fields, with some portions of fields receiving disproportionately more water than others. As indicated on pg. 22 of the *Montgomery & Associates Report*, "the soil water balance model explicitly accounts for irrigation non-uniformity by distributing the monthly volume of irrigation water – derived from both surface and groundwater – over the field according to a common model for the distribution of infiltration over furrow- or basin-irrigated fields (Karmeli, 1978; Warrick, 1983)." The report asserts that the model "…represents continuous reduction in infiltration rates moving from the field inlet to the end of the field." On p. 21, the report also asserts that in these areas that receive more water, "crop consumptive use demands are fully satisfied" while other portions of the field that receive disproportionately less water "are characterized by smaller rates of crop consumptive use."

The supporting evidence given for these statements is the historical aerial imagery analysis by Land IQ, which "demonstrated the effects [of] non-uniform water application on crop growth during the 1950s, prior to improvements in land-leveling technologies and their subsequent adoption in the Rincon and Mesilla basins" (*Montgomery & Associates Report*, p. 21-22).

As discussed above, the *Land IQ Report* remedies the perceived differences in crop consumptive use demands resulting from "irrigation and production differences" over time through PET adjustment using an "Irrigation and Production Factor" (*Land IQ Report*, p. 88). However, the quantitative basis for this adjustment factor is unclear.

Opinion

The soil water budget model developed in this report incorrectly assumes that the entire reduction in consumptive use assumed by Land IQ is due to non-uniform moisture distribution. To correct this, the Land IQ irrigation and production adjustment factors are applied to most crops in the Rincon and Mesilla Valleys from 1936 through the 1970s and 1980s.

While the quantitative basis for this adjustment factor is unclear, it serves to substantially reduce the ET_c of surface irrigated crops in earlier years. In recent years, the lack of any adjustment factor implies that these crops are achieving full PET – the highest potential evapotranspiration rate that can be achieved, assuming ideal or "pristine" conditions with regard to crop health, soil, climate, water availability, etc. PET is not necessarily equivalent to ET under full supply conditions (in which water supply is not limited). In the field, actual conditions of crop health, soil, and climate observed in the Study Area can affect crop stress and consumptive use, even when sufficient water supply is available across an entire field. Because of the differences between "pristine" and actual conditions, PET is generally higher than actual ET_c and is generally less representative of average crop conditions across a large area (**Figure 11-7**).

These assumptions result in physically impossible monthly average soil moisture conditions both in the 1930s and 1940s and between 2006 and 2018. In the 1930s to 1940s, the low ET values provided by Land IQ require the average soil moisture at the end of the field to be below the crops' wilting points. If the average soil moisture was below wilting point for an entire month, the crop in that area would die.

On the other hand, from 2006 through 2018 the average soil moisture across the entire field is consistently above field capacity. As described earlier, soil moisture above field capacity will drain to equal the field capacity within a few days. It is physically impossible for the soil moisture to remain above field capacity, on average, for an entire month unless the groundwater levels are so high that the root zone is water logged. Even if these high average soil moisture conditions were possible, the crop health in that area would suffer due to the lack of oxygen in the root zone as a result of water filling all pores in the soil, and ET would be reduced.

Additionally, the "analysis" mentioned in the *Montgomery & Associates Report* was described in the Land IQ deposition not as an "analysis," but as "an example" of a few selected fields. To support the assertions made in the *Montgomery & Associates Report,* the ends of these sample fields that are farthest from the inlets should generally show poor crop growth. This is not always the case.

Finally, the assertion that the model "…represents continuous reduction in infiltration rates moving from the field inlet to the end of the field" misrepresents the model. The model represents a reduction in infiltration volumes (often referred to as depths) between the field inlet and field end. These differences in volume are generally the result of different opportunity times for water to infiltrate, or enter the ground, rather than differences in infiltration rates.

(Other disagreements with the aerial imagery analysis cited as support for these soil water balance modeling assumptions are described above in the Land IQ rebuttal section "Monthly Adjusted Agricultural Consumptive Use and Yield Analysis.")

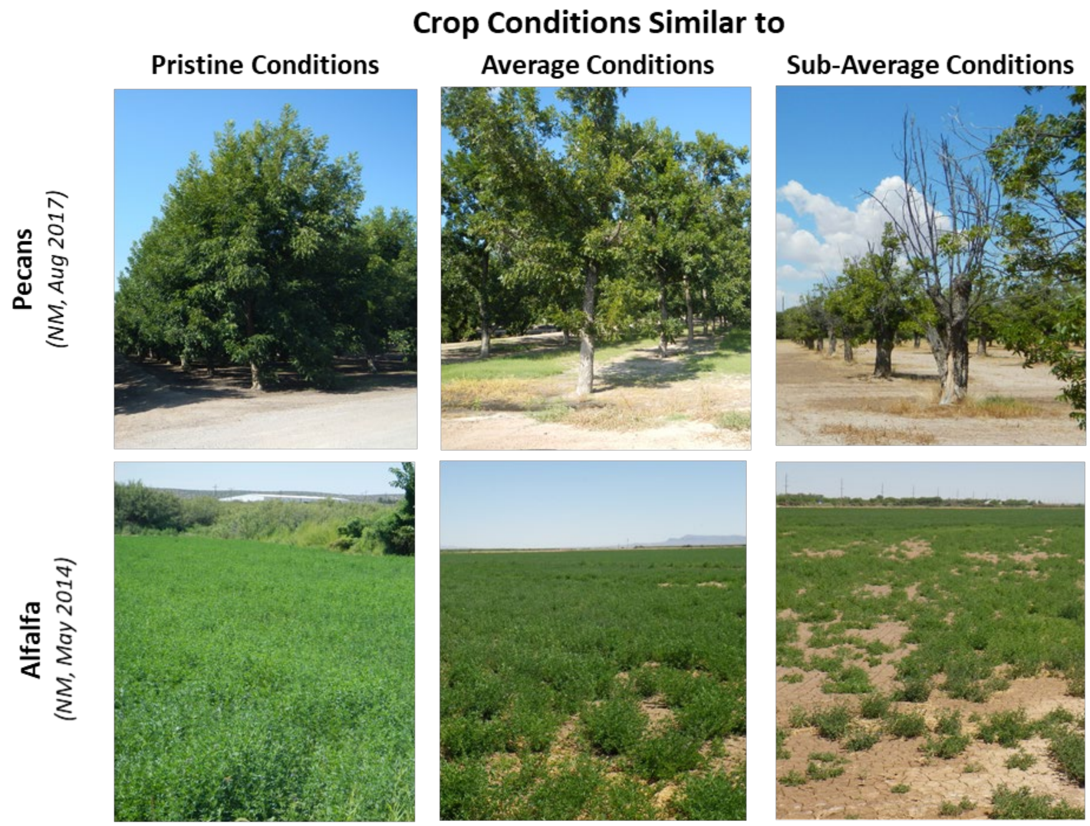

Figure 11-7. Comparison of pecan and alfalfa crops grown under conditions similar to pristine, average, and sub-average conditions, as observed in the New Mexico region of the Study Area (pecan images from August 2017, alfalfa images from May 2014).

Water Stress

Technical Evaluation

On p. 25-26 of the *Montgomery & Associates Report*, a simple model is given for computing actual ET (AET) that adjusts the ET of a well-watered grass reference crop (ET_o) by a crop coefficient (K_c) and a water stress coefficient (K_s) to account for crop-specific water use requirements under potential soil water stress conditions. FAO Irrigation and Drainage Paper 56 (Allen et al., 1998) is given as the reference for this model and for the methodology to compute K_s.

Opinion

Chapter 8 of FAO Irrigation and Drainage Paper 56 states: "The estimation of K_s requires a daily water balance computation for the root zone." However, the methodology applied in the *Montgomery & Associates Report* instead estimates and applies K_s on a monthly time step which contradicts the guidelines in FAO 56. As described in the previous section, the use of a coarse monthly time step can lead to inaccurate estimates of soil moisture changes due to daily root zone inflows and outflows that cannot be accounted for using a monthly timestep, which in turn leads to potential inaccuracies in all calculated or estimated flows in the soil water balance.

Non-Crop Season ET

Technical Evaluation

The Montgomery & Associates Report states on page 26 that actual ET (AET) in cropped areas is calculated as a function of reference ET (ET_o), a crop coefficient (K_c), and a water stress coefficient (K_s), whereas "AET in the non-cropped area is defined as bare soil evaporation."

Opinion

Modeling agricultural fields as bare ground during the non-crop season is not an accurate approach for all crop types or field conditions. For example, permanent crops such as pecans and grapes remain in the ground throughout the year, and their ET is consequently much different than that from bare ground. Likewise, plants and plant materials can remain in the field between harvest and planting and can suppress evaporation from soil (Allen et al., 1998). While ET from these surfaces will not be the same as crop ET during the growing season, these ET rates will still likely not equal ET of bare ground.

Summary

In summary, the monthly timestep that Montgomery & Associates used to develop the soil water balance for the Rincon and Mesilla Valleys does not adhere to best practices for root zone soil water balance modeling. Furthermore, the model calibration process appears to have been driven to match the Land IQ consumptive use estimates (which overestimate the consumptive use for the Rincon and Mesilla Valleys, as discussed in the Land IQ rebuttal opinions), effectively predetermining the results of the soil water balance analysis. The calibration also problematically neglects potential changes in deep percolation, a significant flow path, while adjusting runoff of applied water to match ET and metered groundwater pumping values.

The procedures and assumptions underlying the soil water balance model inputs are also problematic. The Texas technical experts' estimation of water stress-related ET adjustment factors does not obey the underlying assumptions of the standard methodology they used, which require daily or shorter timestep, and also understates water stress conditions in recent years. The soil analysis and methodologies for routing precipitation through the model are also inadequate to accurately characterize different soil and crop surface characteristics across the Rincon and Mesilla Valleys.

These combined characteristics of the model result in unrealistic soil moisture estimates during some months and calls into question the accuracy of the model's consumptive use estimates and subsequent estimates of groundwater pumping.

Appendix 2A. Glossary of Consumptive Use Terms

The definitions below are primarily based on definitions established in publications of the American Society of Civil Engineers (ASCE), American Society of Agricultural and Biological Engineers (ASABE) and Food and Agriculture Organization (FAO). Glossary terms with an asterisk (*) are copyrighted by the American Meteorological Society (2015) and used with permission, via ASCE Manual 70, published in 2016. Page numbers are included when a definition is not found in the referenced document's glossary. Some definitions have been modified (added words are in italics font and removed words are in strikethrough font) here to improve their precision and clarity. A few selected terms that are additionally defined in the Rio Grande Joint Investigation 1938 have been included at the end of this glossary.

Actual Crop Coefficient (ET_oF): The ratio of **Actual Evapotranspiration** to reference evapotranspiration for a specified crop and time period. Sometimes abbreviated K_c. Also referred to as the Fraction of Grass Reference ET_o (ET_oF). Any reduction in K_c due to water stress or other factors such as reduced density, disease, or salinity are encapsulated into the actual crop coefficient. (ASCE, 2016).

Actual Evapotranspiration (ET_{act}): The ET rate that occurs under actual field conditions, often used interchangeably with the term crop ET (ET_c). ET_{act} is important because it is the historical actual consumption of water that affects hydrologic responses and water balances, including groundwater system behavior. (ASCE, 2016)

Alfalfa Reference ET Fraction (ET_rF): The fraction of alfalfa reference ET_r as calculated by the standardized ASCE-EWRI Penman-Monteith equation (ASCE-EWRI, 2005). ET_rF is calculated as the ratio of the computed instantaneous ET from each pixel to the reference ET_r computed from weather data where ET_r is for the standardized 0.5 m tall alfalfa reference at the time of the image. (Allen et al., 2007, p. 389)

Available Waterholding Capacity (AWC): The portion of water in a soil that can be readily absorbed by plant roots. It is the amount of water released between in situ field capacity and permanent wilting point. (ASABE, 2007)

Basal Crop Coefficient (K_{cb}): A crop coefficient representing primarily the transpiration component of ET and a small evaporation component from soil that is visually dry at the surface. Basal crop coefficients are used in soil water modeling to provide more accurate estimates of crop ET on a daily basis. (ASCE, 2016)

Beneficial Use: That part of water withdrawn that supports the production of crops: food, fiber, oil, landscape, turf, ornamentals, or forage. Water consumed to achieve an agronomic objective is beneficial. The major beneficial uses are crop ET and water needed for improving or maintaining soil productivity, that is, salt removal. (Burt, et al., 1997)

Capillary Fringe*: A shallow zone of soil above a water table that is nearly saturated by capillary action in the smaller pore spaces. (ASCE, 2016)

Consumptive Use Fraction (CUF): The fraction of water withdrawn from a surface or ground water source that is evaporated, transpired, incorporated into products or crops, consumed by humans or livestock, or otherwise removed from the immediate water environment. (ASCE, 2016).

Consumptive Irrigation Requirement (CIR): The potential ET for a crop required for full production, including incidental evaporation losses from soil, **in excess of the effective Precipitation**. In other words, the irrigation water needed for full water supply under perfect distribution *uniformity* (no losses (100% efficiency)). Sometimes called crop irrigation requirement. ASCE (2016) uses the synonymous term Net Irrigation Water Requirement (NIWR) with definition: NIWR is the amount of soil water that must be made up to complete the potential ET requirement and avoid undesirable water stress. (ASCE, 2016, p. 435)

Consumptive Use* (CU): That part of water withdrawn that is evaporated, transpired, incorporated into products or crops, consumed by humans or livestock, or otherwise removed from the immediate water environment (also referred to as water consumed). Water consumed may be defined as beneficial if there are economic or environmental benefits or non-beneficial if there are no direct economic or environmental benefits. (ASCE, 2016)

Crop Coefficient*(K_c): The ratio of evapotranspiration occurring with a specific crop at a specific stage of growth to reference crop evapotranspiration ~~at~~ *during* that time *period,* usually denoted by the symbol Kc (Not the same as K used in the Blaney-Criddle method). (ASCE, 2016)

Crop Water Requirement*: The depth of water needed to meet evapotranspiration of a disease-free crop, growing in large fields under nonrestricting soil conditions and achieving full production potential in a given growing environment. (ASCE, 2016)

Deep Percolation*: The drainage of soil water by gravity below the maximum effective depth of the root zone. (ASCE, 2016)

Depletion: Net rate of water use from a stream or groundwater aquifer for beneficial and non-beneficial uses. For irrigation or municipal uses, the depletion is the headgate or well-head diversion less return flow to the same stream or groundwater aquifer. (ASCE, 2016)

Dewpoint*: The temperature to which a given parcel of air must be cooled at constant pressure and at constant water vapor content until saturation occurs, or the temperature at which saturation vapor pressure of the *air* parcel is equal to the actual vapor pressure of the contained water vapor (ASCE, 2016).

Effective Precipitation*: Precipitation that remains on the foliage or in the soil that is available for evapotranspiration, and reduces the withdrawal of soil water by a like amount. (ASCE, 2016)

Grass Reference ET Fraction (ET_oF): The fraction of clipped grass reference ET_o as calculated by the standardized ASCE-EWRI Penman-Monteith equation (ASCE-EWRI, 2005) and representing the relative amount of ET in terms of fraction of grass reference ET occurring from any particular pixel of a satellite image. Typical ranges for ET_oF are 0 to 1.4. ET_oF is synonymous with the crop coefficient as used with a clipped grass reference basis. (ASCE, 2016).

Evaporation*(E): The physical process by which a liquid or solid is transformed to the gaseous state which in irrigation; usually is restricted to the change of water from liquid to gas. (ASCE, 2016)

Evaporation Coefficient (K_e): A coefficient to account for evaporation from the soil surface following rainfall or irrigation. A maximum value of approximately 1.2 is recommended when using clipped grass reference ET. (ASCE, 2016, p. 230 and 235)

Evapotranspiration* (ET): The combined processes by which water is transferred from the earth's surface to the atmosphere; evaporation of liquid or solid water plus transpiration from plants. (also see consumptive use). (ASCE, 2016)

Fetch*: (Also generating area) The length of ~~fetch~~ *upwind* area, measured in the direction of the wind from the site in question*, that has similar vegetation and water availability as the local surroundings of a weather or ET measurement.* (ASCE, 2016)

Field Capacity: The amount of water remaining in a soil when the downward water flow due to gravity becomes negligible. (ASABE, 2007)

Infiltration: The downward entry of water through the soil surface into the soil. (ASABE, 2007)

Irrigation Consumptive Use Coefficient (ICUC): The ratio of volume of irrigation water consumptively used to the total volume of irrigation water applied minus the change in storage in the root zone *(a defined volume)*, both in a specified period of time and expressed as a percentage. (Burt, et al., 1997)

Irrigation Efficiency (IE): The ratio of volume of irrigation water beneficially used to the total volume of irrigation water applied minus the change in storage in the root zone *(a defined volume)*, both in a specified period of time and expressed as a percentage. (Burt, et al., 1997)

Irrigation Water Requirements*: The quantity of water exclusive of *effective* precipitation that is required for various beneficial uses, particularly evapotranspiration. (ASCE, 2016)

Management Allowed Depletion (MAD): The desired soil water deficit at the time of irrigation; can vary with crop growth stage. (ASABE, 2007)

Mean Crop Coefficient (K_{cm}): A crop coefficient where the time-averaged effects of evaporation from the soil surface (from rainfall or irrigation) are included in the crop coefficient value. (ASCE, 2016, p. 268 and 273)

METRIC: Mapping Evapotranspiration at high Resolution using Internalized Calibration. METRIC is a satellite-based image-processing tool *developed by the University of Idaho* for calculating ET as a residual of the energy balance at the Earth's surface. (Allen et al. 2007, p. 380)

NDVI: Normalized Difference Vegetation Index is a dimensionless, radiometric measure that indicates relative abundance and activity of green vegetation. NDVI is estimated from two shortwave bands typically measured by satellites: the red band (~0.6-0.7 µm) and the near infrared band (~0.7-1.3 µm). Typically, NDVI varies between 0.1 and 0.8, with the higher value indicating dense vegetation and values less than about 0.2 associated with soil and rock that is void of vegetation. NDVI is generally negative for water, snow and clouds. (Jensen, 2007, p. 382 and ASCE, 2016, p. 552, Allen et al., 2007, p. 384)

Nonconsumptive Use: That part of water withdrawn that is not evaporated, transpired, incorporated into products or crops, consumed by humans or livestock, or otherwise removed from the immediate water environment. Water withdrawn that is not consumed may be recoverable for further use or *may be* non-recoverable or lost to further use ~~such as~~ *due to* flows to saline sinks or flows to the sea. (ASCE, 2016)

Permanent Wilting Point: The soil water content below which plants cannot ~~readily~~ *sufficiently* obtain water and will permanently wilt. Sometimes called *permanent wilting percentage, fifteen-atmosphere percentage,* or *lower limit*. It is estimated as the soil moisture content at about –1.5 MPa matric potential. (ASABE, 2007)

Pixel: A two-dimensional picture element that is the smallest nondivisible element of a digital image. *In Landsat images, a pixel has dimensions of 30 m x 30 m.* (Jensen, 2007, p. 194)

Potential Crop Coefficient (K_{pot}): The ratio of ET_{pot} to ET_o. The potential, or upper limit on ET for a particular crop, in other words, representing a pristine, well-watered condition. (ASCE, 2016, p. 267).

Potential Evapotranspiration* (ETpot): The rate at which water, if available, would be removed from *wet* soil and plant surfaces, expressed as the rate of latent heat transfer per unit area or an equivalent depth of water. (ASCE, 2016)

Preplant Irrigation: Irrigation applied prior to seeding *of annual crops or greenup of perennial crops*. Sometimes called *preirrigation.* (ASABE, 2007)

QAQC: Quality Assessment (QA) and Quality Control (QC) of data; in the case of weather data, where data are compared against relevant physical extremes, using statistical techniques to identify extreme or anomalous values; and comparing data with neighboring stations. Current ASCE procedures compare weather data, visually, to theoretical values in the case of solar radiation, and compare dewpoint temperature to air temperature, in the case of humidity. (Allen, 2008, p. 192-193)

Reference ET (ET_{ref}, ET_o or ET_r): The ET rate from a reference surface closely resembling an extensive surface of dense, actively growing vegetation having a specified uniform height and surface resistance, not short of soil water, and representing ET from an expanse of at least 100 m of the same or similar vegetation. **ET_o** refers to reference ET from a short crop, having an approximate height of 0.12 meter, generally approximated by a clipped, cool-season grass. **ET_r** refers to reference ET from a tall crop, with an approximate height of 0.50 meter, generally approximated by full-cover alfalfa. In the case of ET_r, reference ET represents the near maximum possible ET as dictated by weather conditions (temperature, wind, humidity, sunshine) and the vegetation surface. (ASCE, 2016, p. 197-198)

Root Zone: The layer of soil that plant roots readily penetrate and in which the predominant root activity *and water extraction* occurs. (ASABE, 2007)

Soil Water: Water present in the soil pores (also called soil moisture, which would include water vapor). (ASCE, 2016)

Soil Water Capacity: The quantity of water that a soil can hold and make available to most plants, usually defined as water held between –33 kPa and –1500 kPa matric potential; the amount of water stored in the soil at field capacity. Also called *available water capacity*. (ASABE, 2007)

Solar Radiation* (R_{so}): The total electromagnetic radiation emitted by the sun. (ASCE, 2016)

Surface Energy Balance (SEB): The surface energy balance relates to the various ways in which net radiation, Rn, is balanced by the inputs or outputs of energy from nonradiative parameters. The vertical energy balance at the soil or water surface, or at the "effective surface" of a crop, is the sum of sensible heat flux to or from the air *(H)* and soil (or water) *(G)*, latent heat *(LE)*, net radiation *(Rn)*, and other miscellaneous fluxes. The energy balance of land and water surfaces…is expressed as…Rn = LE + H + G, *so that LE = Rn – G – H*. (ASCE, 2016, p. 59-60)

Transpiration* (T): The process by which water in plants is transferred as water vapor to the atmosphere. (ASCE, 2016)

Vapor Pressure*: The partial pressure of water vapor in the atmosphere. (ASCE, 2016)

Water Stress Coefficient (K_s): A dimensionless coefficient dependent on available soil water. The value for K_s is 1 unless available soil water limits transpiration, in which case it has a value less than 1.0. (ASCE, 2016, p. 268).

Water Use: Water that is used for a specific purpose such as domestic use, irrigation, or industrial processing. *It includes both consumptive and nonconsumptive components.* (ASCE, 2016)

Appendix 2B. Rio Grande Joint Investigation, 1938 Selected Consumptive Use Terms

Consumptive Use (Evapotranspiration) – The sum of the volumes of water used by the vegetative growth of a given area in transpiration or building of plant tissue and that evaporated from adjacent soil, snow, or intercepted precipitation on the area *during* ~~in~~ any specified time *period*. (Rio Grande Joint Investigation, 1938 (page 88))

Depletion (Stream-flow depletion) – The amount of water which annually flows into a valley, or onto a particular land area (I), minus the amount which flows out of the valley or off from the particular land area (R) is designated "stream-flow depletion" (I-R) and is usually less than *or equal to* the consumptive use and is distinguished from consumptive use in the Rio Grande studies. (Rio Grande Joint Investigation, 1938 (page 326))

Appendix 4A. Field Survey Protocol

Equipment and Material

Each two to three-person team required a laptop, a Global Positioning System (GPS) unit with appropriate software, an automobile power cord and converter, and a standalone ArcMap license. The WUCB has 4 laptops (if all staff can participate) and the ISC has 3 GPS units.

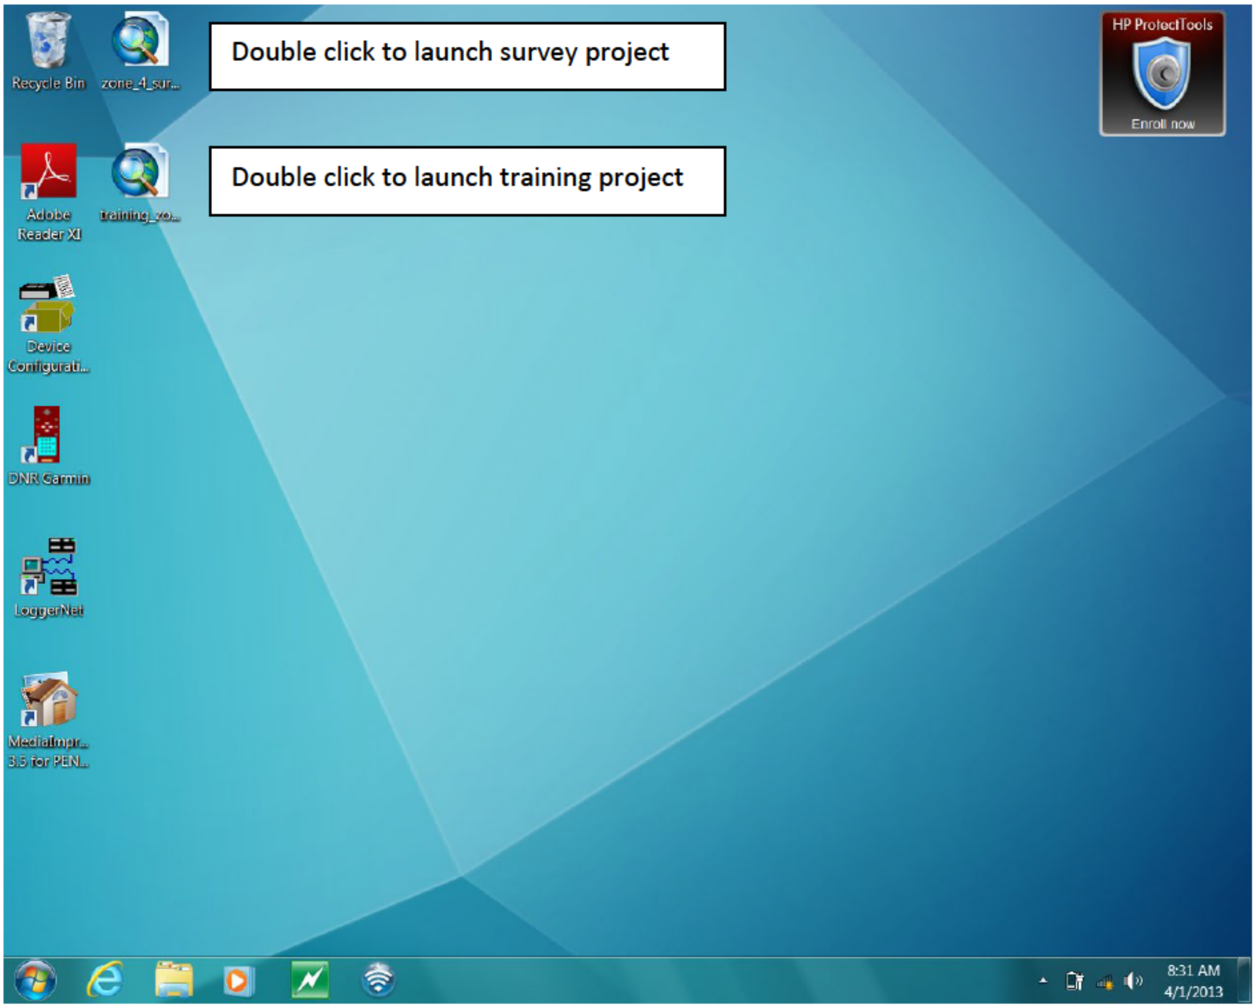
GIS

The GIS consisted of a base polygon layer from INTERA (2016) with drop downs for irrigation (yes/no), irrigation method, crop type, growth stage, field condition, and basic comments, as well as an open field where additional comments could be added. The Geodatabases were loaded onto the laptops. Garmin GPS units were attached to the computers, and Minnesota Department of Natural Resources freeware software was used to connect the Garmins to ArcGIS.

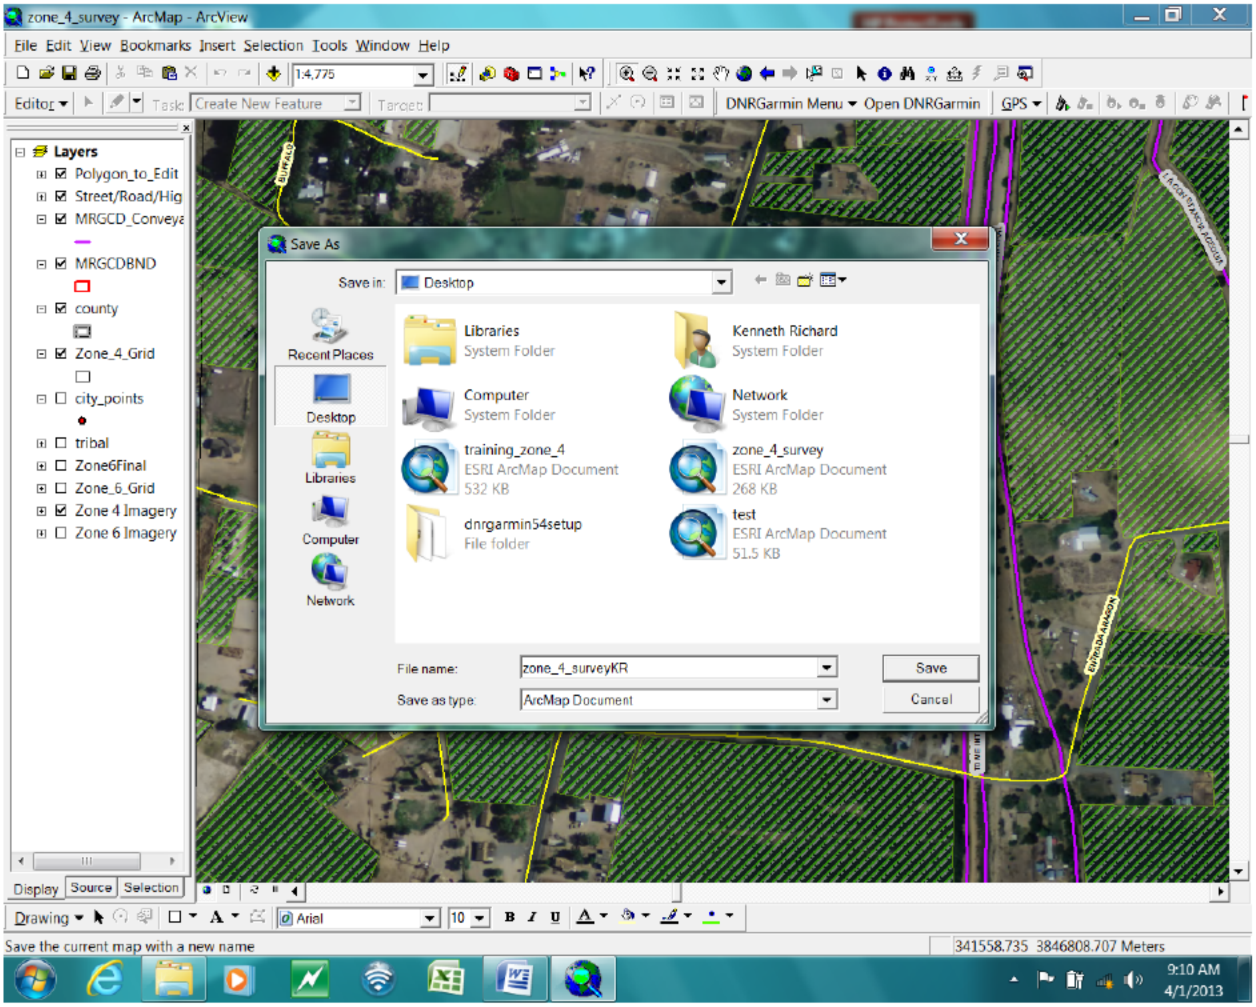
Each team had one person skilled in GIS applications using the laptop and following the detailed steps described below to start the project at the beginning of each day, log the data observed for each field and close out the project at the end of the day.

Starting your project and GPS unit in order to start collecting data.

- Log into computer and double click on Training_zone_# icon in order to practice or Zone_#_Survey for the actual survey project.

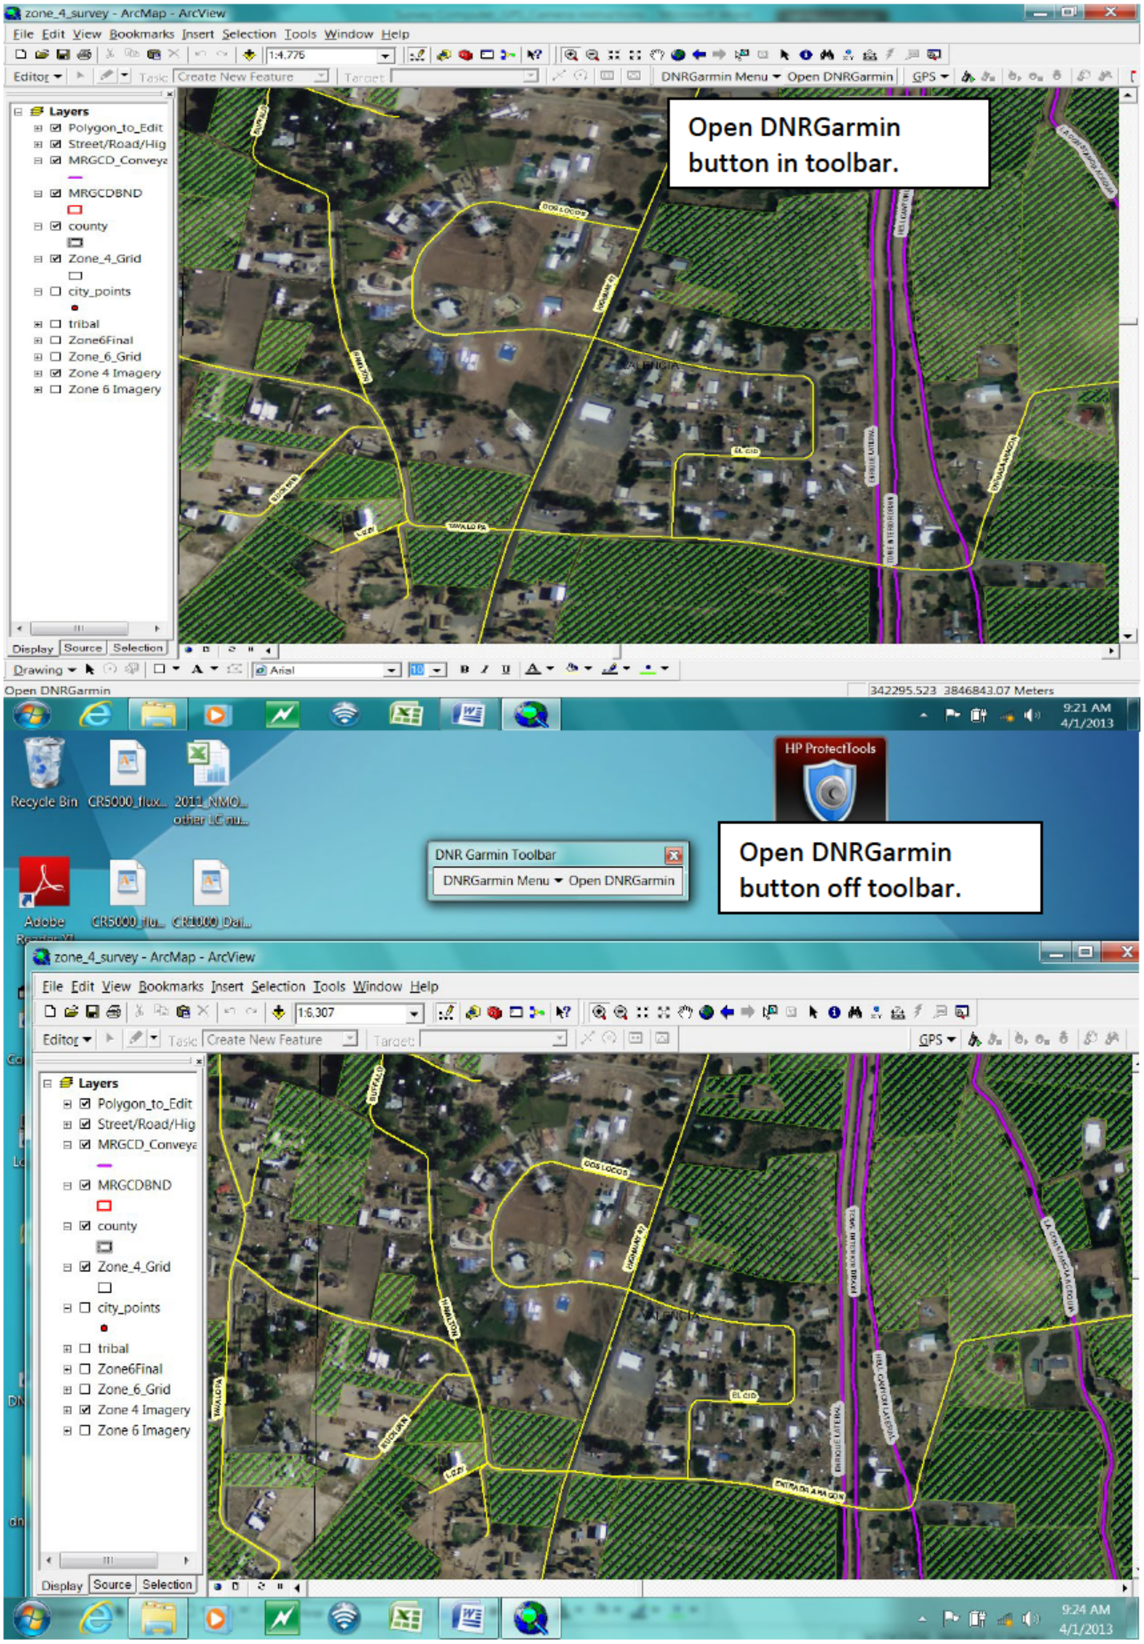


- Save projects immediately as project name plus users initials to desktop. This will allow individual users to create a working project that best fits their needs (line or polygon color). Each person who enters the GIS data may want to save their own project or the team may want to use one project for everyone.



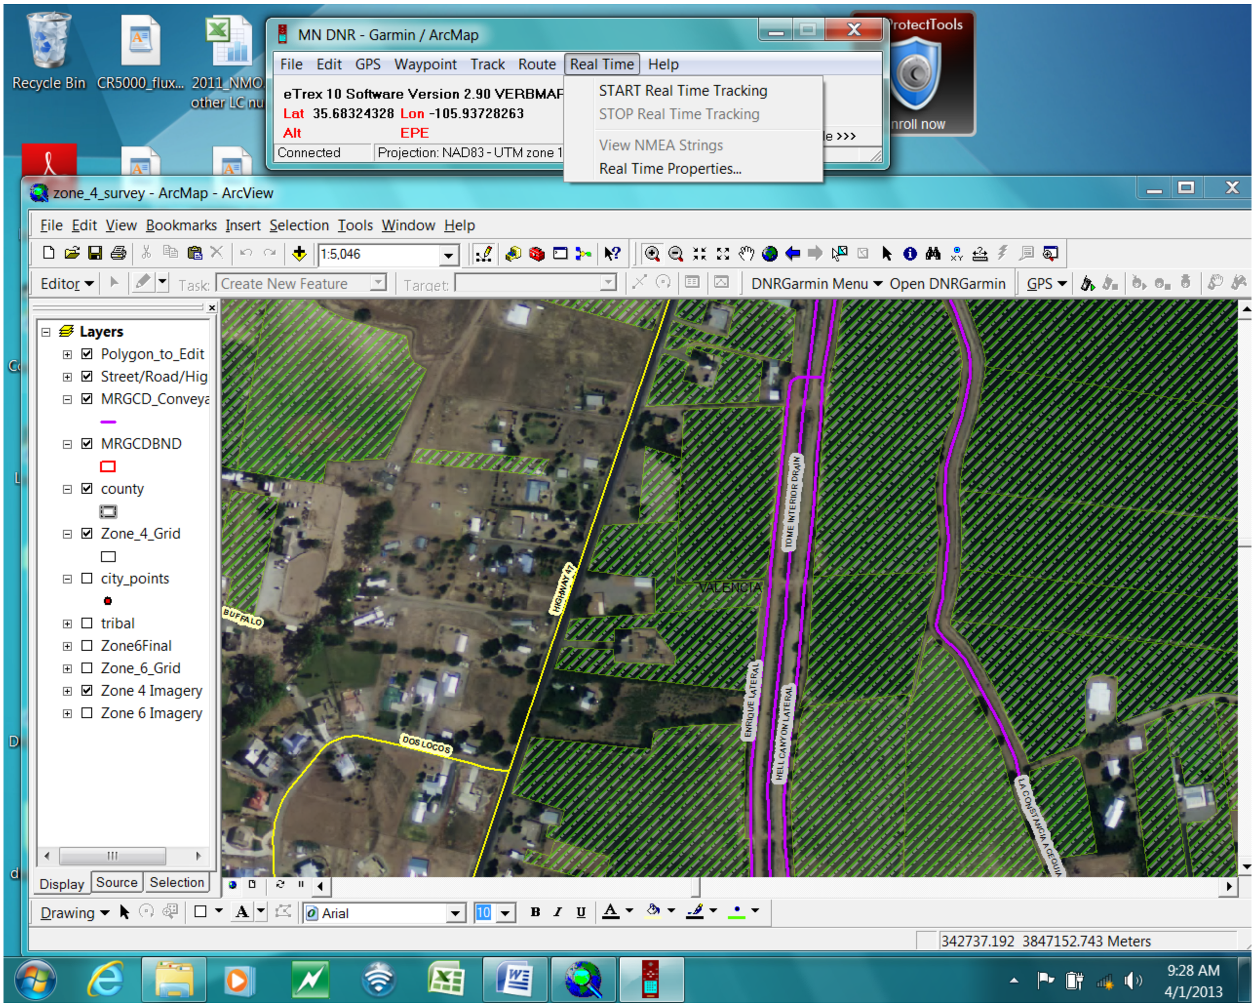
- Once the project is saved, turn on the Garmin GPS etrex 10. The on/off button is located next to the word "light".
- Turn over the unit and lift the rubber flap above the steel loop. Plug the provided cable into the port. Plug the USB side of the cable into the Laptop's front left USB port.
- Look at the Garmin screen and it should say "USB cable detected. Would you like to go to Mass Storage." No should be highlighted black. Select the highlighted "No" by pushing straight down on the navigation bar (toggle switch) located above the Garmin screen to the right.

- Find the "Open DNRGarmin" located either on your ARCGIS toolbar or as a separate toolbar off the ARCGIS Window. See below.



Open DNRGarmin button in toolbar.
Open DNRGarmin button off toolbar.
DNR Garmin Toolbar
DNRGarmin Menu
Open DNRGarmin

- The Garmin should automatically connect once the Open DNRGarmin is clicked. Below you can see active location data in the Lat Lon spaces. Select the Real Time drop down menu and select "Start Real Time Tracking." "MNDNR – Garmin" and "Real Time Window" windows will open.

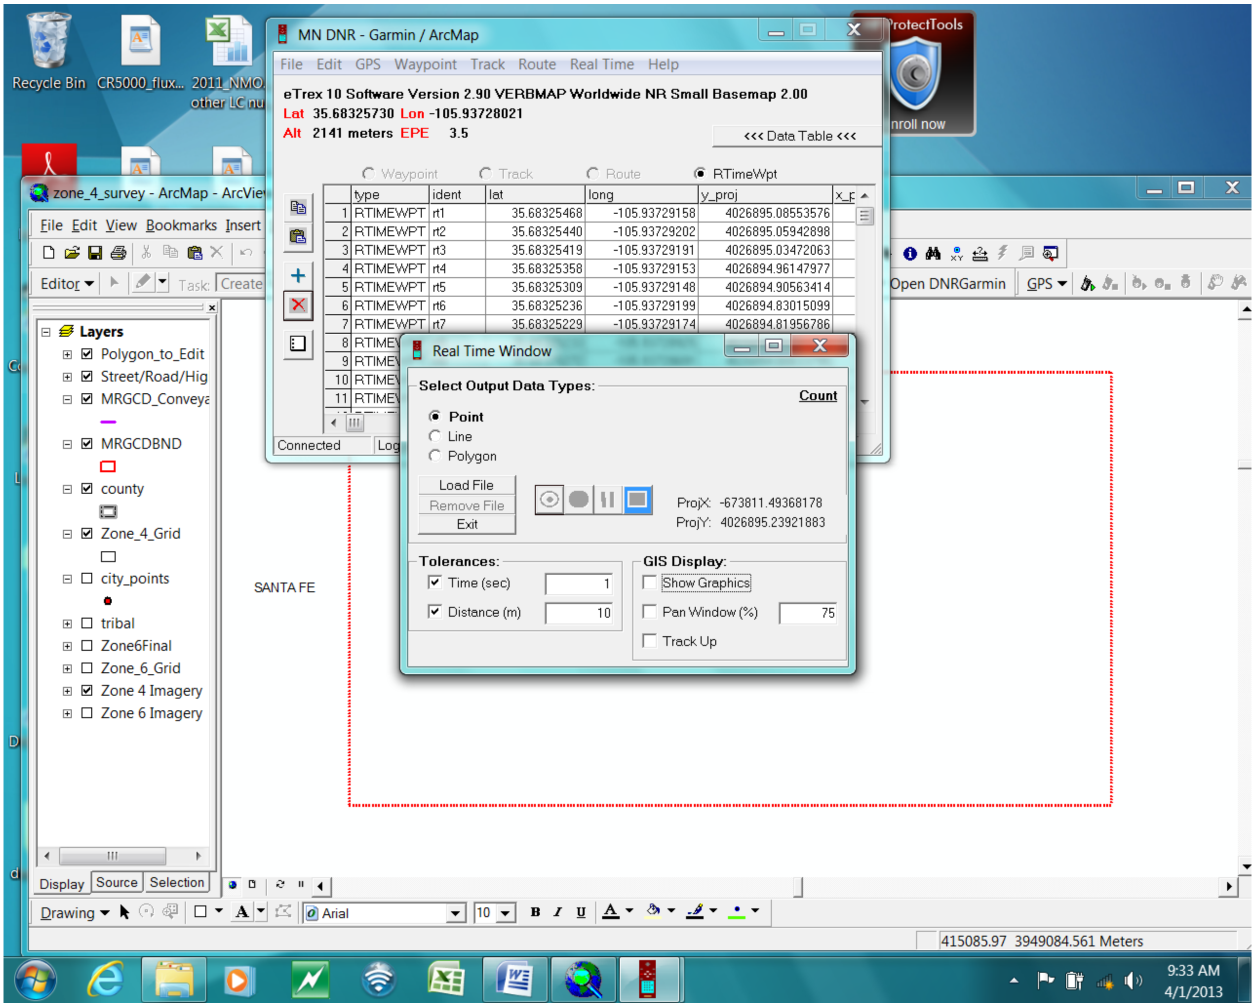


- Based on past surveys, there is a recommendation to change settings to what is seen below.
  - Leave "Select Output Date Types" as point.
  - Select both "Time" and "Distance" and populate with 1 second and 10 meters respectively.
  - Uncheck all "GIS Display"
    - Show Graphics: leaves a trail of markers indicating where you've been in the .mxd. These obstruct the map & are not easily deleted.
    - Pan Window: auto pans to your place in the .mxd. The percentage indicates how big the window (red dashed line) is within the View. Most people have found this annoying or difficult to work with, however it could be useful temporarily if you lose your place.
    - Track Up: orients ArcMap so that "up" is the direction you are traveling rather than north. This causes ArcMap to refresh often, which removes the layers so

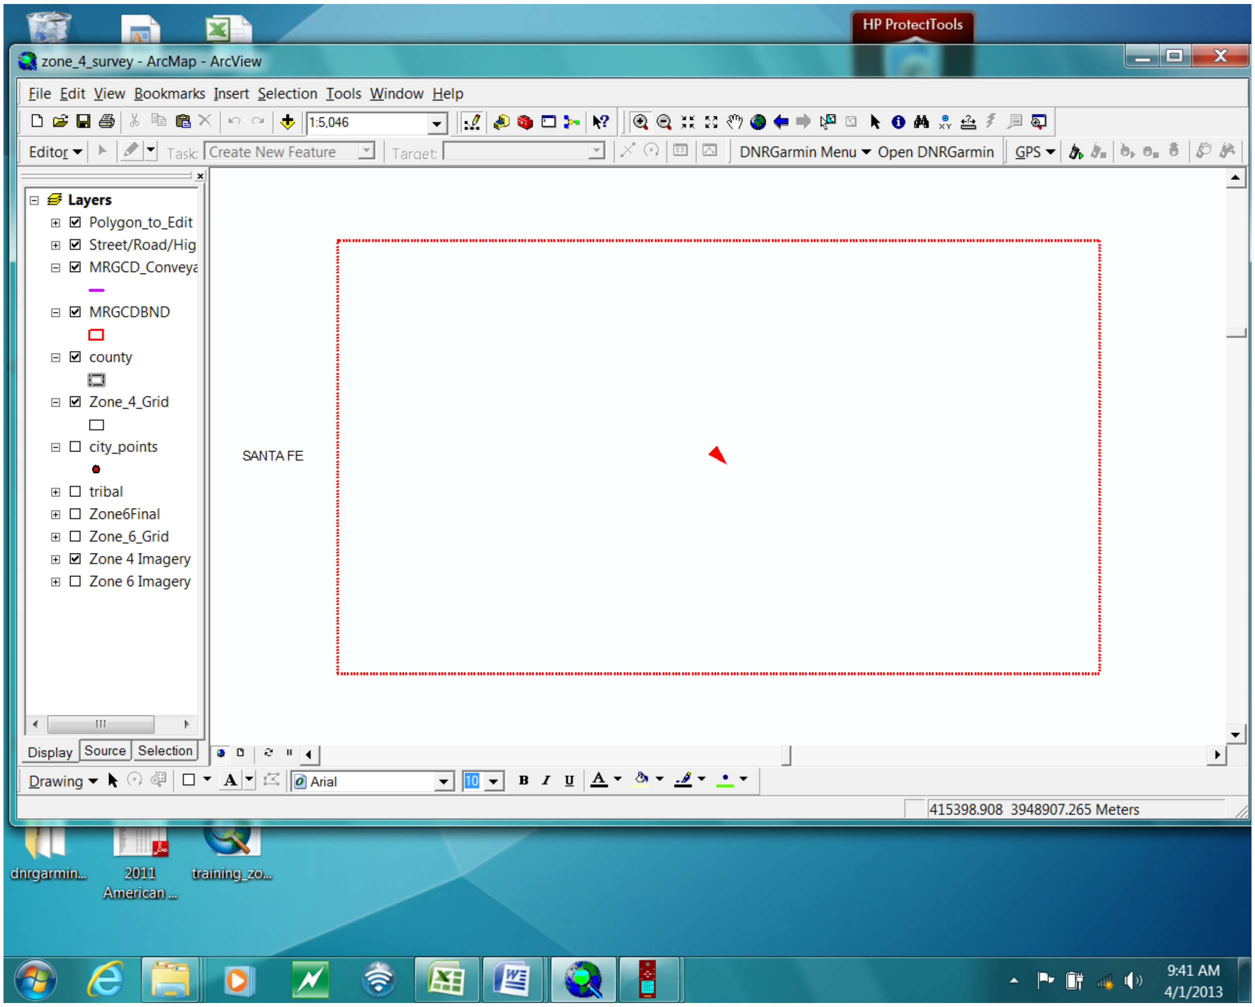
that you can’t see them & you can’t select a polygon. It’s better to keep north up. There will be an arrow that will show you in what direction you are traveling.

  - Minimize both DNRGarmin windows.

- If issues arise with the GPS unit and or software, repeat initial start up and or try another USB port on the left side of the computer.



- You will see a red triangle which is the current location being shown in ARCGIS.

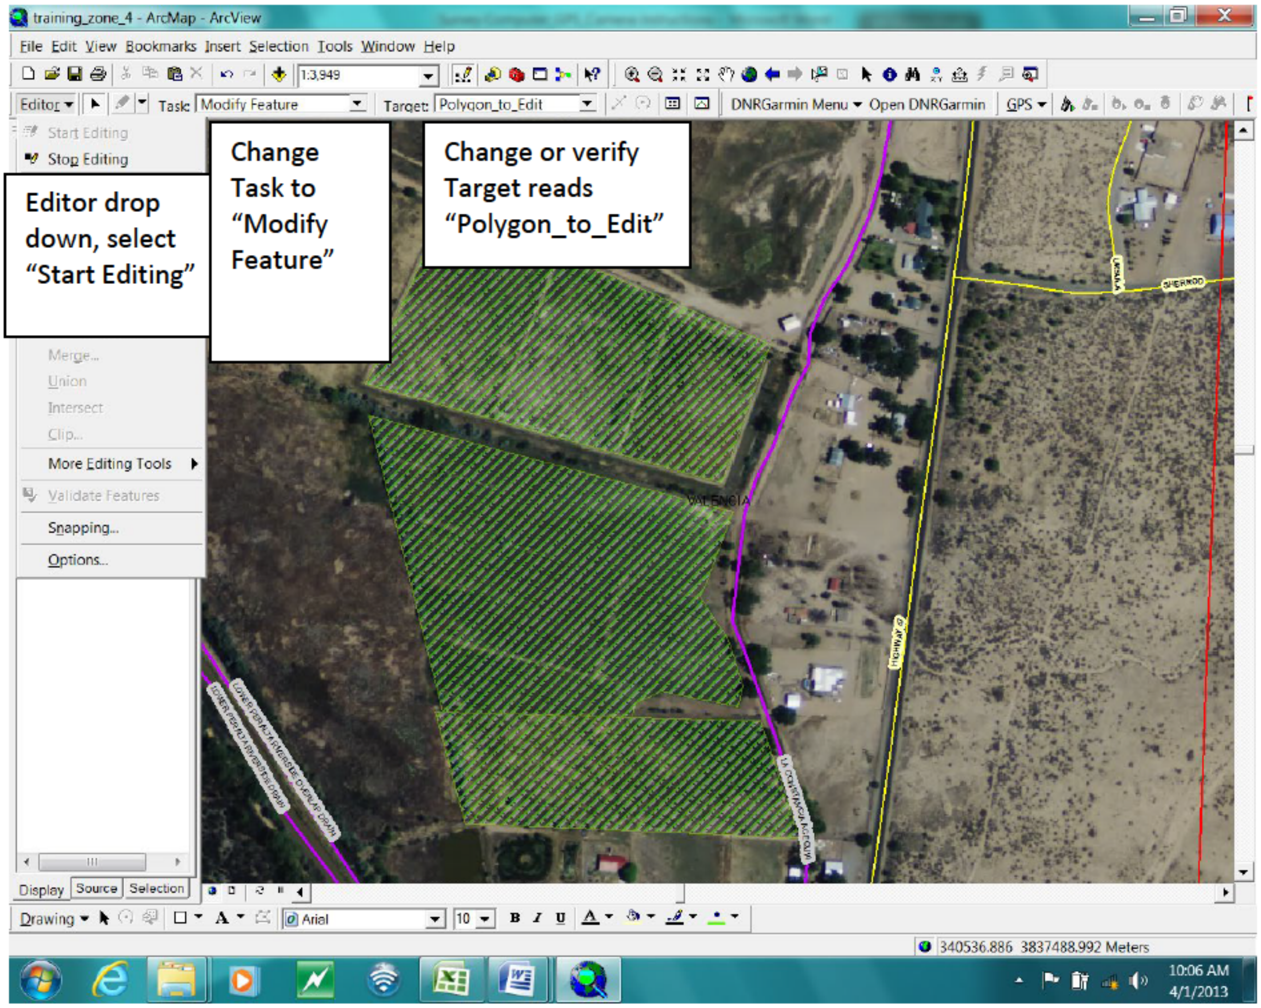


- When done for the day, close the 2 DNRGarmin windows and unhook the GPS unit. Once the GPS unit is unplugged from the computer, it will shut off by itself.

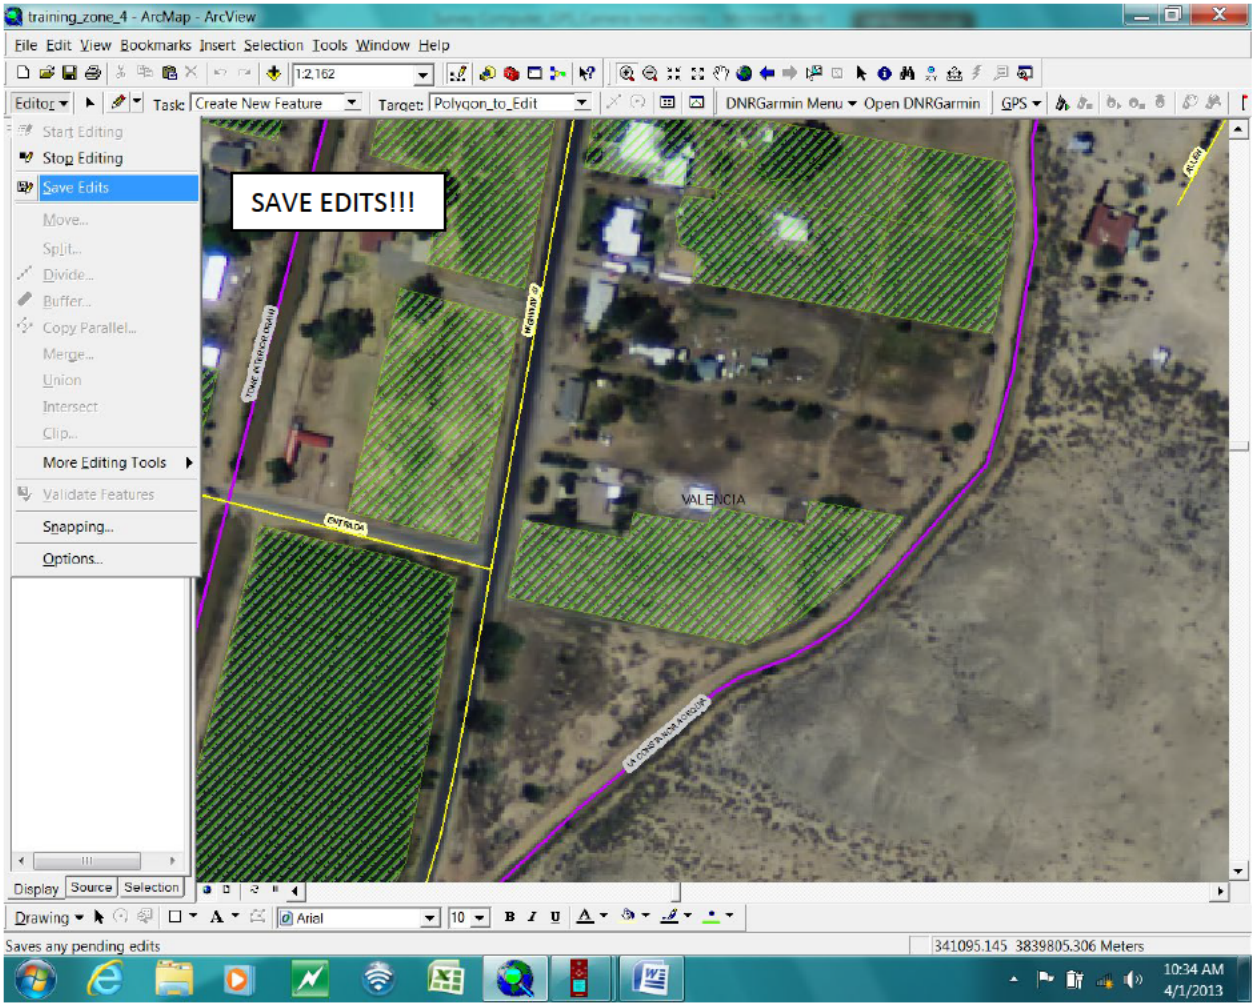
Collection of Crop Data - Populating the GIS projects - Logging changes into the provided Mapbook.

- The Mapbook contains map sheets for the assigned zone. The map sheets represent approximately a 1 mile by ¾ mile area. Mapbooks are used to:
  - Split fields that are shown as one polygon but contain separate crop types. Split the field with the provided Sharpie and write crop types associated with new field boundaries.
  - If a large agricultural field does not have polygon (there should not be any), draw a field boundary and write crop type on page.
  - Mark any page with changes with provided tabs.
  - List everyone's task in the Mapbook
    - List GIS person
    - Mapbook Person
    - Driver

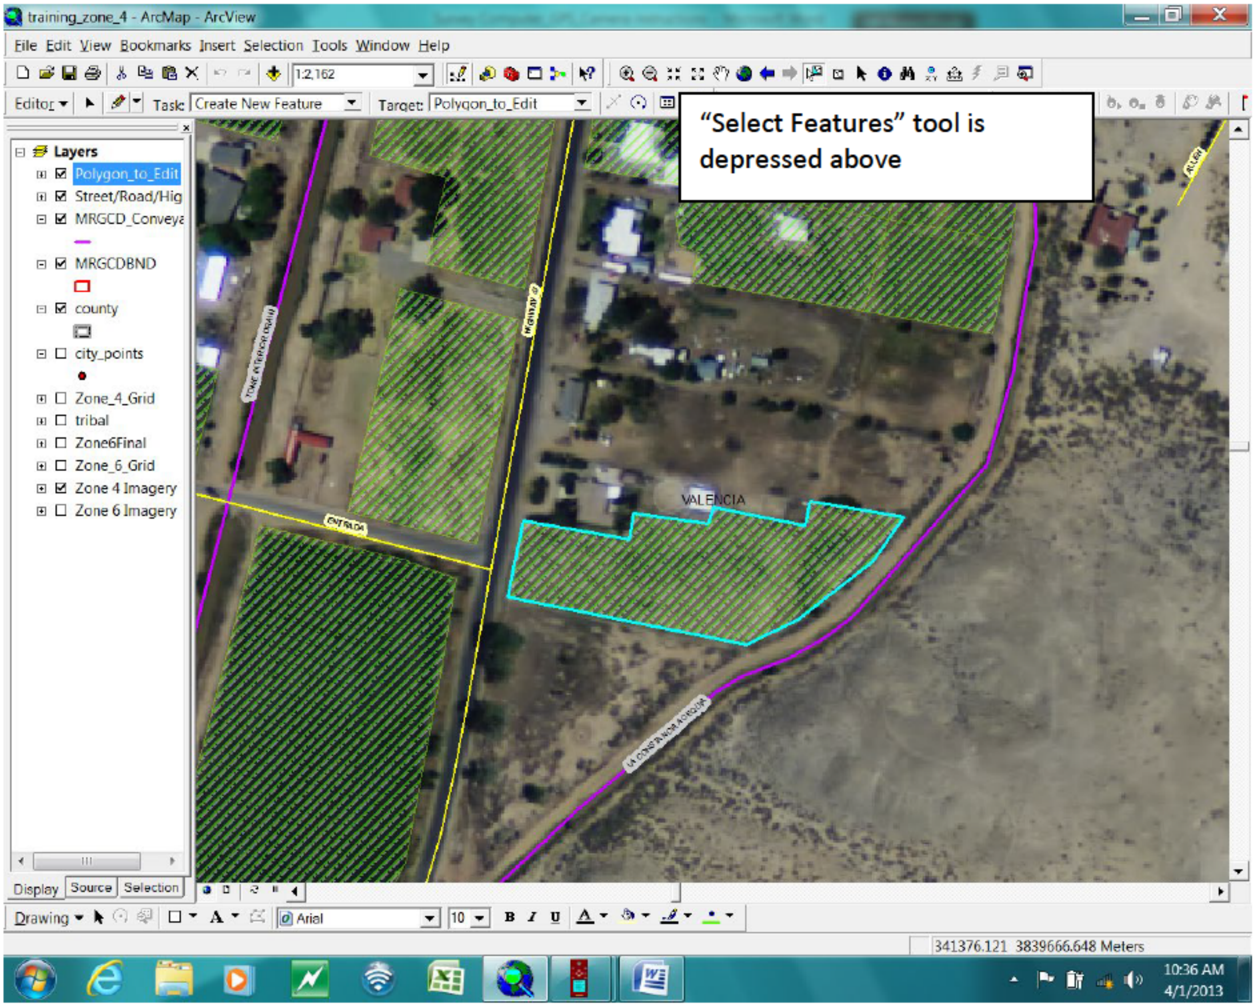
    - If assignments are changed list on Mapbook page when the change occurred.
- At the beginning of each day, find your farthest south Mapbook page and location in the GIS and start collection from the point and collect data moving north.
- To start collecting GIS data under the "Editor" drop down menu, select "Start Editing". The areas represented on the intial project with green hatched polygons need to be collected.
    - Change Task to "Modify Feature" and verify Target reads ""Polygon_to_Edit"



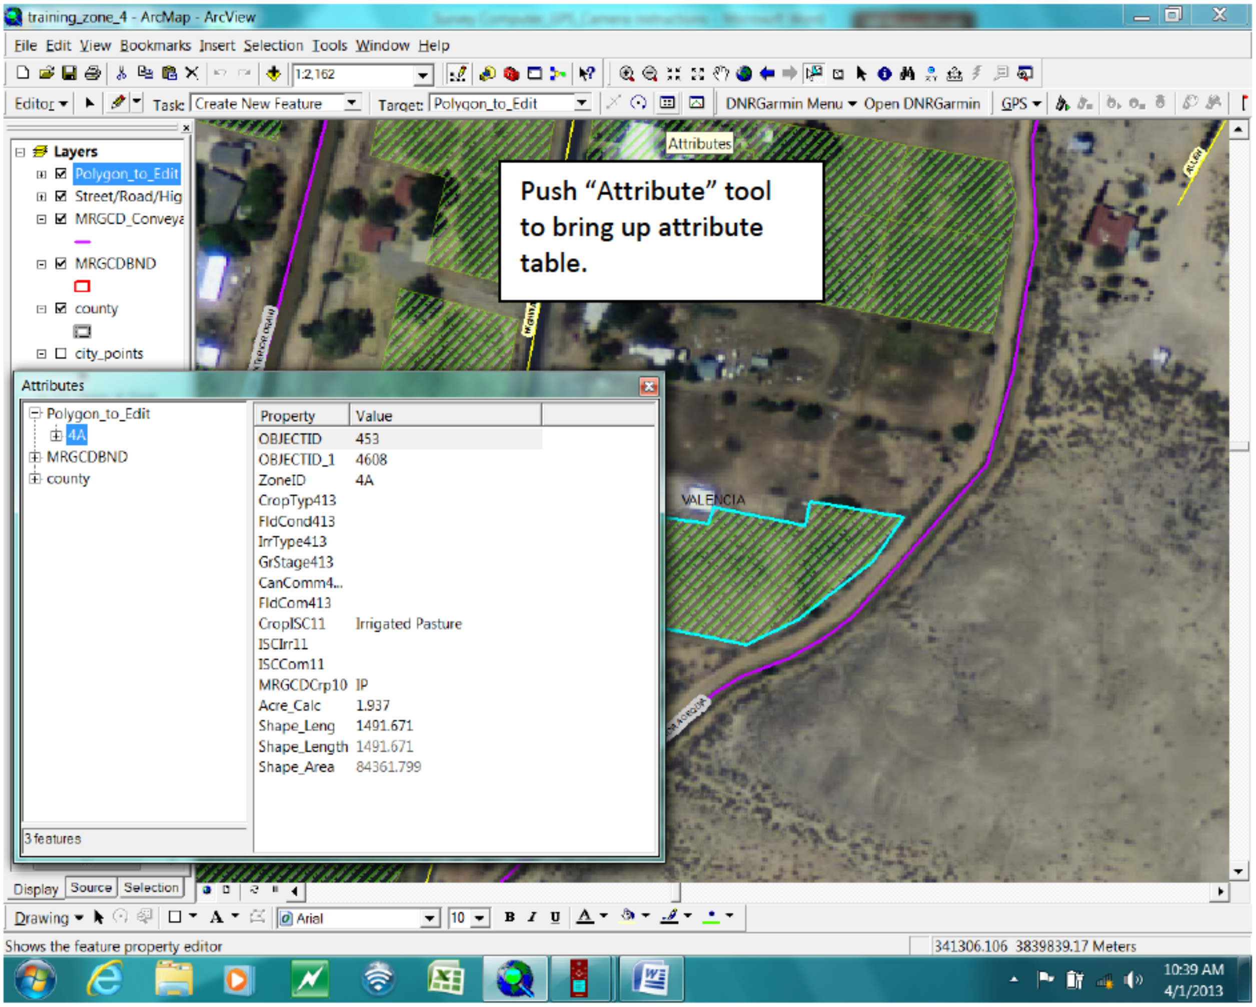
- Start continually saving your updates once you begin collecting data. Changes should be saved every few minutes.



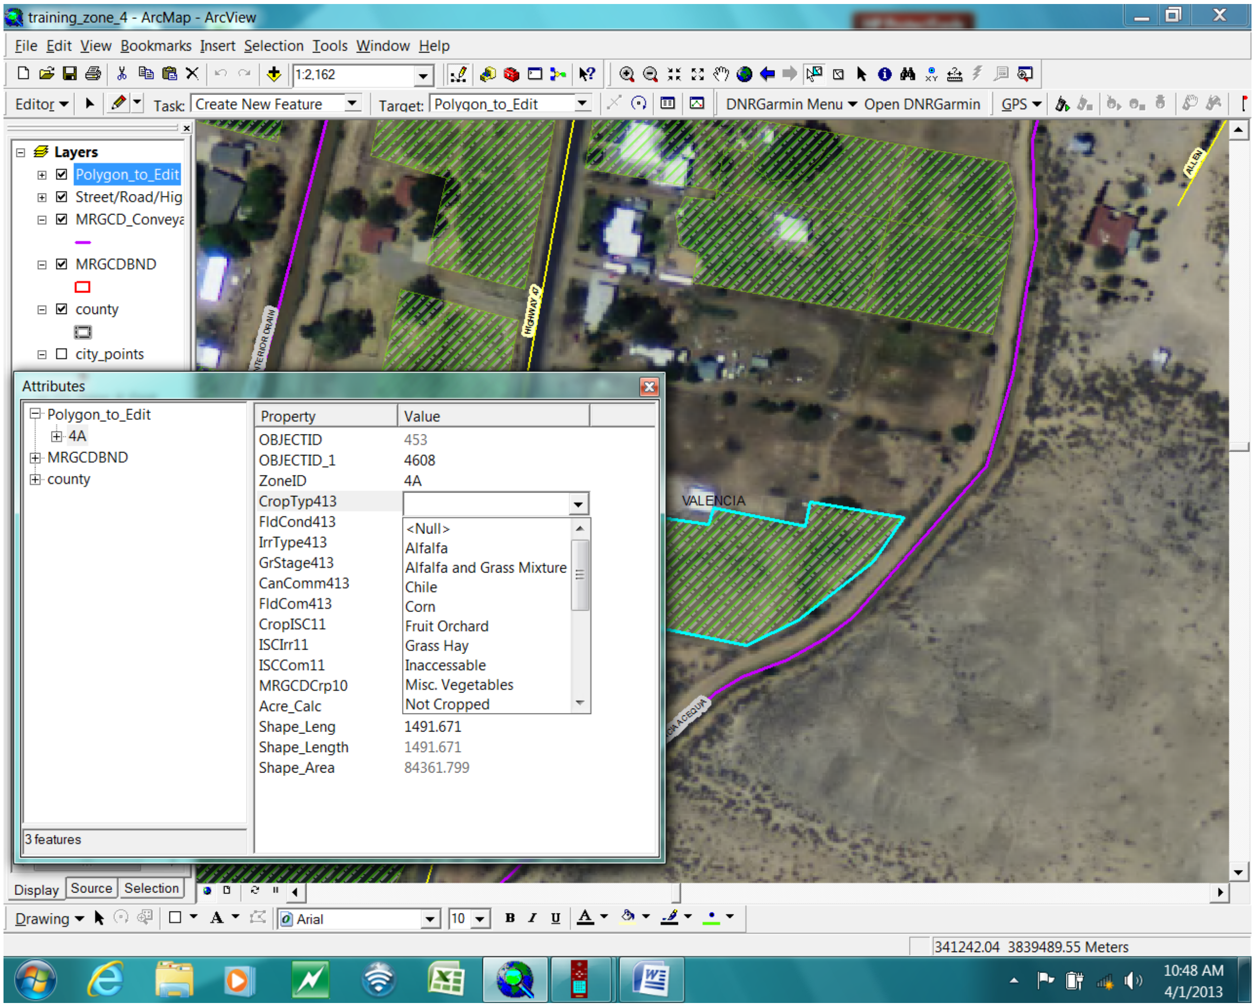
- **Use the "Select Features" tool to choose polygon to update.**



- **After selecting polygon, press attribute table to update polygon attributes.**



- XXXXX413 indicate attributes to be collected on this survey. Below is an example of the drop down menus under the XXXXX413 fields that will be collected on this survey. The only XXXXX413 field that does not have a drop down menu is FieldCom413. This is a space to type field notes into.

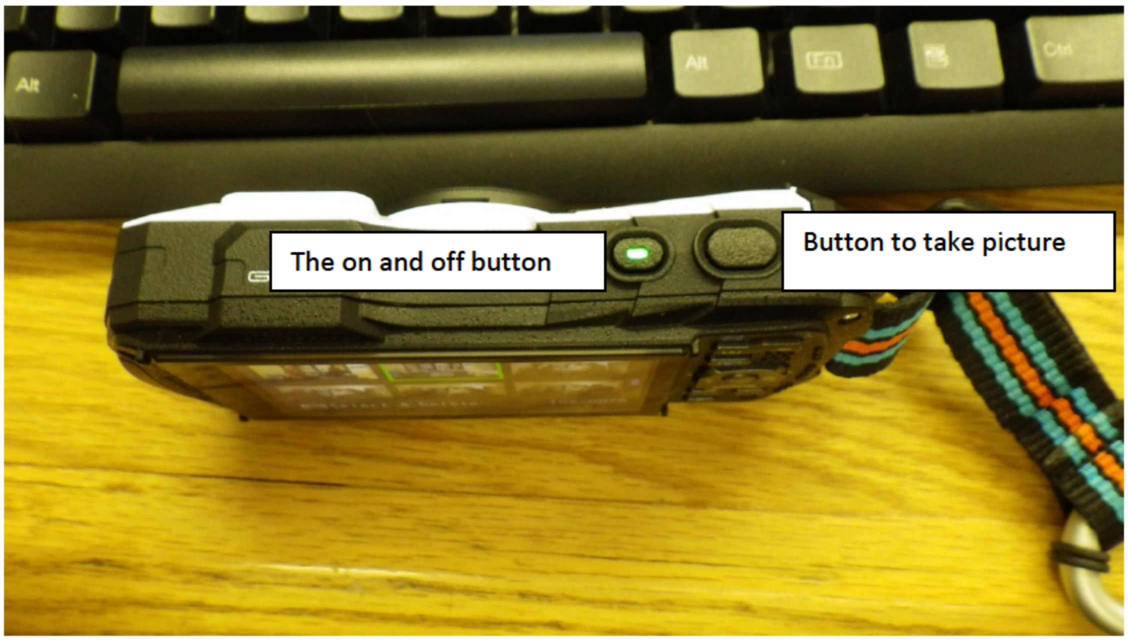


- The following is an explanation of the attribute table above and what must be populated. Only populate or change things that have a XXXXX413 at the end.
  - OBJECTID - ARCGIS field – **Do not change**
  - OBJECTID_1 – **Do not change**
  - ZoneID - **Do not change**
  - CropTyp413 – Populate, dropdown menu Crop Type
    - ALWAYS POPULATE
  - FildCond413 - Populate, dropdown menu Field Condition.
    - ALWAYS POPULATE
  - IrrType413 - Populate, dropdown menu Irrigation Type
    - Populate if irrigation type is visible
  - GrStage413 - Populate, dropdown menu Growth Stage
    - ALWAYS POPULATE unless field is not an agricultural field
  - CanComm413 - Populate, dropdown menu Canned Comments
    - Populate if appropriate
  - FldCom413 - Populate, type into space provided

    - Populate if appropriate
  - Acre_Calc - **Do not change**, Field GIS calculated acreage
  - Shape_Leng - **Do not change**
  - Shape_Length - **Do not change**
  - Shape_Area - **Do not change**

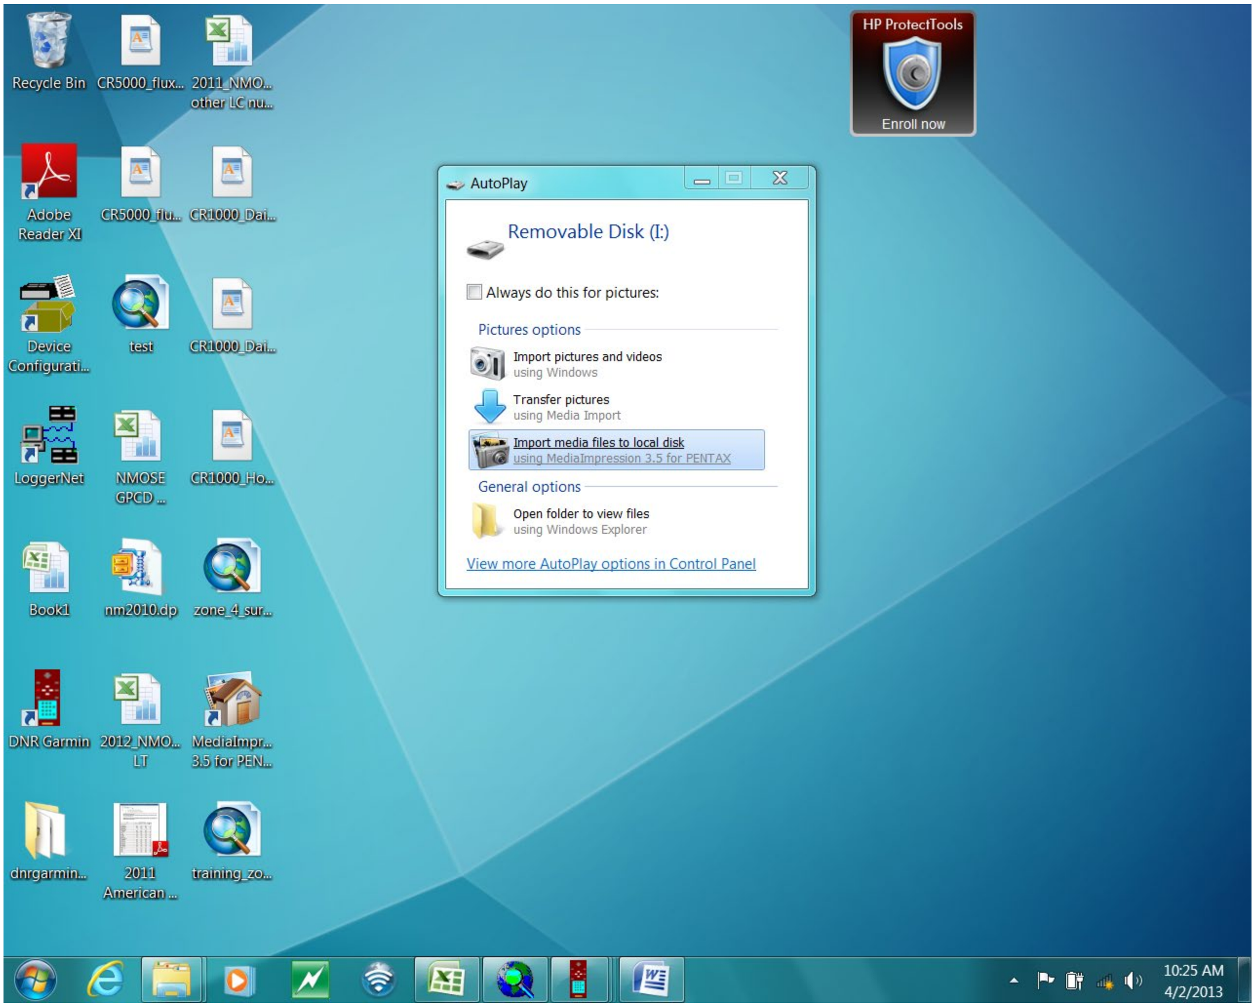
Camera Operation and Uploading Images to Laptop if Memory Card is Full and How to Populate a Photo into the GIS attribute Table

- Turning the camera on and taking a picture. See Below

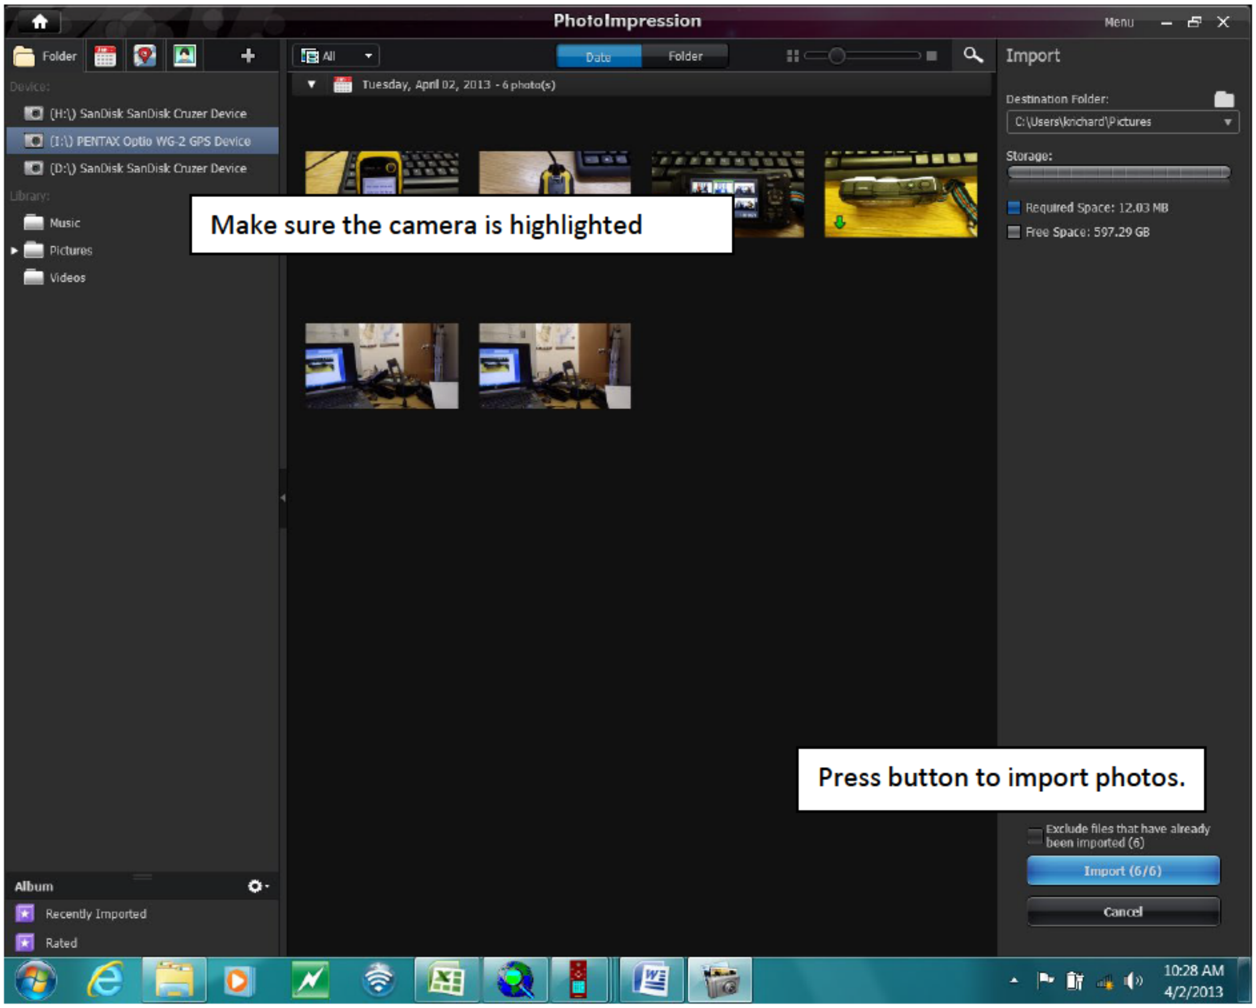


- The first push of the button to take a picture will set the photo and a harder push actual takes the picture. Take a few practice shots.
- Identifying the number associated with the picture to enter into GIS FldCom413 field in the attibute table
  - After taking photo, push the blue play button below the W
  - Push the W to get to the screen below
  - Navigate by using the controller around the okay button
  - Below the photo highlighted with the green border is the number 106-0076
  - Pressing the blue play button below the W will bring you back to the screen to take another picture

- Only take pictures if there is a crop present and if it can't be identified
    - In the CanComm413 attribute field choose "Photo"
    - In the FldCom413 attribute field type the number associated with the photo
- Remember to shut the camera off when not using it to conserve the battery
- If the camera memory card is full connect the provided camera cable to a USB port, the camera holds approximately 50 photos
    - The below menu will pop up
    - Choose "Import Media Files to Local Disk", "MediaImpression 3.5 for PENTAX"



- The screen below will pop up, make sure that the camera is chosen on the left side menu
    - Import photos by pressing button on button right



- To delete photos follow the above steps to determine the number associated with the photo and press the delete button. This button is above the garbage pail and below the word **menu**. See below.

Field Survey Procedure

Fields surveyed were five acres or larger in size. Before beginning each survey, staff training was conducted with a prepared crop ID manual and instructions regarding each category of data being collected.

As noted previously, in order to identify irrigation and crop types, three field surveys were performed: a spring survey, a summer survey, and a fall survey. The survey area was broken into sections based on the samples determined. The field survey teams consisted of a driver/crop identifier, and a GIS person/navigator. Survey participants included Water Use and Conservation Bureau staff, ISC staff, and Las Cruces Water Rights District Office staff.

Appendix 6A. Crop Coefficient Database Development

Developing the crop coefficient database consisted of two steps: 1.) assigning a crop type to each field; and 2.) extracting data pertaining to grass-based crop coefficients and normalized difference vegetation indices (NDVI) by field. The crop coefficient database is used for the Crop Data Layer (CDL) accuracy analysis and for developing crop coefficients. The CDL accuracy analysis was completed prior to developing crop coefficients, as developing crop coefficients relied on the results from the accuracy analysis. Steps required for the accuracy analysis (i.e. field crop information) were also required for developing crop coefficients. Additional steps were needed to extract field crop coefficient and NDVI data to develop crop coefficients for each crop category.

Data Sources

New Mexico field polygons were received on May 7, 2014 by download from the link titled, "DraftPrivilegedandConfidentialPreparedinAnticipationofLigitgation_CropSurveyPolys.mdb." The shapefile is titled "LRGCropSurveyDRAFT021810."

The Texas field polygons were received on May 7, 2014 in a shapefile titled, "EP1Huds10_EBID08_FieldBoundaries." The original Texas shapefile contains both Texas and New Mexico fields. New Mexico field boundaries found in this shapefile were deleted and New Mexico fields from the shapefile, "LRGCropSurveyDRAFT021810" were added to a new shape file. Texas field boundaries found in this shapefile were not used for the CDL accuracy evaluation because ground-based field survey data was not available for the Texas fields. However, CDL crops were assigned to the Texas fields using the procedure described to develop and analyze crop coefficients.

The CDL for 2008 was downloaded from USDA NASS <http://nassgeodata.gmu.edu/CropScape/> on May 28, 2014. Available data covers both the Texas and New Mexico areas within and nearby Elephant Butte Irrigation District (EBID) in New Mexico and the El Paso County Water Improvement District #1 (EPCWID) and the Hudspeth County Conservation & Reclamation District #1 (Hudspeth) in Texas.

Assigning Crop Type to Each Field

Crop types were assigned to each field based on two data sources: the USDA NASS CDL for Texas and New Mexico field survey for New Mexico. The section below outlines steps used to assign a crop to each field using both data sources:

Crop Data Layer

An analysis was completed using spatial crop data and field polygons using the ArcMap GIS software to assign crops to each field. Because each field contains multiple pixels[16], the possibility exists that pixels of more than one crop type may be found with the boundaries of one field. In a few instances, this may be due to the splitting of a field into two crops. But more often a few pixels within a field boundary have a second crop type due to classification error. The crop assignment procedure assigns one crop type to each field based on the number of pixels of each crop type as a percent of the total number of pixels within the field polygon. The purpose of this procedure is to assign a single crop type from the CDL to each field for comparison to the New Mexico ground-based crop survey and to develop $\mathbf{K_{cm}}$ values for crops in areas of the Study Area where ground-based crop survey data are not available.

[16] A single raster element in a computer image that has a constant value across its domain. In Landsat images, a pixel has dimensions of 30 m x 30 m.

Each crop type identified on each field is assigned a "field rank" according to the number of pixels identified as the crop type. The crop with the greatest number of pixels is given a field rank of one, the second highest is given a rank of two, and so on. In the case of multiple crop types occupying the same percent of the field polygon, the crop most commonly grown throughout all districts (EBID, EPCWID, and Hudspeth) based on the CDL data is assigned the higher rank. For example, the CDL identifies two crops on a field and both occupy 50% of a field: cotton and alfalfa. In this hypothetical example, assuming cotton covers the greatest area throughout EBID, EPCWID and Hudspeth, it would receive a rank of 1 and the field would be assigned cotton as the crop. Each field was assigned the crop type with a rank of 1.

Additional steps were completed during the ArcMap procedure to ensure that field identification numbers used later in the CDL analysis could be traced back to the "OBJECTID" found in the original Texas and New Mexico shapefiles. ArcMap re-assigns field identification numbers during geoprocessing steps that produce new spatial data layers. Adding separate, fixed field IDs to each polygon (or field boundary) ensures that the field identification number will not change during geoprocessing.

The steps followed to assign a single crop type to each field from the CDL are outlined below:

1. The 2008 crop data layer from USDA NASS covering both Texas and New Mexico fields was downloaded from http://nassgeodata.gmu.edu/CropScape/. Each 56-meter pixel from the CDL has an integer value representing a crop. The integer value refers to a specific crop type (i.e. cotton, pecans, alfalfa, etc).
2. In the original Texas shapefile ("EP1Huds10_EBID08_FieldBoundaries"), a new field identification number was created in the attribute table named "TX_id." The "TX_id" field is equal to the "OBJECTID" in the original shapefile "EP1Huds10_EBID08_FieldBoundaries."
3. The New Mexico field polygons, identified as those found within the boundaries of EBID (according to the attribute table) were deleted from the Texas shapefile ("EP1Huds10_EBID08_FieldBoundaries").
4. In the original New Mexico field shapefile ("LRGCropSurveyDRAFT021810") a new field identification number was assigned in the original New Mexico field attribute table, titled "NM_id." This id is used to relate extracted data back to the original field polygon layer, "LRGCropSurveyDRAFT021810."
5. The Texas shapefile, "EP1Huds10_EBID08_FieldBoundaries" was merged with the New Mexico field shapefile "LRGCropSurveyDRAFT021810."
6. A new field identification number was created called "FID_New" in the attribute table with the shapefile "TX_NM_Fields." "FID_New" corresponds to either "TX_id" or "NM_id." Fields in Texas have an "NM_id" equal to 0; likewise, fields in New Mexico have a "TX_id" equal to 0. There is a unique "FID_New" value for every "TX_id" and "NM_id."
7. A new shapefile "TX_NM_Fields_buf45" was created by buffering in 45 meters from the field boundaries. Buffering improves the assignment of field crop type by eliminating pixels that may have area in two or more fields, which may be different crop types.
8. The buffering process eliminated nearly all fields less than 1 hectare of actual area in shapefile, "TX_NM_Fields_buf45".
9. The polygon shapefile "TX_NM_Fields_buf45" was converted to a raster image where each pixel value corresponds to a field identification number (or "FID_New"). Pixel size and alignment matches the CDL layer.
10. Used ArcMap's spatial analyst extraction tool "Sample" to relate a CDL pixel value to each polygon pixel value ("FID_New").

11. The data was imported to a personal geodatabase, “Developing_Crop_Coefficient_Database.”
12. The query “001_CDL_Count_by_Field” creates a table that summarizes the data from ArcMap (step 10). The table summarizes the number of pixels within each field with the same CDL pixel value.
13. The query, “002_Number_of_Pixel_by_Field,” calculates the total number of CDL pixels within each field.
14. The query, “003_Percent_of_Pixel_by_Field” lists the percent of each crop type by field. Queries “001_CDL_Count_by_Field” and “002_Number_of_Pixel_by_Field” were used to create this query.
15. The “Make Table” query, “004_CDL_mk_query,” assigns a crop type to each CDL pixel value and creates a table titled “004_CDL_mk.”
16. The “Update” query, “004a_CDL_cropped_area_updt,” fills the column “Cropped_Area_ac” in the table “004_CDL_mk.” Cropped area is equal to field area (from table “Attributes_TX_NM”) times percent of crop type (from table “004_CDL_mk”).
17. The updated (with completed cropped_area_ac column) table “004_CDL_mk” was exported to the Excel file “CDL_Table.”
18. A column, titled “Crop_Order,” was added to table “004_CDL_mk.” A crop order was assigned to each crop type. Crop order ranges from 1 to 32 with one being the crop covering the greatest area and thirty-two being the crop covering the least area.
19. A column, “Field_Rank” was created in table “004_CDL_mk.” Field rank is useful for fields with more than one crop type identified by the CDL. Each crop identified by the CDL is ranked within the field by acreage.
20. The updated table, “CDL_final_mk,” is imported to the database titled “Developing_Crop_Coefficient_Database.”
21. The crop types were organized into ten crop categories by adding a column titled “Assigned_Crop_Group” to table “CDL_final_mk.” **Table 6A-1** shows the crop types based on the CDL and the groupings used for this analysis:

Table “CDL_final_mk” contains CDL data (by field) used in the crop coefficient analysis. The table contains the following columns:

a. FID_New – field identification number (same FID_New may appear multiple times in table depending on the number of crops identified in each field)
b. N_of_Pixels – total number of pixels that fall within field boundaries
c. CDL_Code – pixel value from CDL (pixel value represents crop type)
d. No_of_Pixels – number of pixels within each field with the same CDL pixel value
e. Percent_of_Crop_Type – “No_of_Pixels” divided by “N_of_Pixels”
f. Crop_Type – crop type (or landuse) the pixel value represents
g. Assigned_Crop_Group – re-assigned crop group based on **Table 6A-1**
h. Cropped_Area_ac – total area in acres of specific crop in field (based on “Percent_of_Crop_Type”)
i. Crop_Order – rank of crop throughout EBID, EPCWID, and Hudspeth according to area covered. The crop most covering the greatest area is given “Crop_Order” value of 1 and so on.
j. Field_Rank – rank of number of acres grown of specific crop by field.

Table 6A-1. Assignment of CDL crop categories to the crop groups for the actual ET analysis.

CDL Land Use Category	Assigned Group
Alfalfa	Alfalfa Hay
Peppers	Chile (Peppers)
Corn	Corn, Sweet Corn, and Silage
Sweet Corn	Corn, Sweet Corn, and Silage
Dbl Crop Barley/Corn	Corn, Sweet Corn, and Silage
Cotton	Cotton
Misc Vegs & Fruits	Miscellaneous Vegetables
Watermelons	Miscellaneous Vegetables
Onions	Onions
Other Hay/Non Alfalfa	Alfalfa Hay
Triticale	Wheat and Small Grains
Grass/Pasture	Irrigated Pasture
Other Tree Crops	Pecans
Pistachios	Pecans
Pecans	Pecans
Winter Wheat	Wheat and Small Grains
Oats	Wheat and Small Grains
Spring Wheat	Wheat and Small Grains
Sorghum	Corn, Sweet Corn, and Silage
Durum Wheat	Wheat and Small Grains
Shrubland	Not Irrigated and Water
Fallow/Idle Cropland	Not Irrigated and Water
Developed/Open Space	Not Irrigated and Water
Developed/Low Intensity	Not Irrigated and Water
Open Water	Not Irrigated and Water
Evergreen Forest	Not Irrigated and Water
Woody Wetlands	Not Irrigated and Water
Developed/Medium Intensity	Not Irrigated and Water
Barren	Not Irrigated and Water
Developed/High Intensity	Not Irrigated and Water
Herbaceous Wetlands	Not Irrigated and Water
Deciduous Forest	Not Irrigated and Water

New Mexico Field Survey

Below is a detailed list of the steps used to assign a New Mexico field survey crop to each field:

1. The “make table” query “001_NM_CropSurvey” related “OBJECTID” to “FID_New” and assigned the summer 2008 crop type to each “FID_New.” The new table created was titled “NM_Field_Survey_Crops.”

2. The column titled "Assigned_Crop" was added to table "NM_Field_Survey_Crops" to assign crop types to the eleven land-use categories to be used in the actual ET analysis (**Table 6A-2**).

Additional Steps for Developing Crop Coefficients

Steps required to develop crop coefficients include: extracting data using ArcMap, compiling data into a single table, and developing crop coefficient curves. The following sections give a more detailed description of each step.

Crop Coefficient ArcMap Analysis Procedure

1. Utilized ArcMap's "Model Builder" to run "Zonal Statistics as Table" tool to extract ET_oF and NDVI data for each image date. To obtain necessary data from the original ET_oF and NDVI raster images, the images had to be converted to integer grids. The following steps were completed in ArcMap's Model Builder to turn original images into integer grids and to extract data:
    a. Multiply by 10,000 to carry adequate number of significant figures (i.e. 1.252446 turns into 12524.46)
    b. Convert pixel values into integers (i.e. 12524.46 turns into 12524)
    c. Extract NDVI and ET_oF data by field using "Zonal Statistics as Table"

   These additional steps were necessary because ArcMap only calculates the "median" on integer grids. ArcMap was unable to perform zonal statistics on integer grids created using the model for path 33 ET_oF data. Consequently, integer grids were created using ERDAS Imagine and then the zonal statistics was completed in ArcMap (only for path 33 ET_oF data)
2. Exported raw ET_oF and NDVI data into the common personal geodatabase titled "Developing_Crop_Coefficient_Database."

Crop Coefficient Database

After completing the 45-meter buffering and ArcMap's crop coefficient procedure, a table titled "CropCoefficientDev" (in database "Developing_Crop_Coefficient_Database") was compiled with the following columns.

a. FID_New – field identification number
b. Flag_P32 – value equal to 1 means field boundary overlays Landsat image (path 32) outside region of usable data. Value of 0 means data is usable.
c. Flag_P33 – value equal to 1 means field boundary overlays Landsat image (path 33) outside region of usable data. Value of 0 means data is usable.
d. Image_Date – Landsat image date
e. Path – Landsat path number (i.e. path 32 or 33)
f. District – district field falls within (i.e. EBID, EPCWID, or Hudspeth)
g. Field_Size_ac – area of field in acres
h. No_of_Pixels – number of pixels within each field after buffering (pixel size: 15m by 15m – not the same as Landsat pixel size of 30m by 30m)
i. Mean_NDVI – average NDVI pixel value within each field after buffering
j. Median_NDVI – median NDVI pixel value within each field after buffering
k. Mean_ET_oF – average grass based crop coefficient pixel value within each after buffering
l. Median_ET_oF – median grass based crop coefficient pixel value within each after buffering
m. STD_NDVI – standard deviation of NDVI pixel values within each field after buffering
n. STD_ET_oF – standard deviation of grass based crop coefficient within field boundaries after buffering
o. Days_Since_Last_Rain – number of days since last rain event
p. Total_Rainfall_in_Last_15_Days – cumulative rainfall in last 15 days from image date

Table 6A-2. Assignment of New Mexico Field Survey Crop Categories to the Actual ET Analysis Crop Groups.

Summer08Crop	Assigned Group
Alfalfa	Alfalfa Hay
Chile	Chile (Peppers)
Corn	Corn, Sweet Corn, and Silage
Cotton	Cotton
Misc. Vegetables/Garden	Miscellaneous Vegetables
Melons/Summer Squash	Miscellaneous Vegetables
Cabbage	Miscellaneous Vegetables
Misc. Field Crops	Corn, Sweet Corn, and Silage
Vineyard	Pecans
Onions	Onions
Irrigated Pasture	Irrigated Pasture
Sudan Grass	Irrigated Pasture
Unknown Crop	Irrigated Pasture
Hay	Alfalfa Hay
Turfgrass/Lawn	Irrigated Pasture
Residential-Irrigated	Irrigated Pasture
Fruit Orchard	Pecans
Pistachio Orchards	Pecans
Christmas Trees	Pecans
Pecan Orchards	Pecans
Residential-Pecans	Pecans
Nursery Stock	Pecans
Sorghum	Corn, Sweet Corn, and Silage
Small Grain	Wheat and Small Grains
Plowed	Not Irrigated and Water
Non-Irrigated	Not Irrigated and Water
Fallow	Not Irrigated and Water
Residential-Non-Irrigated	Not Irrigated and Water
Water	Not Irrigated and Water
Residential	Not Irrigated and Water

Developing Crop Coefficient Curves

The following procedures were completed for each crop coefficient curve:

1. Created a query in database, “Developing_Crop_Coefficient_Database,” to export relevant data to Microsoft Excel. Filters were used to only select fields of interest (i.e. fields of specific crop, district, Landsat path number, etc.). The following constraints were used to only extract data

that overlaid pixel values that corresponded to crop coefficients. These constraints were included in all queries:

   a. Mean ET_oF greater than zero to crop coefficients
   b. Mean ET_oF less than two
   c. "Flag_P32" equal to zero

2. Calculated mean, median, percentile, and frequency distribution for the sample of fields obtained from the query
3. Developed plot that shows mean and median ET_oF values derived from the calendar year 2008 METRIC analysis, along with relative frequency values for the distribution of crop coefficients.

Appendix 7A. ET Demands Calibration Results by Crop Group

This appendix presents the ET Demands calibration results by crop group for 2008 and 2013, the years when information on the crop in each field is available. This information is primarily from the NASS CDL, except for 2008 in New Mexico when the NMOSE ground survey data is available. The following sections discuss results for EBID in 2008, the 2008 results for EPCWID, Hudspeth and Juarez and the 2013 results for EBID, EPCWID, Hudspeth and Juarez.

ET Demands Calibration Results for Elephant Butte Irrigation District, 2008

Monthly and seasonal estimates of ET Demands model ET_c for each crop in EBID in 2008, were compared to METRIC ET_c results for each crop (**Figure 7A-1**). The NMOSE 2008 ground-based crop survey identified the crop in each field for the METRIC results. The results presented are for the calibrated ET Demands model.

March through October 2008 METRIC and ET Demands ET_c estimates for each crop in EBID for irrigated lands with access to both surface water (SW) and groundwater (GW) are provided in **Table 7A-1a** and **Figure 7A-2a**. METRIC ET estimates range from 31.5 inches for chile to 44.9 inches for alfalfa with total ET_c estimated as 39.0 inches for the 2008 March to October period. Similarly, ET Demands ET_c estimates range from 32.5 inches for cotton to 46.4 inches for alfalfa with total ET_c estimated as 40.4 inches. ET Demands estimates of ET_c for wheat and other small grains are 1.7 inches less than the METRIC ET_c estimates. For alfalfa hay, ET Demands ET_c estimates are 1.5 inches higher than the METRIC ET_c results for alfalfa hay. On a percentage basis, ET Demands estimates of ET differ from METRIC estimates by -3.9 percent for wheat and small grains to 3.4 percent for alfalfa hay with total ET_c differing by 3.7 percent.

March through October METRIC and ET Demands results by crop for 2008 for irrigated lands in New Mexico with access to only groundwater are provided in **Table 7A-1b** and **Figure 7A-2b**. METRIC ET_c estimates range from 21.2 inches for miscellaneous vegetables to 39.6 inches for alfalfa with total ET_c equal to 30.3 inches for the 2008 March to October period. Similarly, ET Demands ET_c estimates range from 32.5 inches for cotton to 46.4 inches for alfalfa with total ET_c equal to 39.7 inches. ET Demands estimates of ET_c differ from METRIC ET_c estimates by -2.2 inches for onions to 11.6 inches for miscellaneous vegetables with total ET_c differing by 9.4 inches. On a percentage basis, ET Demands estimates of ET_c differ from METRIC estimates by -5.8 percent for onions to 54.5 percent for miscellaneous vegetables with total ET_c differing by 30.9 percent.

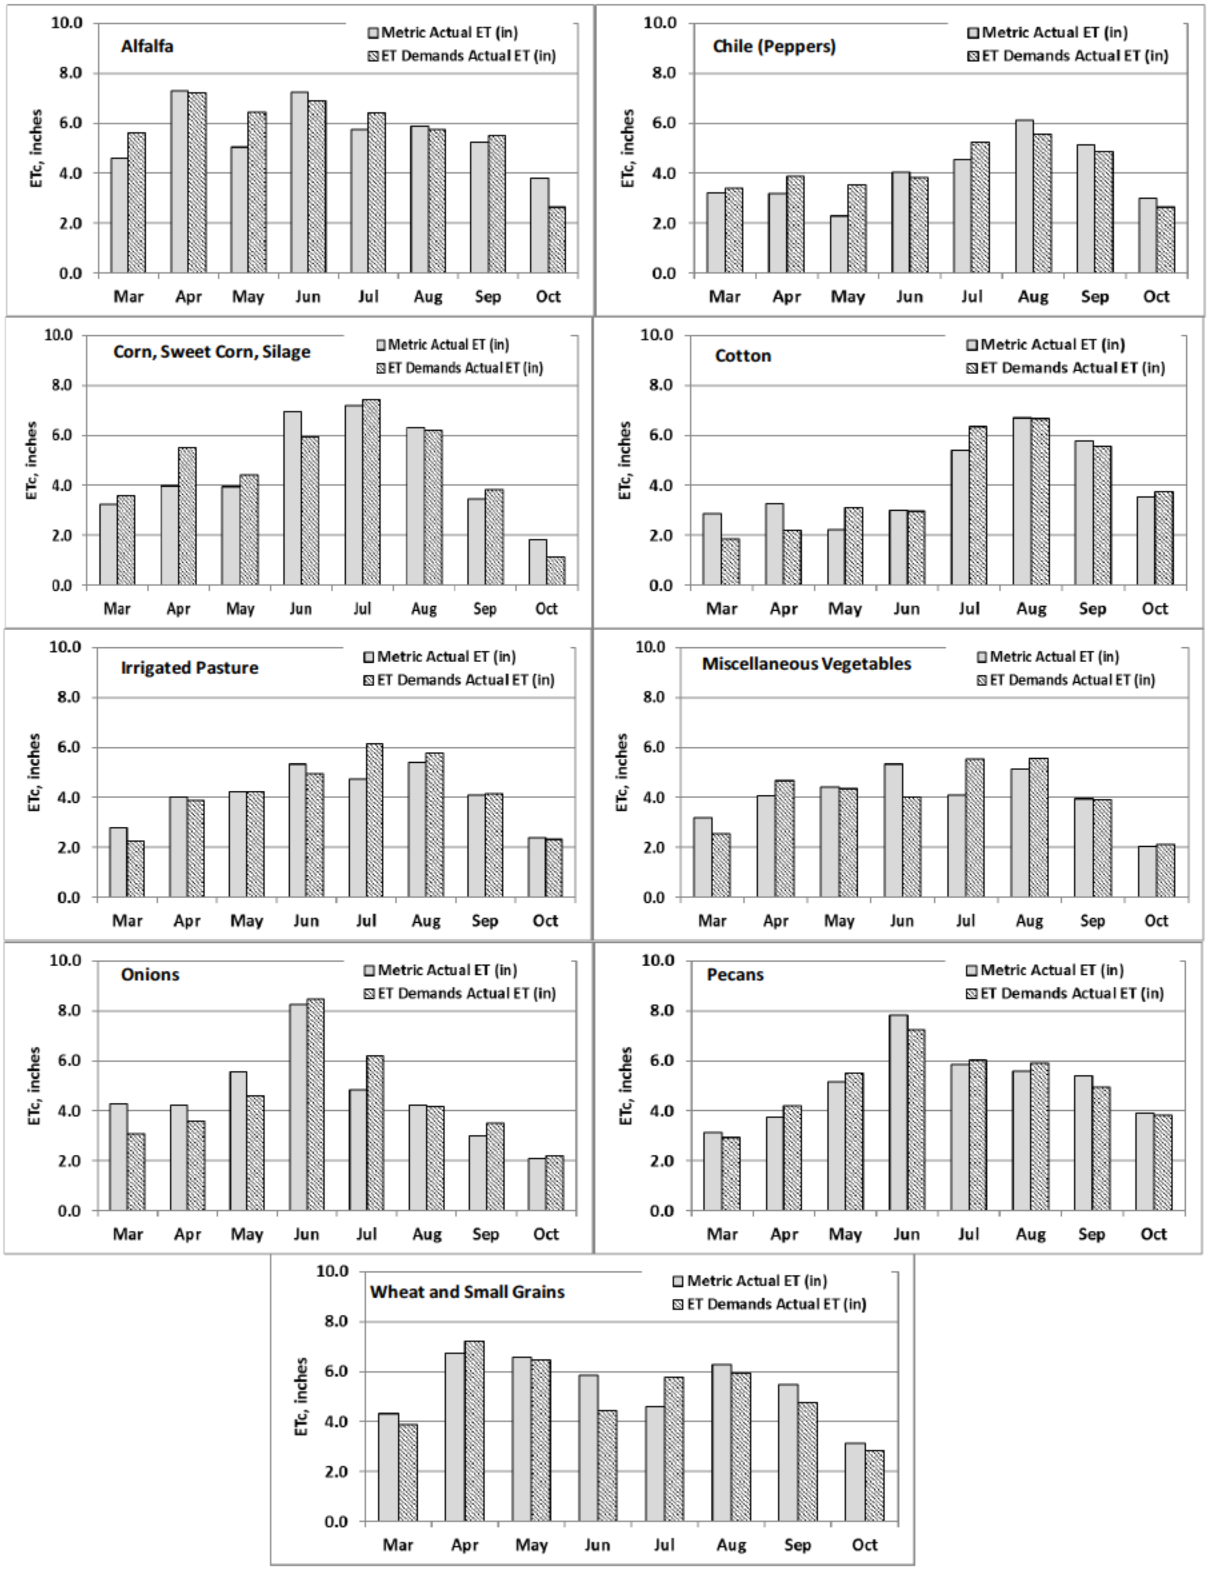

Figure 7A-1. METRIC and ET Demands 2008 Monthly Actual ET Estimates for EBID by Crop.

Table 7A-1a. Summary of METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates by Crop for EBID Irrigated Lands with Access to Surface Water and Groundwater.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Pecans	26,485	40.7	40.6	-0.1	-0.2%
Alfalfa Hay	18,042	44.9	46.4	1.5	3.4%
Cotton	11,885	32.8	32.5	-0.3	-1.0%
Corn, Sweet Corn, and Silage	8,097	36.9	38.1	1.2	3.2%
Onions	4,081	36.5	35.9	-0.6	-1.7%

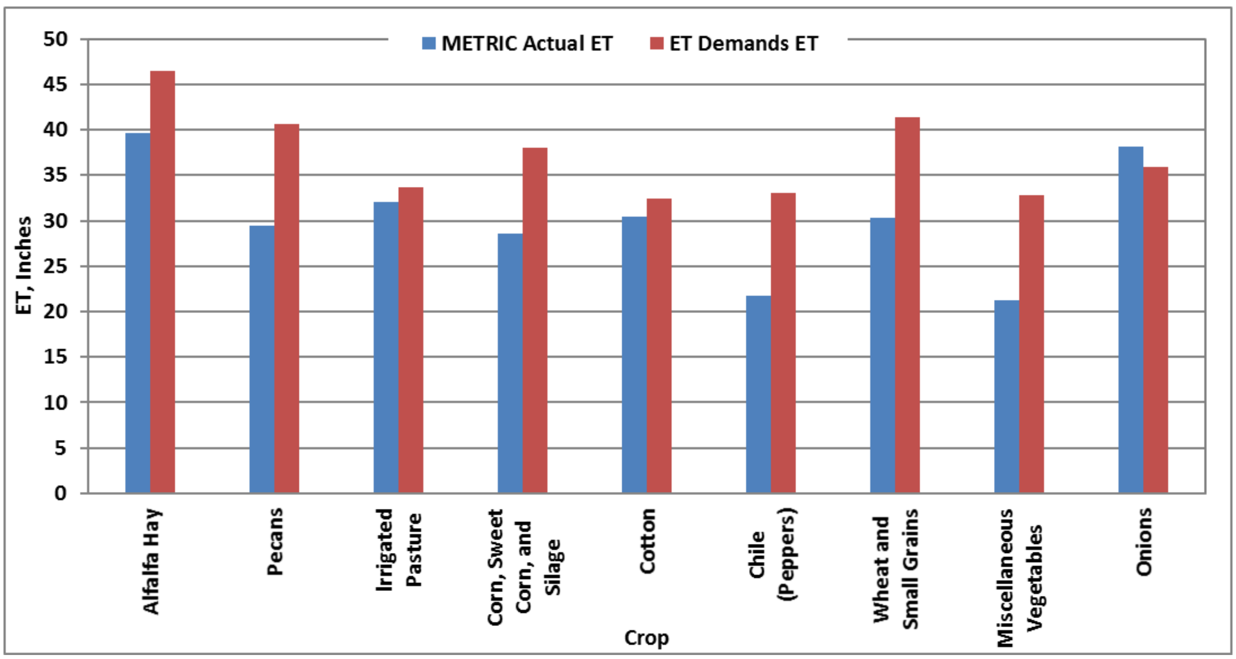

Figure 7A-2b. METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates by Crop for Irrigated Lands in New Mexico with Access to Only Groundwater.

Relatively good agreement between METRIC and ET Demands results for EBID in 2008 is a direct result of the calibration process described previously, in which basal crop coefficients (k_{cb}) and model parameters ($k_{c,maxo}$) were iteratively adjusted to match the METRIC seasonal results within ten percent. This calibration also resulted in relatively good agreement for each month when ET_c from all crops is combined into a single monthly total (**Figure 7A-3**). With the exception of May and October, ET Demands monthly ET_c estimates were within plus or minus 14 percent of the monthly METRIC ET estimate (**Table 7A-2**).

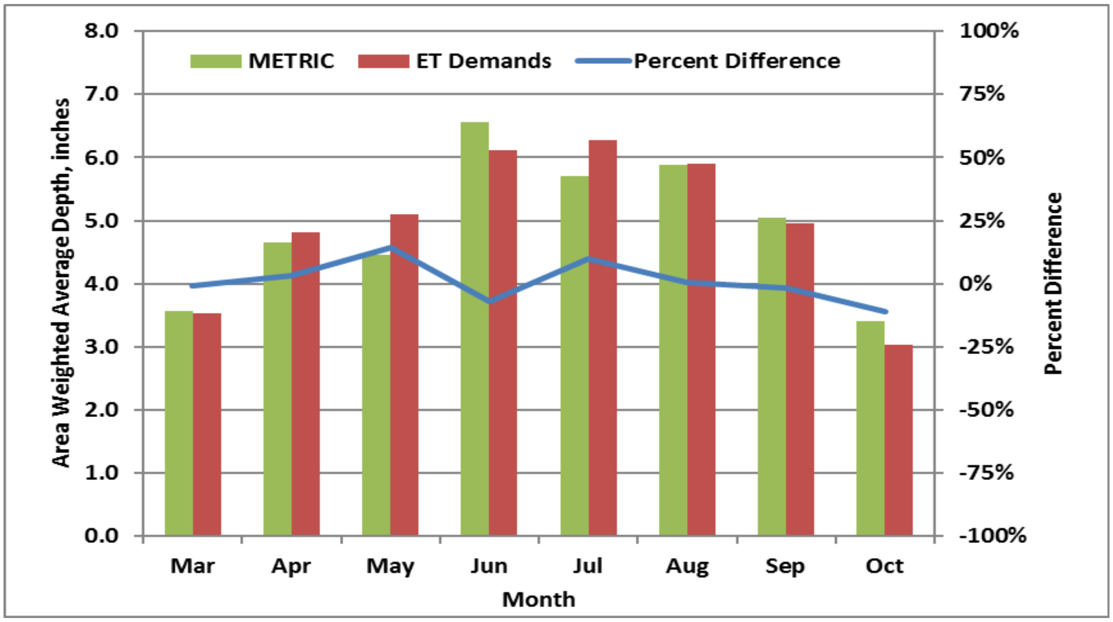

Figure 7A-3. METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for EBID by Month.

Table 7A-2. Summary of METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for EBID (Access to Surface Water) by Month.

Month	Metric ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Mar	3.6	3.5	0.0	-1%
Apr	4.7	4.8	0.1	3%

2008 Comparisons

The crop coefficients that were calibrated to the 2008 METRIC ET_c data in EBID were used in the ET Demands model to compute the ET_c in the service areas of the EPCWID, Hudspeth County, and the Juarez Irrigation District. These ET Demands ET_c estimates were compared to the 2008 METRIC ET_c estimates for each district, and the results of this comparison are described below.

El Paso County Water Improvement District

EPCWID delivers water to about 6,000 acres in the Mesilla Valley and about 40,000 acres in the El Paso Valley. Seasonal METRIC and ET Demands results by crop for 2008 in the EPCWID areas in the Mesilla and El Paso Valleys are provided in **Tables 7A-3a and 7A-3b** and **Figures 7A-4a and 7A-4b**, respectively. In the Mesilla Valley area of EPCWID, totaling about 11 percent of the EPCWID irrigated area in 2008, METRIC ET_c estimates range from 29.1 inches for cotton to 41.2 inches for alfalfa with total ET_c equal to 33.9 inches for the 2008 March to October period. Only crops identified in the CDL can be compared to the METRIC ET_c results, so only those crops and crops with more than 450 acres are discussed. ET Demands ET estimates range from 32.7 inches for cotton to 47.1 inches for alfalfa. ET Demands estimates of ET_c differ from METRIC estimates by 0.4 inches for pecans to 5.9 inches for alfalfa with total ET_c differing by 4.0 inches. ET Demands ET_c estimates for irrigated pasture are nearly twice the METRIC estimates for ET_c of irrigated pasture. This large difference is likely an indication that some of the about 150 acres in pasture identified by the 2008 CDL may have been irrigated for only part of the irrigation season. On a percentage basis, ET Demands estimates of ET_c differ from METRIC estimates by 1.0 percent for pecans to 14.4 percent for alfalfa with total ET_c differing by 11.8 percent.

Table 7A-3a. Summary of METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for the Mesilla Valley Area of EPCWID by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Cotton	1,661	29.1	32.7	3.6	12.4%
Pecans	1,321	40.5	40.9	0.4	1.0%
Alfalfa Hay	480	41.2	47.1	5.9	14.4%
Irrigated Pasture	143	17.5	34.1	16.6	94.7%
Wheat and Small Grains	133	34.9	41.6	6.7	19.1%
Other	201	24.1	39.4	15.3	63.7%
Totals	3,940	33.9	37.9	4.0	11.8%

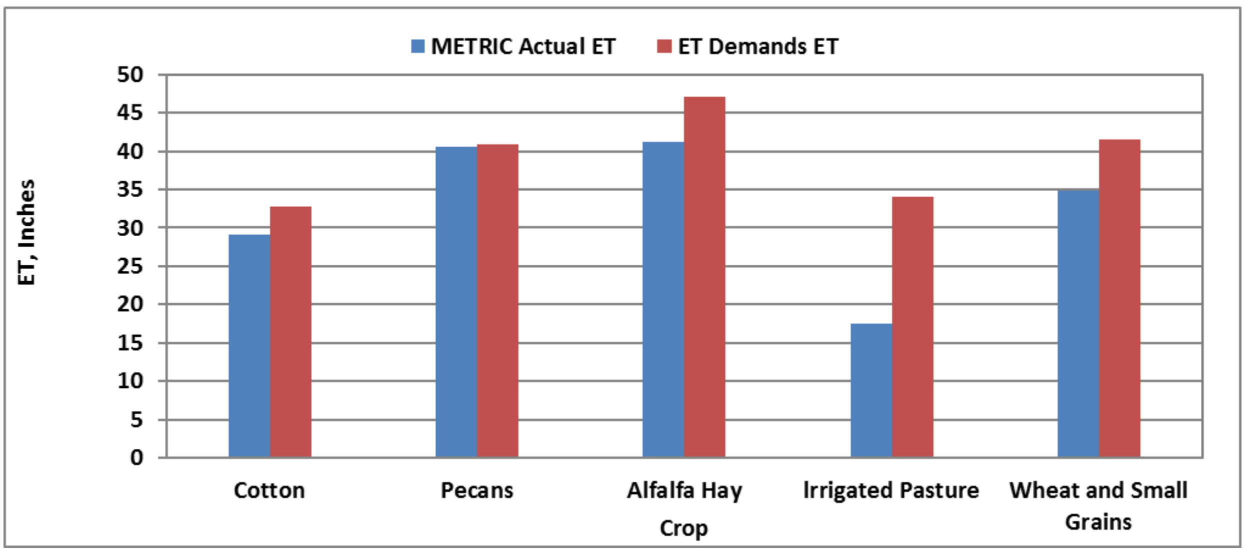

Figure 7A-4a. METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for the Mesilla Valley Area of EPCWID by Crop.

Table 7A-3b. Summary of METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for the El Paso Valley Area of EPCWID by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Cotton	15,583	36.1	33.1	-3.0	-8.4%
Pecans	12,392	41.7	37.4	-4.3	-10.2%
Alfalfa Hay	4,508	46.9	47.5	0.6	1.2%
Wheat and Small Grains	1,251	47.1	42.5	-4.6	-9.7%
Other	3,233	18.9	37.1	18.2	95.9%
Totals	36,968	38.2	37.0	-1.2	-3.2%

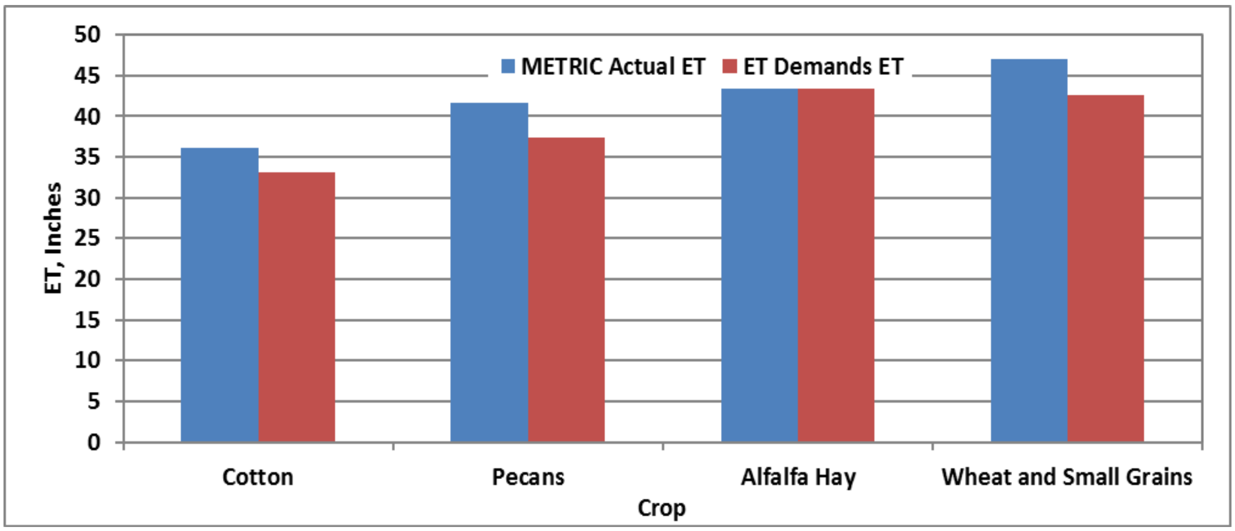

Figure 7A-4b. METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for the El Paso Valley area of EPCWID South by Crop.

In the El Paso Valley area of EPCWID, METRIC ET_c estimates range from 36.1 inches for corn to 47.1 inches for wheat and small grains with total ET_c of 38.2 inches for the 2008 March to October period. Only crops identified in the CDL can be compared to the METRIC ET results, so only those crops are discussed. ET Demands ET_c estimates range from 33.1 inches for cotton to 47.5 inches for alfalfa. ET Demands estimates of ET_c differ from METRIC estimates by -4.3 inches for pecans to 0.6 inches for alfalfa hay with total ET_c differing by -1.2 inches. On a percentage basis, ET Demands estimates of ET_c differ from METRIC estimates by -10.2 percent for cotton to 1.2 percent for alfalfa hay with the total ET_c differing by -3.2 percent.

ET Demands results for the area of EPCWID in the Mesilla Valley agree with METRIC results relatively well, but not as well as for EBID. The generally larger differences likely result from a combination of factors. One factor may be the different methods used to identify crops. Crops were identified in 2008 in EBID via ground-based surveys, whereas crops were identified in EPCWID and Hudspeth based on the Cropland Data Layer (CDL), a satellite based land use classification method (USDA, 2016). CDL results are considered more uncertain than ground-based surveys and could result in biases in the identification of certain crops. As a result, the METRIC ET_c estimates by crop within EPCWID may be influenced to a greater degree by misclassification than the METRIC ET_c results for EBID.

Hudspeth

Seasonal METRIC and ET Demands ET_c results by crop for 2008 in Hudspeth are provided in **Table 7A-4** and **Figure 7A-5**. As indicated, METRIC ET_c estimates range from 17.7 inches for chile to 39.8 inches for alfalfa with total ET_c equal to 28.3 inches for the March to October period. In contrast, ET Demands ET_c estimates range from 33.5 inches for cotton to 47.4 inches for alfalfa. ET Demands modeled ET_c estimates differ from METRIC ET_c estimates by 6.9 inches for cotton to 11.4 inches for corn with total ET_c differing by 7.7 inches. On a percentage basis, ET Demands estimates of ET_c differ from METRIC estimates by 25.8 percent for cotton to 44.9 percent for corn with total ET_c differing by 27.3 percent. In contrast to differences for EPCWID, ET Demands ET_c results for Hudspeth are substantially greater than METRIC ET_c results.

Table 7A-4. Summary of METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for Hudspeth by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Cotton	9,544	26.6	33.5	6.9	25.8%
Alfalfa Hay	1,986	39.8	47.4	7.6	19.2%
Corn, Sweet Corn, and Silage	1,847	25.5	36.9	11.4	44.9%
Chile (Peppers)	198	17.7	32.9	15.2	85.6%
Pecans	57	28.6	37.5	8.9	31.2%
Totals	13,632	28.3	36.0	7.7	27.3%

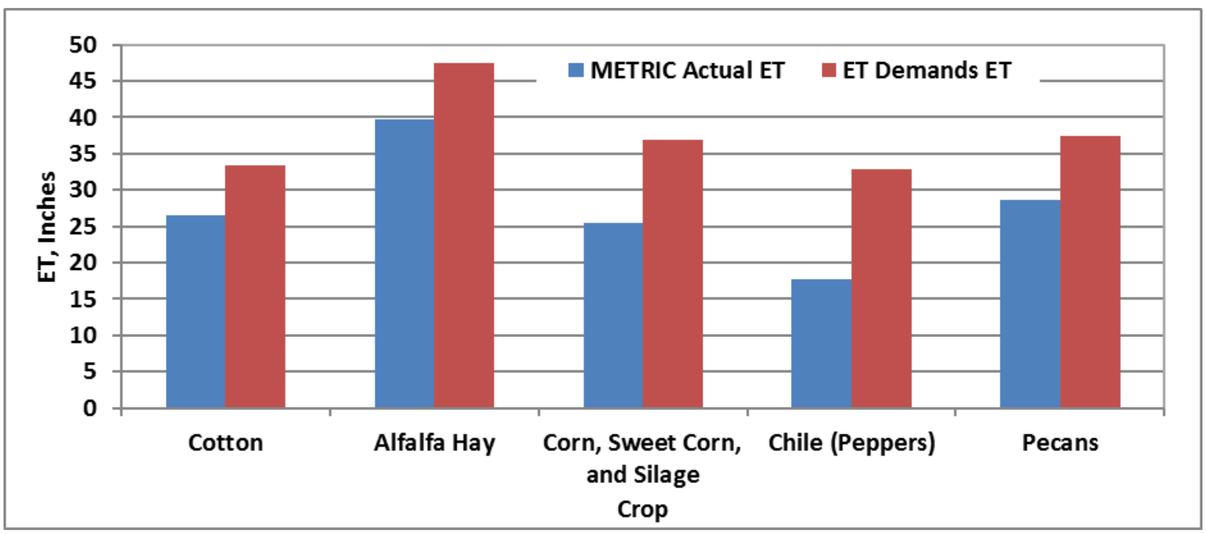

Figure 7A-5. METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for Hudspeth by Crop.

Juarez Valley Irrigation District, Mexico

Spatial crop distributions for the irrigated fields in Juarez were only available for pecans, so results for pecans and for all crops combined are reported. Intera developed pecan coverages for 1976, 1996, 2004 and 2010. Fields identified as pecans in both the 2004 and 2010 coverages were used to calculate ET_c for 2008. According to the fields identified as pecans by Intera, the pecan area in Juarez remained the same from 2004 to 2010. March through October 2008 METRIC ET_c totals for the Juarez Valley Irrigation District irrigated field polygons are 36.9 inches compared to 37.5 inches estimated by ET

Demands for 2008. ET Demands modeled ET_c estimates are 0.6 inches (or 1.5%) more than the METRIC ET_c estimates (**Table 7A-5** and **Figure 7A-6**). Thus, assuming that 2008 was a full supply year for Juarez, the ET Demands modeled ET_c is a reasonable upper limit on ET and will lead to reasonable upper limit for ET_{aw}.

Table 7A-5. Summary of METRIC and ET Demands 2008 Seasonal (March – October) Actual ET Estimates for Juarez by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Pecans	921	36.9	37.5	0.6	1.5%
Other	34,542	36.9	38.4	1.5	4.1%
Totals	35,463	36.9	38.4	1.5	4.0%

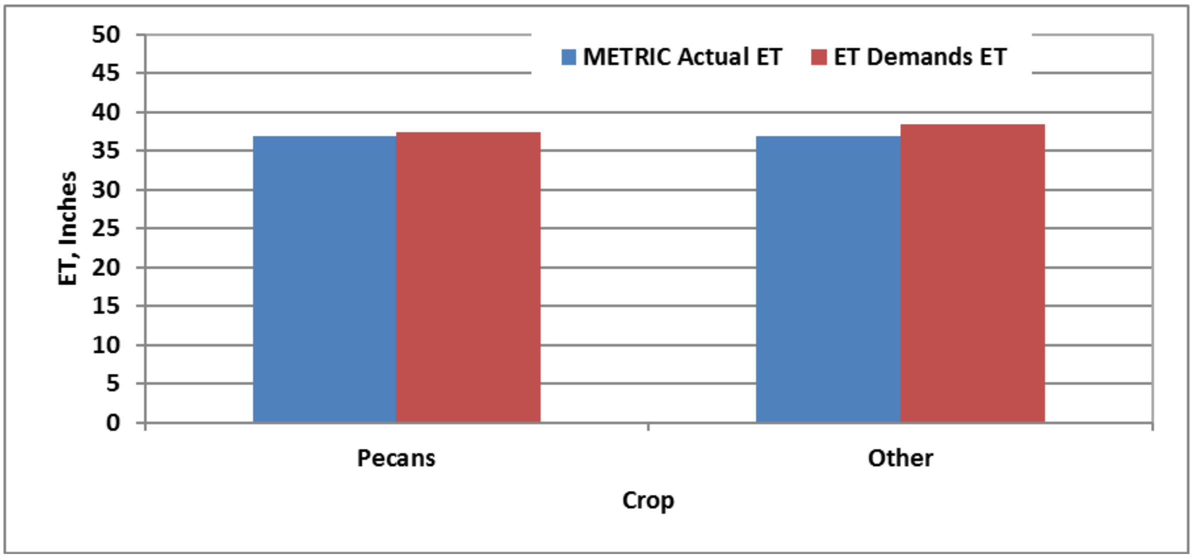

Figure 7A-6. METRIC and ET Demands 2008 Seasonal (March – October) ET_c Estimates for Juarez by Crop.

2013 Comparisons

EBID Elephant Butte Irrigation District

ET Demands results for 2013 were developed using the K_c parameterizations and related ET Demands settings for 2008. Seasonal METRIC and ET Demands results by crop for 2013 in EBID areas with access to both surface water and groundwater are provided in **Table 7A-6a** and **Figure 7A-7a**. As indicated, METRIC ET_c results range from 27.6 inches for miscellaneous vegetables to 48.6 inches for alfalfa with an area-weighted average of 37.4 inches for the March to October period. ET Demands ET_c results range from 30.8 inches for miscellaneous vegetables to 45.1 inches for alfalfa. ET Demands results for ET_c range from 9.0 inches less than METRIC ET_c results for irrigated pasture to 3.2 inches greater for miscellaneous vegetables with total ET_c 1.9 inches greater than the METRIC ET_c results. On a percentage basis, ET Demands results for ET_c range from 21.5 percent less than METRIC for irrigated pasture to 11.6 percent more for miscellaneous vegetables with total ET_c differing by 5.0 percent more.

Table 7A-6a. Summary of METRIC and ET Demands 2013 Seasonal (March – October) ET_c Estimates for EBID areas with SW and GW access by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Pecans	25,347	38.4	39.8	1.4	3.6%
Alfalfa Hay	17,000	48.6	45.1	-3.5	-7.3%
Cotton	9,692	29.6	32.5	2.9	9.9%
Corn, Sweet Corn, and Silage	7,835	33.8	35.3	1.5	4.4%
Onions	4,753	33.5	34.8	1.3	3.8%
Wheat and Small Grains	3,415	38.3	39.9	1.6	4.3%
Chile (Peppers)	3,349	35.2	29.9	-5.3	-15.0%
Irrigated Pasture	1,544	42.0	33.0	-9.0	-21.5%

Totals	73,520	37.4	39.3	1.9	5.0%

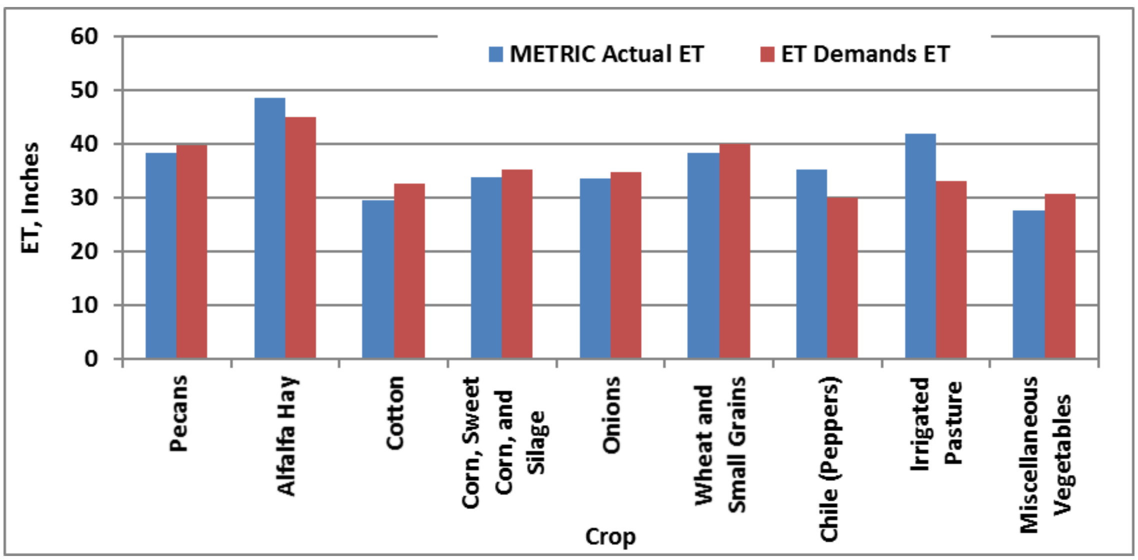

Figure 7A-7a. METRIC and ET Demands 2013 Seasonal (March – October) ET_c Estimates for EBID SW and GW access by Crop.

March through October METRIC and ET Demands results by crop for 2013 for irrigated lands in New Mexico with access to only groundwater are provided in **Table 7A-6b** and **Figure 7A-7b**. METRIC ET_c estimates range from 21.9 inches for cotton to 40.8 inches for alfalfa hay with total ET_c equaling 27.8 inches for the 2013 March to October period. Similarly, ET Demands ET_c estimates range from 29.9 inches for chile to 45.1 inches for alfalfa hay with total ET_c equal to 38.6 inches. ET Demands estimates of ET_c differ from METRIC estimates by 5.5 inches less for miscellaneous vegetables to 10.6 inches more for cotton and pecans with total ET_c differing by 10.7 inches. On a percentage basis, ET Demands estimates of ET_c differ from METRIC estimates by 15.2 percent less for miscellaneous vegetables to 48.5 percent more for cotton with total ET_c differing by 38.6 percent.

Table 7A-6b. Summary of METRIC and ET Demands 2013 Seasonal (March – October) ET_c Estimates for EBID GW only by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Alfalfa Hay	1,654	40.8	45.1	4.3	10.4%
Pecans	1,648	29.2	39.8	10.6	36.3%
Irrigated Pasture	886	36.7	33.0	-3.7	-10.1%
Corn, Sweet Corn, and Silage	400	29.0	35.3	6.3	21.7%
Cotton	176	21.9	32.5	10.6	48.5%
Chile (Peppers)	175	28.0	29.9	1.9	6.8%
Wheat and Small Grains	47	32.3	39.9	7.6	23.7%
Miscellaneous Vegetables	42	36.3	30.8	-5.5	-15.2%
Onions	39	27.7	34.8	7.1	25.5%
Totals	5,066	27.8	38.6	10.7	38.6%

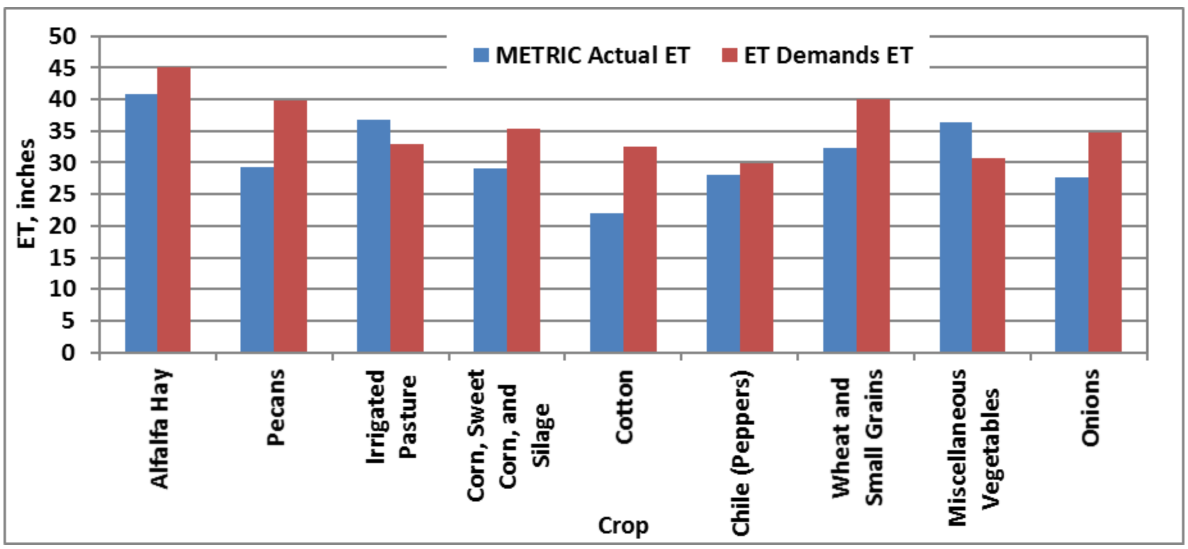

Figure 7A-7b. METRIC and ET Demands 2013 Seasonal (March – October) ET_c Estimates for EBID GW only by Crop.

ET Demands results for EBID agree with METRIC results relatively well, but not as well as for 2008. The generally larger differences likely result from a combination of factors. One potential factor is the method of identifying crops. Crops were identified in 2008 in EBID via ground-based surveys, whereas crops were identified in 2013 in EBID based on CDL. As a result, the METRIC ET_c results by crop in 2013 may be influenced to a greater degree by misclassification than the 2008 METRIC ET_c results. Modeled ET Demands ET_c greater than the METRIC ET_c is consistent with the objective of developing ET_{aw} data intended to represent a reasonable upper limit on ET_{aw} that would occur under "full supply" conditions.

El Paso County Water Improvement District

Seasonal METRIC and ET Demands ET_c results by crop for 2013 in the EPCWID areas in the Mesilla and El Paso Valleys are provided in **Tables 7A-7a and 7A-7b** and **Figures 7A-8a and 7A-8b**, respectively. In the Mesilla Valley area of EPCWID, METRIC ET_c estimates range from 30.4 inches for cotton to 41.9 inches for pecans with total ET_c equal to 36.9 inches for the 2013 March to October period. Crops not identified by the CDL do not have METRIC results. ET Demands ET_c estimates range from 32.4 inches for cotton to 45.1 inches for alfalfa. ET Demands estimates of ET_c differ from METRIC ET_c results by 2.3 inches less for pecans to 3.8 inches for alfalfa hay with total ET_c differing by 4.5 inches. On a percentage basis, ET Demands results for ET_c differ from METRIC ET_c estimates by 5.5 percent less for pecans to 9.1 percent more for alfalfa hay with total ET_c differing by 13.6 percent.

Table 7A-7a. Summary of METRIC and ET Demands 2013 Seasonal (March – October) ET_c Estimates for the Mesilla Valley Area of EPCWID by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Cotton	1,511	30.4	32.4	2.0	6.6%
Pecans	1,419	41.9	39.6	-2.3	-5.5%
Alfalfa Hay	569	41.3	45.1	3.8	9.1%
Other	36	NA*	35.3	NA*	NA*
Totals	3,536	32.9	37.4	4.5	13.6%

*METRIC ET_c was not available crops other than cotton, pecans and alfalfa hay due to the small area of the other crops.

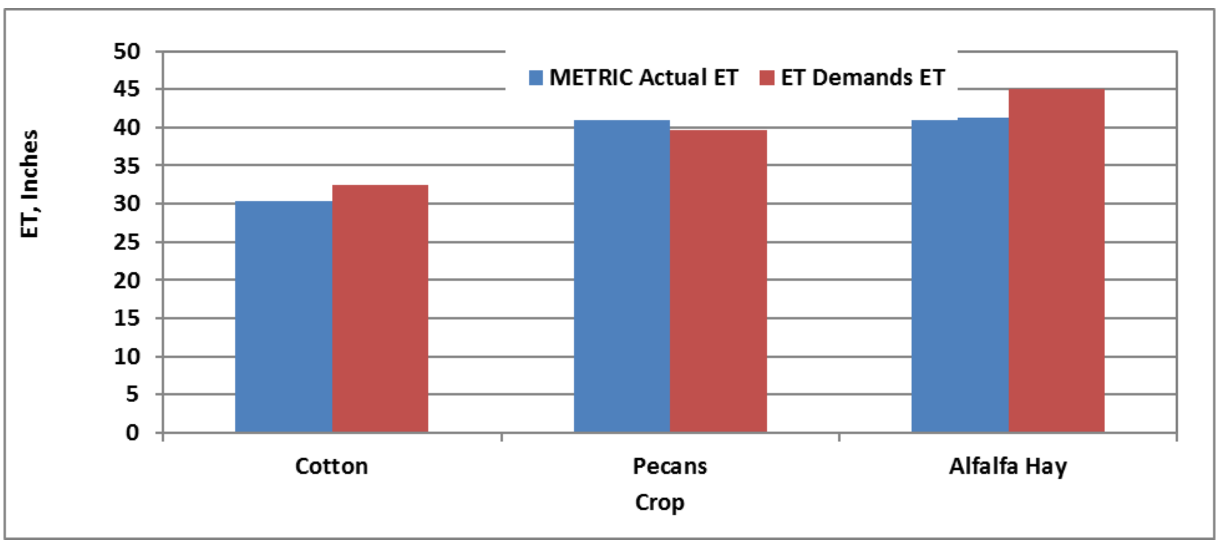

Figure 7A-8a. METRIC and ET Demands 2013 Seasonal (March – October) ET_c Results for the Mesilla Valley Area of EPCWID by Crop.

Table 7A-7b. Summary of METRIC and ET Demands 2013 Seasonal (March – October) ET_c Estimates for the El Paso Valley Area of EPCWID by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Cotton	11,306	33.2	32.9	-0.3	-1.0%
Pecans	10,617	36.5	39.8	3.3	9.2%
Alfalfa Hay	4,259	40.1	45.1	5.0	12.5%
Other	270	NA*	36.4	NA*	NA*
Totals	26,451	34.1	37.7	3.6	10.6%

*METRIC ET_c was not available crops other than cotton, pecans and alfalfa hay due to the small area of the other crops.

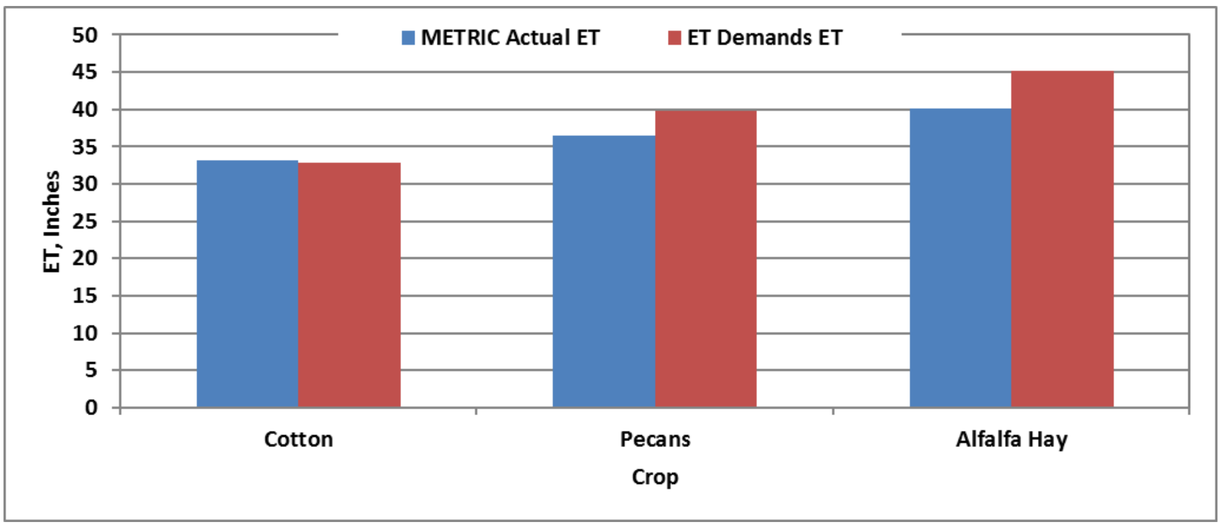

Figure 7A-8b. METRIC and ET Demands 2013 Seasonal (March – October) ET_c Results for the El Paso Valley Area of EPCWID by Crop.

In the El Paso Valley area of EPCWID, METRIC ET_c results range from 33.2 inches for cotton to 40.1 inches for alfalfa hay with total ET_c equal to 34.1 inches for the 2013 March to October period. Crops not identified in the CDL do not have METRIC results and are not discussed. ET Demands ET_c results range from 32.9 inches for cotton to 45.1 inches for alfalfa hay. ET Demands results for ET_c differ from METRIC results by 0.3 inches less for cotton to 5.0 inches more for alfalfa hay with total ET_c differing by 3.6 inches. On a percentage basis, ET Demands results for ET_c differ from METRIC results by 1.0 percent less for cotton to 12.5 percent more for alfalfa hay with total ET_c differing by 10.6 percent. The METRIC ET_c results for pecans could be higher than the ET Demands ET_c results because the "average" level of stress due to water shortage and other factors in EPCWID in 2013 is less than the "average" level of stress in the calibration data from EBID in 2008.

ET Demands ET_c results for EPCWID in the Mesilla and El Paso Valleys agree with METRIC ET_c results relatively well, but not as well as for EBID. The generally larger differences likely result from a combination of factors. The METRIC ET_c results are likely lower than the ET Demands ET_c results because the "average" level of stress due to water shortage and other factors in EPCWID in 2013 is more than the "average" level of stress in the calibration data from EBID in 2008.

Hudspeth

Seasonal METRIC and ET Demands ET_c results by crop for 2013 in Hudspeth are provided in **Table 7A-8** and **Figure 7A-9**. As indicated, METRIC ET_c results range from 24.8 inches for cotton to 31.8 inches for alfalfa hay with total ET_c equal to 26.5 inches for the March to October period. ET Demands ET_c results range from 33.0 inches for cotton to 45.8 inches for alfalfa hay. ET Demands results for ET_c differ from METRIC results by 8.2 inches for cotton to 14.0 inches for alfalfa hay with total ET_c differing by 8.2 inches. On a percentage basis, ET Demands results for ET_c differ from METRIC ET_c results by 33.1 percent for cotton to 44.0 percent for alfalfa with total ET_c differing by 30.9 percent.

Table 7A-8. Summary of METRIC and ET Demands 2013 Seasonal (March – October) ET_c Results for Hudspeth by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Cotton	5,253	24.8	33.0	8.2	33.1%
Alfalfa Hay	725	31.8	45.8	14.0	44.0%
Other	183	NA*	38.2	NA*	NA*
Totals	6,160	26.5	34.7	8.2	30.9%

*METRIC ET_c was not available crops other than cotton, pecans and alfalfa hay due to the small area of the other crops.

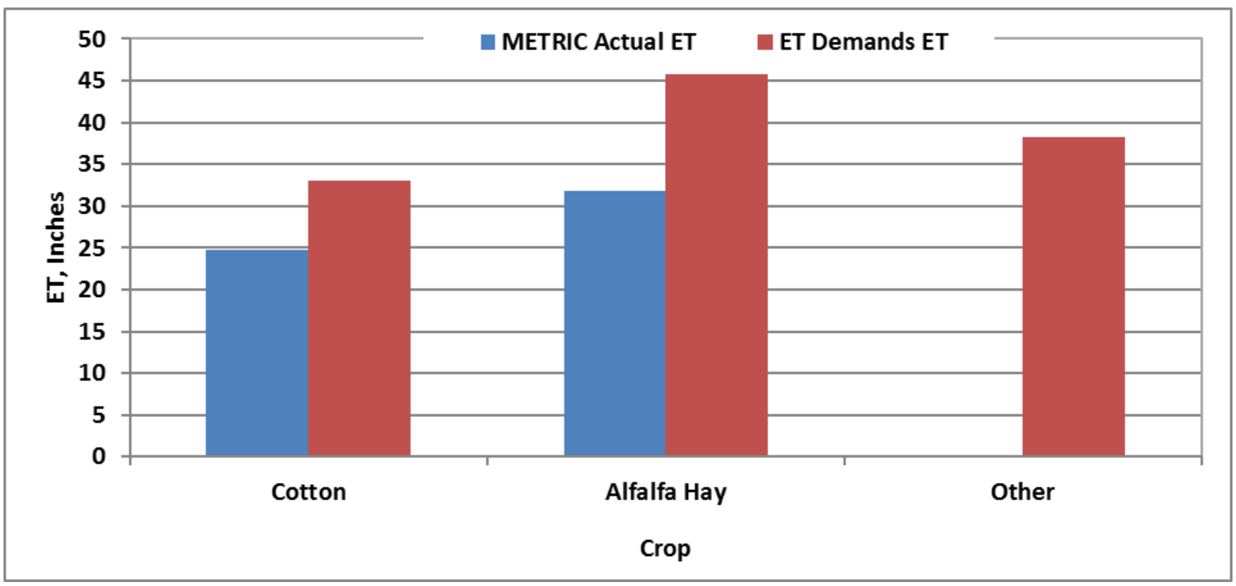

Figure 7A-9. METRIC and ET Demands 2013 Seasonal (March – October) ET_c Results for Hudspeth by Crop.

ET Demands ET_c results for Hudspeth are 33.1, and 44.0 percent higher than the METRIC ET_c results for the two major crops of cotton and alfalfa grown in 2013. Possible reasons for lower METRIC ET_c compared to ET Demands ET_c results include water shortages and poor water quality, perhaps due to increased salinity. Modeled ET Demands ET_c greater than the METRIC ET_c is consistent with the objective of developing ET_{aw} data intended to represent a reasonable upper limit on ET_{aw} that would occur under "full supply" conditions.

Juarez Valley Irrigation District, Mexico

Spatial crop distributions across the irrigated fields in Juarez were only available for pecans, so results for pecans and for all other crops combined are reported. Pecan fields identified by Intera in the 2010 coverage were assumed to still be pecans in 2013 and used to calculate ET_c for 2013. March through October 2013 METRIC ET_c totals for the Juarez Valley Irrigation District irrigated field polygons are 35.6 inches compared to ET Demands ET_c results of 37.0 inches. ET Demands modeled ET_c results are 1.4 inches (3.9 percent) greater than the METRIC ET_c results. Possible reasons for lower METRIC ET_c compared to ET Demands ET_c results include water shortages and poor water quality, perhaps due to salinity. Thus, the ET Demands modeled ET_c is a reasonable upper limit on ET and will lead to reasonable upper limit for ET_{aw}. **Table 7A-9** and **Figure 7A-10** summarize the results for Juarez.

Table 7A-9. Summary of METRIC and ET Demands 2013 Seasonal (March – October) ET_c Estimates for Juarez by Crop.

Crop	Acres	METRIC ET_c (in)	ET Demands ET_c (in)	Difference (in)	Difference (%)
Pecans	921	37.5	39.9	2.4	6.3%
Other	31,314	35.5	37.0	1.4	3.9%
Totals	32,235	35.6	37.0	1.4	4.0%

Appendix 8B. Selected Historical Alfalfa Photos

Alfalfa Bulletin 139-1923

Quesenberry, G. R. 1923. Alfalfa. Agricultural Experiment Station of the New Mexico College of Agriculture and Mechanic Arts, Bulletin No. 139. (Photos 8B.1 and 8B.2)

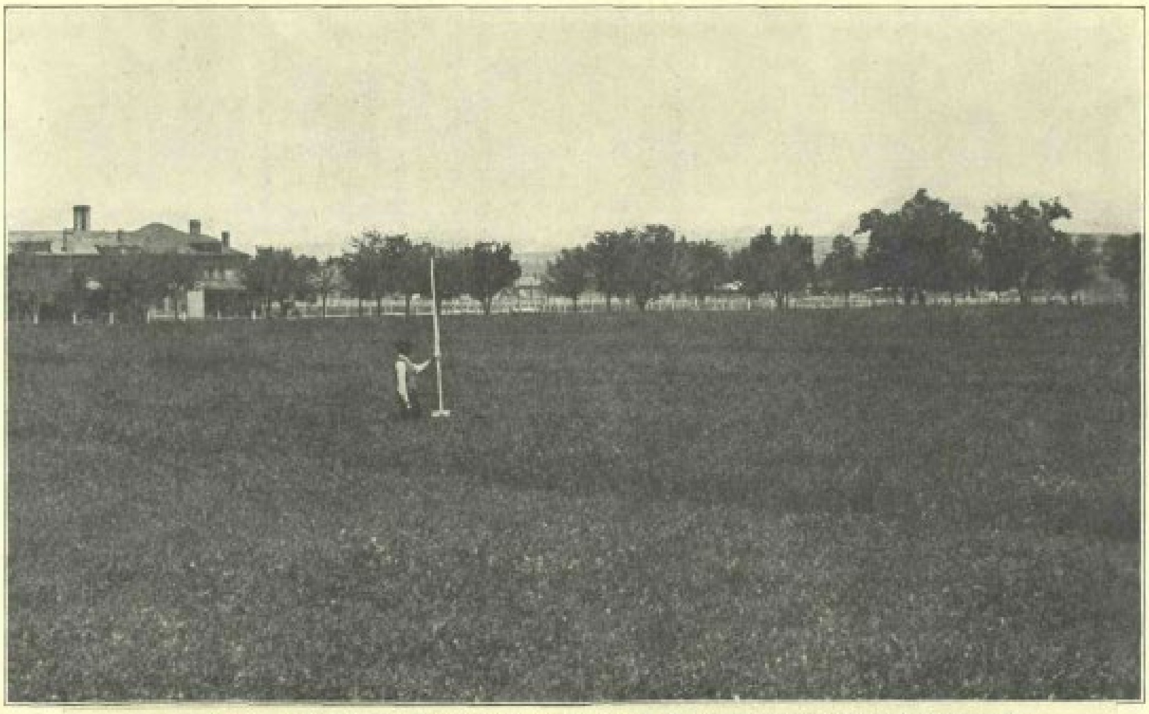

Fig. 2. Varietal experimental plats, State College, N. M. Hairy Peruvian shown in foreground.

ERRATA.

The next to the last sentence of the first paragraph, page 3, should read: "The first plantings were made by the Mexicans."

The second word of next to the last line of the first paragraph, page 9, should be "emerge."

The third word, line 8 of the second paragraph, page 18, should be "Mexicans," instead of "Spaniards."

Photo 8B-1

Fig. 4. Alfalfa treated with seven tons of manure per acre, four years after seeding had an average stand of fourteen plants per square foot.

Alfalfa Bulletin 323-1945

Staten, G. and J. Carter, Jr. 1945. Alfalfa Production Investigations in New Mexico. Agricultural Experiment Station of the New Mexico College of Agriculture and Mechanic Arts, Bulletin 323. (Photo 8B.3)

Top: Uniform alfalfa nursery at State College, photographed March 8, 1941, showing the difference in early spring growth of different strains. Center row is New Mexico Common.

Bottom: The same nursery, photographed March 8, 1945, showing the decrease in stand and vigor due to alfalfa wilt.

Hauter, L. H. 1928. Economics of crop production on the Elephant Butte Irrigation Project. New Mexico College of Agriculture and Mechanic Arts Agricultural Extension Service, Extension Circular 97. (Photo 8B.5)

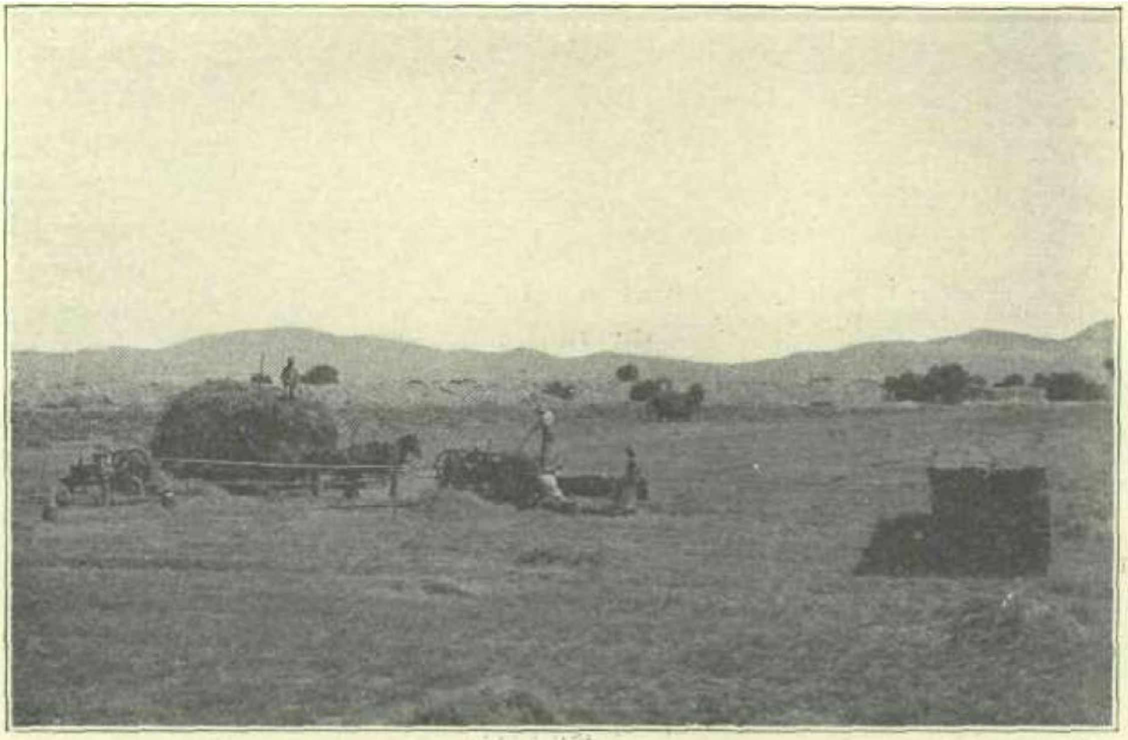

Fig. 16.—Alfalfa hay has always been an important crop on the Project, ranking as the most important crop until the introduction of cotton several years ago. The Project has had a good market for its alfalfa in southeastern Texas points.

Appendix 11. Resume for Bryan P. Thoreson PhD, PE

Bryan P. Thoreson, Ph.D., P. E.

Education

Ph.D., Agricultural Engineering, University of Arizona, Tucson

M.S., Agricultural Engineering, South Dakota State University, Brookings

B.S., Agricultural Engineering, South Dakota State University, Brookings

Registration

Years of Experience:

25 Years

Distinguishing Qualifications

- Crop consumptive water use
- Complex water balance development

Summary

Dr. Thoreson has 25 years of professional experience in water resources and irrigation engineering both in the western United States and overseas. Dr. Thoreson specializes in crop consumptive water use and water balances of agricultural areas including database development for water balances, water flow measurement and uncertainty analysis water right analysis, land use analysis, and reservoir operations. Dr. Thoreson has worked extensively using Access and Oracle databases to store time series data for assembling and computing water balances. Dr. Thoreson has played a major role in developing water balances and quantifying water conserved by various conservation practices for irrigation and water districts in the Sacramento, San Joaquin and Imperial Valleys of California and elsewhere. These water balances have ranged from the field to basin scale and included analysis and formulation of conjunctive management strategies. Dr. Thoreson has authored more than 50 papers focusing on analysis of crop ET developed from remote sensing (SEBAL®) techniques and on data management for irrigation water resources planning and management.

Relevant Experience

Project Manager and Lead Engineer, Crop Consumptive Water Use and Agricultural Water Budget Projects. Dr. Thoreson has served as project manager and lead engineer developing agricultural water budgets for numerous irrigation and water districts in the Sacramento and San Joaquin Valleys. Technical aspects of Dr. Thoreson's work in these projects involved estimating agricultural applied water use and using a root zone water budget to estimate evapotranspiration (ET) of applied water and precipitation. In each of these projects, Dr. Thoreson worked closely with local staff to develop the water use estimates and water budgets. Remotely sensed ET estimates are typically used to develop crop coefficients for these projects. Customized semi-automatic water budget tools to assemble data from supplier spreadsheets and databases and develop the water budget were developed for the first three entities on the following partial list of the entities and time periods for which Dr. Thoreson has led or substantially contributed to development of agricultural water budgets.

1. Imperial Irrigation District (2006 – 2009 completed by Dr. Thoreson, 2010 – 2016 District completed with tool)
2. Turlock Irrigation District (1950 – 2010 completed by Dr. Thoreson, 2011 – 2016 District completed with tool)
3. Sonoma County Water Agency (2002-2014 completed by Dr. Thoreson)
4. Yuba County Water Agency (2001-2015)
5. Oakdale Irrigation District (2005-2016)
6. South San Joaquin Irrigation District (1994-2015)
7. Merced Irrigation District (1970-2009)
8. Stony Creek Fan Area includes Orland Unit Water Users' Association, Orland-Artois Water District, Glen Colusa Irrigation District and surrounding groundwater pumpers (1970-1999)
9. Chowchilla Water District (1991-2015)
10. Glenn-Colusa Irrigation District (1970-2012)
11. Orland Unit Water Users Association (1970-2016)
12. RD108 Water District (1986-2010)
13. Dunnigan Water District (1961-2004)
14. Solano Irrigation District (1991-2014)
15. Benton Irrigation District in Washington
16. Madera Irrigation District (1991-2015)
17. Root Creek Water District (1991-2015)
18. Gravelly Ford Water District (1991-2015)
19. New Stone Water District (1991-2015)
20. Triangle T Water District (1991-2015)
21. Sierra Vista Mutual Water Company (1991-2015)
22. Madera County Groundwater Sustainability Agency (1991-2015)

Project Manager, GSP Development and SGMA Data Collection and Analysis Projects, Madera County, Madera, CA. Dr. Thoreson served as the project manager for the SGMA Data Collection and Analysis projects for the critically overdrafted Chowchilla and Madera subbasins in Madera County completed in the spring of 2018. He more recently served as project manager for the GSP Development for both subbasins, with draft GSPs released in August 2019. The objective in both subbasins for the data collection and analysis project was to identify significant data gaps that must be addressed during GSP preparation. The technical approach inventoried all data needed to prepare a compliant GSP based on California Department of Water Resources' (DWR's) GSP regulations and anticipated measures to achieve sustainability. Immediately after the conclusion of the data collection and analysis project, the GSP development project began. In addition to coordinating overall development of the GSPs, which included extensive stakeholder outreach and coordination with technical experts representing various GSAs in each subbasin, Dr. Thoreson oversaw development of basin boundary and GSA water budgets and managed the development of projects and management actions. Dr. Thoreson was an active participant in the development of minimum thresholds and measurable objectives for the sustainability management criteria in each subbasin. The work has included numerous technical meetings with GSA representatives and public meetings, including coordination with neighboring subbasins to ensure consistency in understanding of interbasin flows.

Lead Engineer, IWFM Demand Calculator Parameter Development, Yolo County, CA. Dr. Thoreson served as lead engineer on this project to review and calibrate the soil and irrigation management input parameters used in the Integrated Water Flow Model (IWFM) Demand Calculator (IDC) for the Yolo County IWFM (YCIWFM) application. The IDC was used to develop estimates of agriculture water use and partition the use between applied water (surface water or groundwater) and precipitation. Dr. Thoreson completed a comprehensive literature review of soil drainage characteristics to serve as the basis for IDC calibration.

Confidential Client. Assist a confidential client develop crop water use requirements for cotton and various other crops and achievable on-farm application efficiencies in an arid climate in the U.S. Southwest.

California Department of Water Resources. Spatial Mapping of ET in the Sacramento-San Joaquin River Delta using SEBAL. Dr. Thoreson led a project to estimate ET_a for crops and native vegetation for the 2007 crop growing season in the Sacramento-San Joaquin River Delta. The California Department of Water Resources (DWR) uses several models to estimate water demand and consumptive use in the Delta. Improving estimates of water demand and consumptive use for crops and native vegetation in the Delta is important in planning for future water conveyance options through the Delta. DWR completed a detailed land use survey for the area in 2007 to support the computation of daily evapotranspiration of applied water (ET_{aw}) using three, existing models and comparison to the SEBAL results. Nine Landsat multispectral satellite images acquired between March and September 2007 were analyzed using the Surface energy Balance Algorithm for Land (SEBAL®). DWR developed actual crop coefficients for use in estimating applied water within the Delta. To determine if these crop coefficients accurately estimated actual ET, and the corresponding applied water, of the various crops grown in the Delta, an additional SEBAL ET analysis was completed for 2009. DWR found that model estimates of water demand and applied water in 2009 using the actual crop coefficients developed from the 2007 SEBAL results were in good agreement with the 2009 SEBAL results.

Data Management and Water Resources Planning. Imperial Irrigation District. Led the SEBAL application and data management effort for water resources planning and management in support of the Quantification Settlement Agreement (QSA) Definite Plan for the Imperial Irrigation District. This included providing data management support and assisting with database and analysis design in support of the project GIS, developing computer programs and databases in support of crop water use and land use analysis, and surface water operational models. These databases and models also track the surface water hydrology of rainfall and runoff.

Time Series Evapotranspiration and Applied Water Estimates from Remote Sensing. Kaweah Delta Water Conservation District. Dr. Thoreson provided senior review of the development of SEBAL actual ET (ET_a) estimates and the development and review of a daily root zone water balance model to leverage available SEBAL results for three years over a 14-year period. Actual ET estimates for the additional years were developed using crop coefficients estimated based on the normalized difference vegetation index (NDVI). Combining these estimates with a daily rootzone water balance model avoided the relatively high cost of estimating spatially distributed ET_a on an annual basis using SEBAL. NDVI imagery was acquired at monthly or more frequent intervals and used to develop a daily time series of the basal crop coefficient, which describes crop transpiration, for each field within the District.

The daily root zone water balance model was developed based on the procedures described in FAO Irrigation and Drainage Paper No. 56 for the dual crop coefficient approach. This model was implemented in a database environment and used to estimate inflows to and outflows from each field from applied irrigation water and precipitation. Model results for an independent set of fields were used to validate the approach, and it was found that total ET estimated based the combination of NDVI imagery and the daily root zone water balance model agree with SEBAL results within 1% for each of the three years for which SEBAL results were available.

This approach to quantifying ET_a and applied water demand at highly discrete spatial and temporal scales over a multi-year time period has resulted in increased reliability in estimates of total pumpage and changes in groundwater storage by reducing reliance on cropping data, inherently accounting for changes in crop timing and intensity from year to year, and inherently accounting for differences between actual growing conditions and the idealized conditions upon which many published crop coefficients were developed. Because of the relatively low cost of running the NDVI-based model, the District is able to incorporate annual updates into its analysis and reporting processes.

Lead Engineer, Water Data Analysis Support and Water Information System Development, Imperial Irrigation District, Imperial, CA. Dr. Thoreson has led the effort to develop IID's Water Information System (WIS), an integrated data management system that supports water accounting and IID's on-farm and canal distribution system conservation programs. The data management system calculates ET of applied water and precipitation for thousands of fields in IID every month. The results are compiled into crop season water budgets for each field. The WIS also performs ongoing accounting of on-farm and system level water conservation. Dr. Thoreson developed a semi-automated water balance application including accounting centers for the water distribution system, irrigated lands, and drainage system. This semi-automated water balance, programmed in IID's WIS, compiles flow records, computes estimates for all flow paths, and assembles monthly and annual water balances for each accounting center. Models run daily and monthly, tracking water use and conservation.

Lead Engineer, Water Management Planning, Turlock Irrigation District, Turlock, CA. In 1998, Dr. Thoreson developed a database to complete a 25-year monthly water budget for Turlock Irrigation District in support of the District's Agricultural Water Management Plan (AWMP). This AWMP was developed under the guidelines of the Agricultural Water Management Council created by the Agricultural Water Suppliers Efficient Water Management Practices Act and approved in 2001. Dr. Thoreson served as the project manager and lead engineer for updating the water balance through 2008 and to update the initial AWMP. An assessment of accuracy and computation of confidence intervals (uncertainty) for each flow path in the water balance was also completed. In 2011, Dr. Thoreson led the development of a semi-automated TID water balance application to be utilized by TID staff. The application was programmed in an MS Access database. With this application, TID is able to complete each year's water balance analysis soon after the calendar year ends. Again in 2012 and in 2015, TID called on Dr. Thoreson to serve as the project manager for the preparation of the District's AWMP. Dr. Thoreson is also supporting TID's efforts to improve delivery measurement accuracy to directly measure agricultural water demands.

Solano Irrigation District. System Optimization Review. Dr. Thoreson is serving as the project manager for a water balance supporting a System Optimization Review for the Solano Irrigation District (SID). Agricultural water demands were quantified using a daily root zone water balance model to estimate the portion of total crop evapotranspiration resulting from applied irrigation water (ET_{aw}) over time (1991 to 2010) on the basis of cropping, soil characteristics, and weather (evaporative demand and precipitation). These demands were then incorporated into a full water balance analysis to identify water conservation opportunities. Dr. Thoreson led the quantification of demands and the water balance analysis. The water balance results will focus the development of cost effective programs and projects to optimize management of SID's water resources.

Project Manager, Water Management Planning and Feasibility Assessment of Pressurized Water Delivery, South San Joaquin Irrigation District, Manteca, CA. Dr. Thoreson served as the project manager for the preparation of the South San Joaquin Irrigation District (SSJID) Agricultural Water Management Plan (AWMP) in 2012 and 2015. Dr. Thoreson also assisted the District with a feasibility assessment of pressurized water delivery service. Technical aspects of Dr. Thoreson's work included developing projections of future cropping, associated water demands, and associated water supply requirements. These projections are based on historical cropping, grower interviews, and a District water budget analysis including a root zone water budget to partition evapotranspiration between applied water and precipitation. Dr. Thoreson worked closely with SSJID staff to interview growers and develop the water budget. The feasibility assessment evaluated different pressurization options ranging from pressurization of the entire distribution system to pressurization in selected areas with high concentrations of permanent crops irrigated with pressurized on farm irrigation systems.

Imperial Irrigation District. Efficiency Conservation Definite Plan and Efficiency Conservation Program. Dr. Thoreson managed the data component of the Efficiency Conservation Definite Plan (ECDP). Since the completion of the ECDP in 2007, Dr. Thoreson has continued to support Imperial Irrigation District's (IID) Efficiency Conservation Program implementing the ECDP. As part of this work, Dr. Thoreson has led the effort to develop IID's Water Information System (WIS), an integrated data management system that supports water accounting and on-farm and distribution system conservation programs. The data management system calculates ET of applied water and precipitation for thousands of fields in IID every month based on IID delivery data. The results are then compiled into crop season water balance for each field. For the on-farm conservation program, the WIS supports enrollment of growers in the program and management of grower contracts. The WIS also performs on ongoing accounting of on-farm and system level water conservation, thereby documenting IID's compliance with the terms of the Colorado River Quantification Settlement Agreement (QSA). Dr. Thoreson developed a semi-automated water balance including the water distribution system, irrigated lands and drainage system tracking surface water imports and rainfall. This semi-automated water balance, programmed in IID's WIS, assembles flow records and computes estimates for other flow paths into monthly and annual system water balances. Models run daily and monthly tracking water use and conservation.

Project Manager, 2012 and 2015 SBx7-7 Agricultural Water Management Plans, Yuba County Water Agency and Oakdale Irrigation District, Marysville and Oakdale, CA. Dr. Thoreson served as project manager for the Oakdale Irrigation District agricultural water management plan (AWMPs) completed in 2012 and is assisting with the 2015 AWMP. Dr. Thoreson served as the water budget task leader for the development of the Yuba County Water Agency's 2012 AWMP and assisted with the development of the 2015 AWMP. For both AWMPs, Dr. Thoreson supported various aspects of the technical analyses, which included the preparation of detailed, multi-year water budgets for irrigation distribution (canal) systems, farmed lands, and drainage systems. Additionally, Dr. Thoreson assisted with the evaluation of each district's Efficient Water Management Practice (EWMPs) implementation status.

Data Management Task Leader, Water Conservation Verification, Imperial Irrigation District, Imperial, CA. Dr. Thoreson led the data management for the water conservation verification for the Imperial Irrigation District under its Water Conservation and Transfer Program with Metropolitan Water District of Southern California (MWD). He conducted data analyses supporting determination of the water conserved by a suite of 18 projects encompassing on-farm and system conservation. Dr. Thoreson implemented the final verification algorithm for each project in a data management system supporting automatic annual computation of water savings based on information collected, quality-controlled and stored in IID's Water Information System (WIS).

Water Balance Task Leader, Merced Irrigation District Water Management Plan, Merced Irrigation District, Merced, CA. Dr. Thoreson developed a database used to complete a multi-year water balance for Merced Irrigation District in support of the District's Water Management Plan (WMP). In this water balance, separate water balances were completed for various regions of the district. This WMP was developed under the guidelines of the Agricultural Water Management Council created by the Agricultural Water Suppliers Efficient Water Management Practices Act, referred to as AB 3616. Dr. Thoreson led the water balance task, developing a water balance structure, quantifying monthly flow path volumes, assembling the balance and presenting the results.

SPECIALIZATIONS:

Hydrology and Water Resources – Surface and Subsurface Systems, Modeling, Wetlands
Evapotranspiration – Remote Sensing, Calculation, Energy Balance, Wetlands, Crop Water Requirements, Climate Change Impacts, Measurement: Eddy Covariance, Bowen Ratio, Lysimeters, Scintillometers, Standardization, Quality Assessment and Quality Control
Irrigation – Water Management, Demands, System Design, Soil Water – Flow Processes
Electronic Instrumentation

DEGREES:

B.S. Agricultural Engineering, Iowa State University, November 1974
M.S. Agricultural Engineering, University of Idaho, June 1977
Ph.D. Civil Engineering, University Idaho, May 1984

PROFESSIONAL REGISTRATION:

Civil Engineer, State of Idaho, #4351, July 1981 (U.S. Citizen)

PROFESSIONAL POSITIONS:

Professor of Soil and Water Systems, December 2015 to Present. University of Idaho.
Professor of Civil Engineering and Biological and Agricultural Engineering, December 1998 to 2015. University of Idaho.
Member, Landsat Science Team, National Aeronautics and Space Administration and U.S. Geological Survey, 2006-2017.
Owner/Proprietor of Evapotranspiration, Plus, LLC (ET+) 2010 to Present.
Professor of Biological and Irrigation Engineering, May 1998 to December 1998. Utah State University.
Assistant/Associate Professor of Biological and Irrigation Engineering, January 1986 to April 1998. Utah State University.
Assistant Professor of Civil Engineering, January 1984 to December 1985. Iowa State University.
Research Associate, May 1977 to December 1983. University of Idaho.
Owner and Principal, Allen Engineering, 631 Saratoga Drive, No. 201, Twin Falls, Idaho 83301 – 2005 to present.

SIGNIFICANT PUBLICATIONS:

162 Papers in **Refereed Journals and Chapters** - primary author on 46
H-Index from the Web of Science (Jan 2018) is 40

PROFESSIONAL ORGANIZATIONS:

American Society of Civil Engineers:
Environmental and Water Resources Institute –Past Chair, Technical Committee on Evapotranspiration in Irrigation and Hydrology, Vice-Chair, Task Committee on Crop Coefficients
International Commission on Irrigation and Drainage

U.S. Representative to the Working Group on Sustainable Crops and Water Use

U.S. Committee on Irrigation and Drainage

Ex-officio Member of the National Board of Directors

American Geophysical Union
Irrigation Association - *Water Management Committee – former member*
Honoraries: Tau Beta Pi, Phi Kappa Phi, Alpha Epsilon, Chi Epsilon, Sigma Xi, Gamma Sigma Delta

PROFESSIONAL CONSULTING:

Irrigation system design, water requirements, water rights, remote sensing of evapotranspiration, hydrologic systems, hydropower, evapotranspiration, lysimeter measurement of evapotranspiration, software development, water balances, impacts of climate change on irrigation water requirements, electronic weather stations, expert witness.

INTERNATIONAL EXPERT PANELS:

Member of the **Landsat Science Team**, 2006 – 2017.
Expert Meeting on Water Security, Land and Water Development Division, United Nations Food and Agriculture Service, **Rome**, Italy, Oct. 2012.
Advisory Board, PLEIADeS Remote Sensing for Irrigation Water Management, European Union, Albacete, **Spain**, 2006 – 2009.
Advisory Board, DEMETER Remote Sensing Study for Irrigation Water Management, European Union, Albacete, **Spain**, 2002 – 2005.
Expert Meeting on Evaporation and Evapotranspiration Standardization, (U.S. Rep.), Meteorological Organization, Vozokany, **Slovakia**, May, 1995.
Intl. Expert Panel on Irrig. Res. Needs in Middle East. UN-FAO, **Cairo**, Egypt, Nov. 1994.
World Expert Consultation on Procedures for Revision of FAO Guidelines for Prediction of Crop Water Requirements. Land and Water Development Division, United Nations Food and Agriculture Service, **Rome**, Italy, May, 1990.

EXPERT WITNESS TESTIMONY AND WORK IN THE LAST SIX YEARS:

Year	Court	Client	Case	Type of Expert Work	Court appearance
2013	US Supreme Court	State of Montana	Montana v. Wyoming, N.Dakota – Tongue River	ET mapping by Satellite	Yes

OTHER INTERNATIONAL EXPERIENCE:

July 2018. **Indian National Agricultural Research Institute**, New Delhi. National training course on Satellite-based production of Evapotranspiration (METRIC and EEFlux)

Sept. 2015, Dec. 2016, Nov. 2018. **Chinese Academy of Science – Center for Agricultural Resources Research**, Shijiazhuang. Satellite-based ET mapping.

Jan. 2014. **Univ. Talca, Chile.** Advisory on application of METRIC processing to vine and tree crops.

July 2012. **Federal Univ. Bahia, Brazil.** Advisory on studies for evaporation from open water and application of METRIC to tropical vegetation.

June 2011. **King Saud Univ., Riyadh, Saudi Arabia.** Advisory on application of METRIC to the Arabian Pennisula and advisory on irrigation water management research.

Oct. 2009. **Univ. Natal, Pretoria, South Africa.** Collaboration on satellite-based sensing of evapotranspiration.

July 2005. **Cordoba, Spain**. One month visiting scientist, Centro Alameda del Obispo, Instituto de Investigación y Formación Agraria y Pesquera (IFAPA) – CICE

February 2001. **Amman, Jordan**. Irrigation specialist and advisor to Jordan Ministry of Water and Irrigation on National Water Development Plan. (US-AID)

2001, 2000, 1999, 1998, 1997. Four day guest lecturer at Institute for Infrastructure, Hydraulics, and Environment, **Delft, Netherlands**.

1995 - 2001. Various consultancy meetings with UN-FAO in Rome, Belgium, Lisbon.

October 1994. **Spain**. National Research Program Reviewer, National Irrigation Water Management Program of Spain (Zaragoza, Valencia, Badajoz, Tenerife).

April 1998, April 1999. Intercomparison Workshop on Evapotranspiration from Remote Sensing. Sponsored by Int. Water Man. Inst., **Menemen, Turkey** and **Wageningen, Netherlands**.

April-May 1998. Three week lecturer at Katholic University of Leuven**, Leuven, Belgium**.

November 1994. **Cairo, Egypt**. Int. Expert Panel on Irrigation Research. (UN-FAO)

September 1993. **Rabat, Morocco**. Review of irrigation research program of Inst. Agronomique et Veterinaire Hassan II. (USAID).

April - May 1992. **Sana'a, Yemen**. Senior Irrigation Specialist for simulation of groundwater recharge and extraction. (UNDP).

March - April 1991. Central Soil Salinity Research Institute, **Karnal, India**. Designed and installed two precision, electronic weighing lysimeter systems (2m x 2m x 2m) for evapotranspiration research and installed associated weather and data acquisition equipment. (FAO/UNDP).

May - June 1990. Participation in 12-Member Panel of International Expert Consultants on Crop Water Requirements, UN-FAO, **Rome, Italy**, revision of FAO publication ID-24.

May 1990 & Aug 1991. **Amman, Jordan**. Irrigation specialist and advisor to Jordan Ministry of Water and Irrigation on National Water Development Plan. (UNDP)

Nov. - Dec. 1989. **Peshawar, Pakistan**. Conducted a 4 week training course on irrigation principles and design (USAID).

July - Sept. 1988. **Lahore, Pakistan**. Conducted 3 week training course in Irrigation Scheduling Research. (US-AID ISM/R, Univ. Idaho)

Nov. - Dec. 1988. Central Soil Salinity Research Institute, **Karnal, India**. Instructed training course in Water Management Research. (FAO/UNDP)

NATIONAL PROGRAM REVIEWS:

2013, 2010, 2004, 2002, 2000, 1999, 1998. **Centro de Estudos de Engenharia rural (CEER) (Center for Agricultural Engineering Research)**. Instituto Superior de Agronomia, Universidade Téchica de Lisboa. Research Program Review, Lisbon, Portugal.

2008. National Programme on Remote Sensing of Evapotranspiration, **South Africa**.

February, 1999. **National Science Foundation**. Review and Site Visit, Center for Excellence in Hydrology of Arid Lands, Univ. Arizona Dept. Hydrology. Tucson, AZ.

October, 1994. **National Irrigation Water Management Program of Spain**. National Research Program Review and Site Visits (Zaragoza, Valencia, Badajoz, Tenerife).

PROFESSIONAL TASK COMMITTEES:

ASCE Task Committee on Remote Sensing of Evapotranspiration. 2012-2019.

ASCE Task Committee on Standardization of Calibration and Usage of Neutron Moisture Profile Gauges. Chair, and Vice-Chair. 1992 – 1998.

ASCE Task Committee on Standardization of Calculations for Reference Evapotranspiration. Vice-Chairman. 1999 - 2004.

ASCE Task Committee on Crop Coefficients. Vice-Chairman. 2004 - 2011.

FORMAL UNIVERSITY COURSES TAUGHT:

Engineering Hydrology (Iowa State University)
Water Resources Planning (Iowa State University)
Water Management (Utah State University)
Irrigation Engineering Principles (Utah State University)
Sprinkle and Trickle Design (Utah State University)
Physical Properties of Biological Materials (Utah State University)
Modeling Biological Systems (Utah State University)
Freshman Biological Engineering Seminar (Utah State University)

TOP FIVE SOFTWARE DEVELOPMENTS:

Allen, R.G. 1999, 2000, 2011, 2017. REF-ET Standard Reference Evapotranspiration computer model, Windows Version: User's Manual. University of Idaho, Research and Extension Center, Kimberly, ID 83341, 70 p.

Allen, R.G., M. Tasumi, R. Trezza, J. Kjaersgaard. 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009, 2010, 2011, 2013, 2016. METRIC Evapotranspiration from Satellite – User's Manual.

Allen, R.G. and C.W. Robison. 2007-2017. ETIdaho Crop Evapotranspiration Calculation for the State of Idaho. Visual Basic code for calculating daily ET for approximately 120 weather stations in Idaho for periods of record. Univ. Idaho, Kimberly, Idaho.

Allen, R.G. and J. Huntington. 2009-2013. ETNevada Crop Evapotranspiration Calculation for the State of Nevada. Visual Basic code for calculating daily ET for approximately 100 weather stations in Nevada for periods of record. Univ. Idaho, Kimberly, Idaho and Desert Research Institute/Nevada Office of the State Engineer.

Allen, R.G. 2011-2014. ET Calculation code for the USBR Penman-Monteith (PM) Model (also referred to as the ET-Demands model). Visual Basic code for calculating daily ET for extended time periods over large regions using weather station data. The ET calculation code has been incorporated with a graphical interface by the US Bureau of Reclamation, Denver Technical Center.

PROFESSIONAL AWARDS:

(in reverse chronological order)

The **2016 Irrigation Association Person of the Year Award** for "*Outstanding contributions toward the acceptance of sound irrigation practices*"

The U.S. Dept. Interior / NASA ***William T. Pecora Award.*** **Nov. 2014** *to the* ***Landsat Science Team*** *for their contributions to study of Earth's land surface and coastal regions, and meeting the challenge of continuing and advancing the Landsat legacy of observations. Mission performance has exceeded expectations, providing more imagery, higher quality measurements, and new capabilities over previous missions.*

Outstanding Faculty Award, College of Engineering, University of Idaho. **May 2010. University of Idaho. *"For his exemplary contributions to research"***

***Innovations in American Government Award*, 2009, Ash Center for Democratic Governance and Innovation of the Harvard Kennedy School of Government, Harvard University.** *Mapping Evapotranspiration*. Award shared by the University of Idaho and Idaho Department of Water Resources. http://ash.harvard.edu/Home/News-Events/Press-Releases/Innovations/Mapping-Evapotranspiration-Wins-Innovations-Award

Best Paper Award, Am. Society Civil Engineers, Journal of Irrigation and Drainage Engineering. 2009. *(Satellite-based energy balance for mapping evapotranspiration with internalized calibration (METRIC) –I. Model, II. Applications*, R.G. Allen and others, 2007, 133(4):380-406*).* *http://www.kimberly.uidaho.edu/water/papers/remote/ASCE_JIDE_Allen_et_al_METRIC_model_2007_QIR000380.pdf*

ASCE 2005 Arid Lands Hydraulic Engineering Award, *"For his research on conjunctive management of groundwater and surface water, evapotranspiration and irrigation systems operation and design in arid lands"* May 18, 2005.

Founding Diplomate, American Academy of Water Resources Engineers, EWRI 2005

ASCE Task Committee Excellence Award: Task Committee on Standardization of Reference evapotranspiration. *"For excellence and diligence in producing a national standardization for the calculation of reference evapotranspiration that will advance engineering practice and water resources management."* May 18, 2005.

Distinguished Service Award, College of Engineering, Utah State University, 2004

ASCE 2003 Royce J. Tipton Award, *"For outstanding contributions to irrigation engineering through system simulation, software development, teaching, and research and for advancements in the knowledge of evapotranspiration theory and concepts for world-wide application"* May 12, 2003.

United States Committee on Irrigation and Drainage 'USCID Service to the Profession Award,' *"In Recognition of a distinguished career in water resources engineering and education and for exceptional contributions to the irrigation and drainage profession."* May 15, 2003.

Best Paper Award, Am. Society Civil Engineers, Journal of Hydrologic Engineering. 1999. *(Translating Wind Measurements from Weather Stations to Agricultural Crops*, **R.G. Allen** and J.L. Wright, 1997, 2(1): 26-35*).* *http://www.kimberly.uidaho.edu/water/papers/evapotranspiration/Weather%20ET/Allen_Wright_1997_ASCE_JIDE_Translating_wind_measurements_from_weather_stations.pdf*

Innovation and Excellence in Teaching Award, Dept. Biological and Irrigation Engineering, Utah State University, 1998

Top Professor Award, Utah State University Mortar Board. 1998

Best Reviewer Award, Am. Society Civil Engineers, Journal Irrig. Drain. Engineering. 1997

Outstanding Journal Paper Award, American Society of Civil Engineers, Journal of Irrigation and Drainage Engineering. 1997. (*Assessing Integrity of Weather Data for use in Reference Evapotranspiration Estimation,* **R.G. Allen**, 1996, 122(2):97-106).

Outstanding Researcher Award, Dept. Biological and Irrigation Engineering, Utah State University, 1996

Excellence in Research Award, College of Engineering, Utah State University, 1996

Outstanding Service Award, American Society of Civil Engineers, 1994

ASCE State-of-the-Art of Civil Engineering Award, Am. Society Civil Engineers, 1992

Excellence in Teaching Award, Dept. Biological and Irrigation Engineering, Utah State University, 1992
Outstanding Journal Paper Award, Am. Society Civil Engineers, Journal of Irrigation and Drainage Engineering. 1987. (*A Penman for All Seasons,* R.G.Allen*,* 1986, 112(4):348-368)*.*

JOURNAL EDITORIAL BOARDS:

2001 - present. Editorial Board, *Irrigation and Drainage Systems* **Kluwer**, Dordrecht.
2002 - present. Editorial Board, *Irrigation Science* Springer-Verlag, Heidleberg.
2003 - present. Editorial Board, *Agricultural Water Management.* Elsevier, Amsterdam.

BOOKS/CHAPTERS/EDITED PROCEEDINGS

Influence of Landsat Revisit Frequency on Time-Integration of Evapotranspiration for Agricultural Water Management. In Evapotranspiration. 2018. Trezza, R., Allen, R.G., Kilic, A., Ratcliffe, I. and Tasumi, M., 2018. IntechOpen**.**

Evaporation, Evapotranspiration and Irrigation Water Requirements. ASCE Manuals and Reports on Engineering Practice No. 70, 2nd Edition. M.E. Jensen and **R.G. Allen** (ed). 2016. American Society of Civil Engineers. 782 p.

Operational Remote Sensing of ET and Challenges. Irmak, A., **R.G. Allen**, J. Kjaersgaard, J. Huntington, B. Kamble, R. Trezza, and I. Ratcliffe. 2011. Chapter in *Evapotranspiration* (A. Irmak, editor), Publisher: InTech (on-line).

Irrigation Water Requirements. 2011. **R.G. Allen**, T.A. Howell and R.L. Snyder. Chapter 5, p. 93-172 in *Irrigation*, sixth edition, L.E. Stetson and B.Q. Mecham (ed.), Irrigation Assoc., Falls Church, VA.

Hydraulics of Irrigation Systems. 2011. R.E. Sneed and R.G. **Allen**. Chapter 7, p. 216-270, in *Irrigation*, sixth edition, L.E. Stetson and B.Q. Mecham (ed.), Irrigation Assoc., Falls Church, VA.

Water Requirements for Irrigation and the Environment. 2009. M.G. Bos, R.A.L. Kselik, **R.G. Allen**, D. Molden. Springer., ISBN: 978-1-4020-8947-3. 6 chapters and 170 pages.

Thermal Remote Sensing: Theory, Sensors and Applications. Quattrochi, D.A., A. Prakash, M. Eneva, R. Wright, D.K. Hall, M. Anderson, W.P. Kusta, **R.G. Allen**, T. Pagano, and M.F. Coolbaugh. 2008. Chapter 3 in *Earth Observing Platforms & Sensors - Manual of Remote Sensing, 3rd Edition, Volume 1.1*: 81 pages.

Chapter 8 ***"Water Requirements,"*** by **Allen, R.G.**, J.L. Wright, W.O. Pruitt, L.S. Pereira, M.E. Jensen. 2007. in *Design and Operation of Farm Irrigation Systems,* American Society of Agricultural Engineers. pages 208-297.

Chapter 5 *"An Energy Balance Approach to Computing and Mapping Evapotranspiration,"* in *Advances in Water Science Methodologies*, (ed.) U. Aswathanarayana, Taylor and Francis, The Netherlands. Allen, R.G., A. Morse, M. Tasumi, W.J. Kramber and W.G.M. Bastiaanssen. 2005.

The ASCE Standardized Reference Evapotranspiration Equation. ASCE Press, ISBN: 078440805X, Stock No: 40805. **Allen, R.G.**, Walter, I.A., Elliot, R.L., Howell, T.A., and Itenfisu, D. (Ed.). 2005. 216 p. http://www.kimberly.uidaho.edu/water/asceewri/

Crop Evapotranspiration: Guidelines for Computing Crop Water Requirements. United Nations FAO, Irrigation and Drainage Paper 56. **Allen, R.G.**, L.S. Pereira, D. Raes, and M. Smith. 1998. Rome, Italy. 300 p. http://www.fao.org/docrep/X0490E/X0490E00.htm

Section 1.5.1 ***"Crop Water Requirements"*** of the CIGR (International Association of Agricultural Engineers) ***Handbook of Agricultural Engineering***, Vol. I: Land and Water Engineering. L.S. Pereira and **R.G. Allen**. 1998. p. 213-262.

Center Pivot Design. **R.G. Allen**, J. Keller, and D. Martin. 1998, 2000 (rev). Design textbook, Irrigation Association. 303 p.

Chapter 4 ***"Evaporation and Transpiration"*** in ASCE ***Hydrology Handbook***. New York, NY. **Allen, R.G.**, Pruitt, W.O., Businger, J.A., Fritschen, L.J, Jensen, M.E., and Quinn, F.H., p. 125-252, 1996.

Crop-Water-Simulation Models in Practice. Pereira, L.S., B.J. van den Broek, P. Kabat, and **R.G. Allen**. (eds.) 1995. Wageningen Press, Wageningen, The Netherlands. ISBN 90-74134-26-2. Hardbound. 339 p.

Management of Irrigation and Drainage Systems: Integrated Perspectives. **Allen, R.G.** and C.M.U. Neale. 1993. (Editors). Proceedings ASCE National Conference on Irrigation and Drainage Engineering. ISBN 0-87262-919-8, 1204 p.

Lysimeters for Evapotranspiration and Environmental Measurements, Proceedings ASCE International Symposium on Lysimetry, Honolulu, HA, **Allen, R.G.**, et al., July 23-25, 1991. ISBN 0-87262-813-2, 444 p.

Evapotranspiration and Irrigation Water Requirements, ASCE Manuals and Reports on Engineering Practice No. 70. M.E. Jensen, R.D. Burman and **R.G. Allen**. (eds.) 1990. ISBN 0-87262-763-2, 332 p.

Publication H-Index:

H-Index = 40 for cited publications by R. Allen on Web of Science, Jan. 2018, meaning 40 publications have been cited 40 or more times each. 80 publications have been cited more than 10 times each, with a total of 6280 citations. When the 2998 FAO-56 publication is included, with 9680 citations, the total number of citations is 15,960.

Idaho Completion Report subitted to United States Forest Service, December, 2011.

Trezza, Ricardo, **Richard Allen**, Eric Kra and C.W. Robison. 2012. Final Report on the Production of Evapotranspiration Maps for Year 2008 from Landsat Images for the Eastern Snake Plain Region of Southern Idaho with the METRIC Model. Report submitted to Idaho Department of Water Resources by the University of Idaho.

Trezza, Ricardo, **Richard Allen**, Jeremy Greth, and C.W. Robison. 2015. Report on the Calibration of Evapotranspiration Maps from Landsat Images for the Eastern Snake Plain Region, Paths 39 and 40, Idaho for Year 1992 using the METRIC Model. Report submitted to Idaho Department of Water Resources by the University of Idaho.

Kelly, Carlos, Jeremy Greth, Ricardo Trezza, **Richard Allen**, and C.W. Robison. 2015. Report on the Production of Evapotranspiration Maps from Landsat Images for the Eastern Snake Plain Region, Paths 39 and 40, Idaho for Year 2011 using the METRIC Model. Report submitted to Idaho Department of Water Resources by the University of Idaho

Trezza, Ricardo, Jeremy Greth, **Richard Allen**, and C.W. Robison. 2016. Report on the Production of Evapotranspiration Maps from Landsat Images for the Eastern Snake Plain Region, Paths 39 and 40, Idaho for Year 1986 using the METRIC Model. Report submitted to Idaho Department of Water Resources by the University of Idaho.

Kelly, Carlos, Ricardo Trezza, **Richard Allen**, and Mr. Clarence Robison. 2016. Report on the Production of Evapotranspiration Maps from Landsat Images for the Eastern Snake Plain Region, Paths 39 and 40, Idaho for Year 2013 using the METRIC Model. Report submitted to Idaho Department of Water Resources by the University of Idaho

Trezza, Ricardo, C.W. Robison, C. Kelly and **Richard Allen**. 2016. Report on the Production of Provisional Near-Real-Time Evapotranspiration Maps using the METRIC Model for the Eastern Snake Plain Region, Idaho April-October 2016. Report submitted to Idaho Department of Water Resources by University of Idaho, Kimberly, Idaho

Evapotranspiration Plus. 2014. Production of Satellite-based Maps of Evapotranspiration using the METRIC[tm] Model for Year 2008 in the Rio Grande Area of Texas, Landsat Path 32 Rows 38 and 39. Completion Report by Evapotranspiration Plus (ET+), Submitted to Davids Engineering, Davis, California, May 1, 2014. 89 p.

Evapotranspiration Plus. 2017. Production of Satellite-based Maps of Evapotranspiration for Year 2002 in the Rio Grande Area of New Mexico and Texas, Landsat Paths 32 and 33, Rows 37, 38 and 39 using the METRIC[tm] Model. Completion Report by Evapotranspiration Plus (ET+). Submitted to Davids Engineering, Davis, California, March 2017. 81 p.

Evapotranspiration Plus. 2017. Production of Satellite-based Maps of Evapotranspiration for Year 2013 in the Rio Grande Area of New Mexico and Texas, Landsat Paths 32 and 33, Rows 37, 38 and 39 using the METRIC[tm] Model. Completion Report by Evapotranspiration Plus (ET+) submitted to Davids Engineering, Davis, California, March 2017. 115 p.

Robison, C.W., R. Trezza, **R.G. Allen**, B. Urie and J. Stewart. 2018. Report on the Production of Near-Real-Time Evapotranspiration Maps using the METRIC Model for the Eastern Snake Plain Region, Idaho April -- October 2017 – Final report submitted to Idaho Department of Water Resources by University of Idaho, Kimberly, Idaho

Robison, C.W., R. Trezza, **R.G. Allen**, and B. Urie. 2019. Report on the Production of Near-Real-Time Evapotranspiration Maps using the METRIC Model for the Eastern Snake Plain Region, Idaho April -- October 2018 – Final report submitted to Idaho Department of Water Resources by University of Idaho, Kimberly, Idaho

W. Zhao, **R.G. Allen**, C.W. Robison, Q. Huang and R. Trezza. 2018. Report on the Production of Evapotranspiration Maps using the METRIC^{tm} Model for the Treasure Valley Region, Idaho -- March -- October 2007. Report submitted to Idaho Department of Water Resources

RECENT PRESENTATIONS

Allen, R.G. June 2018. Status on METRIC applications with ECOSTRESS thermal data. ECOSTRESS annual meeting, Cape Canaveral, Florida.

Allen, R.G. and A. Kilic. Sept. 2018. Production of Spatial Water Consumption via the Web. New Mexico Water Law Conference, Santa Fe, NM.

Allen, R.G. Nov. 2018. Evapotranspiration tools – METRIC and EEFlux with applications in the USA. Invited speaker at Graduate Student Seminar, Guangxi Teachers Education University, Nanning, China.

Allen, R.G. Nov. 2018. Hydrological Impacts of Water Conservation in Irrigation. International Meeting on Precision in Agriculture and Remote Sensing. Chinese Academy of Science, Shijiazhuang, China.

Allen, R.G. Dec. 2018. Developing maps of Water Consumption in Idaho. Annual Meeting of the Idaho Farm Bureau, Boise, Idaho.

Allen, R.G. Dec. 2017. Evapotranspiration mapping for water management – METRIC and EEFlux applications in the USA. Invited keynote presentation at the 2017 Silk Road Innovation Forum on Surveying, Remote Sensing and Geographical Information Sciences (IFSRG), Xi'an, China.

Allen, R.G. Dec. 2017. The University of Idaho METRIC ET mapping process and Google EEFlux – model and applications. Seminar presented to the Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China.

Allen, R.G., A. Kilic and R. Trezza. Nov. 2017. The METRIC model for surface energy balance-derived ET from Landsat imagery and the importance of calibration and accuracy for water management in operational agricultural decision-making. Annual Meeting of the American Society of Agronomy, Tampa, FL. Invited Speaker, with abstract.

Allen, R.G. and A. Kilic. Oct. 2017. Google Earth Engine App for Residential Water Use and Preservation --- GEARUP ---. International Conference on Innovations in Irrigated Agriculture, Fortaleza, Brazil. Invited Speaker.

Kilic, A. and **R.G. Allen**. Oct. 2017. Google Earth Engine Evapotranspiration Flux --- EEFlux: - Application, Parameterization, Accuracy, Challenges and Successes. International Conference on Innovations in Irrigated Agriculture, Fortaleza, Brazil. Invited Speaker.

Allen, R.G. and W. Zhao. August 2017. METRIC results for the Treasure Valley Region. Presentation to the Treasure Valley Groundwater Modeling Committee. IDWR, Boise.

Allen, R.G. and A. Kilic. July 2017. Status Update on EEFlux Google Application. Presentation to the Landsat Science Team, Sioux Falls, SD.

Allen, R.G. and C.W. Robison. July 2017. Status on ETIdaho Update. Presentation to the Eastern Snake River Plain Hydrologic Modeling Committee. IDWR, Boise.

Allen, R.G., June 2017. METRIC, SEBAL and Google EEFlux Models for Spatial Evapotranspiration at the Field Scale. New Mexico Conference on Evapotranspiration, Las Cruces, NM. Invited Speaker. With Abstract.

Allen, R.G. and A. Kilic. May 2017. ECOSTRESS METRIC Evapotranspiration Algorithm. ECOSTRESS Science Team meeting, Davis, CA. Invited Speaker.

Allen, R.G., C. Robison, A. Kilic, and R. Trezza. 2016. A Technique to Retain Original Georegistration Accuracy of VIIRS Imagery for use at Landsat Scales. Presentation to the Landsat Science Team, January 12-14, 2016, Blacksburg, VA. (invited)

Allen, R.G., A. Kilic and J. Huntington. 2016. METRIC/EEFlux - Application, Parameterization, Accuracy, Challenges, Successes. Presentation at the Remote Sensing of Evapotranspiration Workshop, Davis, CA, February 10, 2016. (invited)

Allen, R.G., A. Kilic and J. Huntington. 2016. METRIC/EEFlux - Application, Parameterization, Accuracy, Challenges, Successes. Presentation at the Remote Sensing of Water Consumption Workshop for Philanthropic Organizations, Technology Companies, and Key Decision Makers. NASA Ames, Mountain View, CA, March 24-25, 2016. (invited)

Allen, R.G. and A. Kilic. 2016. Landsat-based (Field-Scale) Evapotranspiration Estimates - METRIC Overview and Applications. Seminar presented to the NASA Applied Remote Sensing Training Program (ARSET) -- SMAP and ET Applications Webinar series, September 22, 2016. (invited)

Allen, R.G. and M.E. Jensen. 2016. ASCE Manual on Evapotranspiration. USCID 9th International Conference on Irrigation and Drainage, October 11-14, 2016, Fort Collins, CO. (invited)

Allen, R.G. and A. Kilic. 2016. EEFlux: Google Earth Engine ET — ET Maps for the Public — Current Status. USCID 9th International Conference on Irrigation and Drainage, October 11-14, 2016, Fort Collins, CO. (invited)

Allen, R.G. Adapting Crop Coefficients for Local Conditions. USCID 9th International Conference on Irrigation and Drainage, October 11-14, 2016, Fort Collins, CO. (invited)

Allen, R.G. and A. Kilic, Applications of Remote Sensing for Evapotranspiration in the USA at Landsat Spatial Scales for Agricultural Water Management and to Support Climate Change Research Univ. Talca, Chile, Water Resources Seminar Series. Invited Speaker, Jan. 2014.

Allen, R.G. Remote Sensing for Evapotranspiration in Idaho at Field Spatial Scales for Agricultural Water Management. Idaho Agricultural Appraisers Meeting, Twin Falls, ID, Feb. 2014 Featured Speaker.

Allen, R.G. and R. Trezza. Determining Evapotranspiration Coefficients (Crop Coefficients) from Satellite-based Energy Balance, INOVAGRI International Innovations in Irrigation Conference, Fortaleza, Brazil. Invited Speaker. April 2014.

Kilic, A., **Allen, R.G.** and J. Huntington. Landsat Energy Balance in Managing Water Consumption. Landsat Science Team meeting. EROS Center, USGS, Sioux Falls. July 2014

Allen, R.G. ECOSTRESS METRIC Evapotranspiration Algorithm, HyspIRI TQ3 Science Support. HyspIRI Science Meeting, Jet Propulsion Lab, Pasadena, CA, Oct 2014.

Where the Water Goes: Retrieving Evapotranspiration from Landsat's Thermal Imager. GIS Day, Univ. Idaho, Moscow, ID. Invited Speaker, Nov. 2014.

Hendrickx, J.; Umstot T.; Stephens, D.; Wilson, J.; **Allen, R**.; Trezza, R. Remote sensing of soil water storage capacity using the LANDSAT and MODIS Images archive, 2014. AGU-Fall Meeting. San Francisco, 15-19 December 2014,

Geli, H; Neale, C.; Verdin, J.; Senay, G.; **Allen, R**.; Trezza, R.; Ershadi, A.; McCabe, M.; Elhaddad, A.; Yan, Y.; Anderson, M. Intercomparison of remote sensing models for estimating daily and seasonal evapotranspiration. 2014. AGU-Fall Meeting. San Francisco, 15-19 December 2014

Allen, R.G. and Trezza, R. The application of METRIC in the Palo Verde Irrigation District. USU/USGS Workshop on Estimating Crop Water Use with Remote Sensing. 2014. June 31th. USGS/USU Intercomparison of Remote Sensing of ET Workshop. Department of Civil and Environmental Engineering. Logan, Utah.

Allen, R.G. 2008. Evapotranspiration from Satellite. CSIR of South Africa. Pietermaritzberg and Stellenbosch. October 2008.

Allen, R.G. 2009. Water Science and Research Issues associated with the Future of Water for Food. Featured speaker in Water for Food: First Annual International Conference. Lincoln, Nebraska, May, 2009.

SOFTWARE DEVELOPMENT

Allen, R.G. 1988, 1991. IRRISKED irrigation scheduling computer model user's manual. Dept. Biol. and Irrig. Engrg, Utah State University, 189 p.

Allen, R.G. 1989-92. CATCH-3D sprinkler catch-can overlap computer model user's manual. Dept. Biol. and Irrig. Engrg, Utah State University, 25 p.

Allen, R.G. 1989, 1991. REF-ET Standard Reference Evapotranspiration computer model user's manual. Dept. Biol. Irrig. Engrg, Utah State University, 40 p.

Allen, R.G. 1989. USU-PIVOT Center Pivot nozzle selection and simulation user's manual. Dept. Agr. and Irrig. Engrg, Utah State University, 8 p.

Andrade, C. and **Allen, R.G.** 1997. SPRINKMOD: Sprinkler pipe network hydraulic simulator for Windows. Dept. Biol. Irrig. Engrg. Utah State University. 50 p.

Andrade, C. and **Allen, R.G.** 1997. PUMPCOM: Multiple pump combination program for Windows. Dept. Biol. Irrig. Engrg. Utah State University, Logan, UT. 20 p.

Allen, R.G. 1999, 2000, 2011, 2016. REF-ET Standard Reference Evapotranspiration computer model, Windows Version: User's Manual. University of Idaho, Research and Extension Center, Kimberly, ID 83341, 70 p.

Allen, R.G., M. Tasumi, R. Trezza, J. Kjaersgaard. 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009, 2010, 2011. METRIC Evapotranspiration from Satellite – User's Manual.

Allen, R.G. and C.W. Robison. 2007-2013. ETIdaho Crop Evapotranspiration Calculation for the State of Idaho. Visual Basic code for calculating daily ET for approximately 120 weather stations in Idaho for periods of record. Univ. Idaho, Kimberly, Idaho.

Allen, R.G. and J. Huntington. 2009-2013. ETNevada Crop Evapotranspiration Calculation for the State of Nevada. Visual Basic code for calculating daily ET for approximately 100 weather stations in Nevada for periods of record. Univ. Idaho, Kimberly, Idaho and Desert Research Institute/Nevada Office of the State Engineer.

Allen, R.G. 2011-2014. ET Calculation code for the USBR Penman-Monteith (PM) Model (also referred to as the ET-Demands model). Visual Basic code for calculating daily ET for extended time periods over large regions using weather station data. The ET calculation code has been incorporated with a graphical interface by the US Bureau of Reclamation, Denver Technical Center.

Ph.D. Students Supervised as Major Professor

Name	Date of Degree	Dissertation Title
Carlos Hernandez-Yanez	1990	A time-series-based planning model for management of grass and beef production
Paul Vanderkimpen	1991	Estimation of crop evapotranspiration by means of the Penman-Monteith equation
Majid Mirlatifi	1991	Quantification of aerodynamic and canopy resistance terms for estimating reference evapotranspiration
Wigdan Ahmad	1991	Evaporation and transpiration as related to subsurface flow
John Prueger	1992	Evapotranspiration from isolated stands of hydrophytes: cattail and bulrush
Camilo Andrade	1997	Pressure and discharge distribution simulation in pressurized irrigation systems
Daniel Itenfisu	1997	Direct application of resistance-based evapotranspiration methods to row crops
Ricardo Trezza	2002	Evapotranspiration using a satellite-based surface energy balance with standardized ground control
Masahiro Tasumi	2003	Progress in operational estimation of regional evapotranspiration using satellite imagery
Maria Gloria Romero	2003	Daily evapotranspiration estimation from instantaneous values by means of evaporative fraction and reference evapotranspiration fraction
Ramesh Dhungel	2014	Interpolation between satellite overpass dates using the Penman-Monteith method

M.S. Students Supervised as Major Professor

Name	Date of Degree	Thesis Title
Mohammed Al-Thamary	1987	Evaluating irrigation uniformity of a side roll sprinkler system under various catch can spacings
Shadab Shadzad	1988	Estimation of weather parameters required in evapotranspiration calculations
Hossein Moazami	1988	Infiltration rate and times of ponding under a rainfall sprinkler simulator and double ring infiltrometer
Daniel Segura	1989	Effect of the microenvironment on soil-moisture determination by a neutron moisture meter
Joao Costa	1989	The irrigation design toolbox computer application
Gerald Fernandez	1989	Development of a computer model for diagnostic analysis of sprinkler and pumping systems
Naglaa Eid	1990	Evaluation of the Shany method for estimating the hydraulic properties of soil
D. Ken Fisher	1990	Evaluating performance of electronic weighing lysimeters
Walkyria Gonzalez	1991	Runoff and uniformities under gridded sprinkler systems

Eugenia Molina	1991	Simulation model to predict operating pressures and flow rates for a sprinkler system in operation
Luis Olivarez	1991	Refinement of computer software for hydraulic analysis of sprinkle irrigation systems
Abdulhadi Alghori	1992	Development of insulative covers for surface mounted lysimeter load cells
Bekele Temesgen	1995	Temperature and humidity data correction for calculating reference evapotranspiration at nonreference weather stations
Shrikanth Vemulapali	1996	Wetland evapotranspiration (nonthesis opt.)
Yaseen Al-Mula	1997	Interactive software for design of laterals and tapered manifolds for trickle irrigation systems
Christopher Bright	2001	Evapotranspiration from wetland communities (did not complete)
Patrick Ferrell	2004	Impacts of reservoir level change on landslope stability in the Hagermann National Monument, Idaho
Brock Dillé	2004	Impacts of irrigation and ground-water on spring flows and landslope stability in the Hagermann National Monument, Idaho
Boyd Burnett	2007	Influence of evaporation from soil during estimation of evapotranspiration from vegetation indices
Bibha Dhungara	2012	A look at conditioning of arid weather data - nonthesis
John Stewart	2016	QAQC of energy balance fluxes from pine forest and grasslands and comparisons with satellite-based retrievals.

Table of Contents

Introduction

I, Scott A. Miltenberger, Ph.D., am a partner at JRP Historical Consulting, LLC (JRP), located at 2850 Spafford Street, Davis, California. This expert report was prepared by me for Somach Simmons & Dunn, attorneys representing the State of Texas before the Supreme Court of the United States in *State of Texas v. State of New Mexico and State of Colorado*, No. 141, Original. I have been asked to provide opinions on the following questions regarding the Rio Grande Compact of 1938 and its historical interpretation:

1. What was the purpose of the 1938 Rio Grande Compact?
2. Did the amount of water apportioned to Texas by the 1938 Rio Grande Compact include water to address water quality concerns on Rio Grande Project lands in Texas?
3. What comprised the water supply for the Rio Grande Project, circa 1938?
4. What did delivery of water by the State of New Mexico to San Marcial, under the terms of the 1938 Rio Grande Compact, constitute?
5. Did the 1938 Rio Grande Compact limit the uses to which water in the Upper Rio Grande Basin could be put?
6. Did the Special Master fairly describe the background history leading to the 1938 Rio Grande Compact on pages 31 through 187 and 203 through 209 of the *First Interim Report of the Special Master*, dated February 9, 2017?

In addressing these questions, I have relied upon my education and nearly 13 years of experience as a professional historian, primarily of western water and land use, as well as my review and analysis of archival documents, published sources, and academic monographs. Together with my former business partner (now retired) Mr. Stephen Wee and JRP staff under my direction (all of whom possess graduate degrees in history), I undertook research and collected historical material from a number of federal, state, and local repositories. These include: the National Archives in Washington, DC, at College Park, Maryland, at Denver, Colorado, and at Fort Worth, Texas; the Dolph Briscoe Center for American History at The University of Texas at Austin; the Texas State Archives in Austin; the C.L. Sonnichsen Special Collections Department of the University of Texas at El Paso; the El Paso Historical Society; the New Mexico State Archives in Santa Fe; the University of New Mexico Special Collections in Albuquerque; the New Mexico State University Archives and Special Collections in Las Cruces; History Colorado (formerly the Colorado Historical Society) in Denver; the Water Resource Archives at Colorado State University, Fort Collins; the American Heritage Center at the University of Wyoming in Laramie; the Water Resources Collections and Archives at the University of California, Riverside; and the Harvard Law School Library, Historical and Special Collections, in Cambridge, Massachusetts. I also examined documents produced by the states of Texas, Colorado, and New Mexico, and the United States in this action as well as the materials appended to the *First Interim Report of the Special Master*.

Initial review of these documents was a collaborative effort between Mr. Wee and myself, but I am the sole author of this expert report. My current (as of May 31, 2019) resume is included in the **Appendix** to this report.

My compensation for this matter is $154 per hour for time spent in research, analysis, and preparation of this expert report. My compensation for deposition and trial testimony is $308. A list of cases for which I have provided expert testimony at deposition or trial over the past four years is included in my resume, along with a list of my publications in the previous 10 years.

As indicated above, I have based my opinions on primary and secondary sources known to me, gathered by me or those under my direction, or produced in this action. Those sources are cited in the history profession's preferred footnote citation format as detailed in the *Chicago Manual of Style*. There are other documents that support my opinions which are not cited herein. In the interests of brevity and to avoid repetition, I have chosen to discuss the historical evidence that most directly informs my responses to the questions posed to me. If any other historical material is presented or made known to me, or if I review any additional documents, it may have some effect on the specific opinions offered herein.

Opinion I: The purpose of the 1938 Rio Grande Compact was to protect the water supply of the federal Rio Grande Project while making possible new water developments in Colorado and New Mexico above the project's Elephant Butte Reservoir by equitably apportioning the waters of the Upper Rio Grande Basin among the states of Colorado, New Mexico, and Texas.

Since the 1880s, the Rio Grande had been a source of international and interstate conflict with the US and Mexico, and Colorado, New Mexico, and Texas each making claims to the river's waters. The Rio Grande Project, authorized in 1905, offered a partial solution by delivering water via its Elephant Butte Reservoir to Mexico under the terms of a 1906 treaty, and to lands in southern New Mexico and western Texas that had been deprived by upstream diversions near the river's headwaters. The so-called Rio Grande "embargo," enacted to prevent further upstream diversions from inflaming international tensions until a settlement with Mexico could be negotiated, supported the project's development into the 1920s yet restricted further utilization of the Rio Grande above Elephant Butte. Revocation of the embargo in 1925 created momentum for the negotiation of a tristate compact, with Colorado seeking the opportunity to develop its own water resources projects comparable to the Rio Grande Project. Texas and New Mexico, while not entirely opposed to Colorado, nonetheless sought to safeguard not only the water necessary for the federal reclamation project but also for Texas, the water necessary for lands down to Fort Quitman. Texas and New Mexico's subsequent dispute over the Middle Rio Grande Conservancy District's proposed development above Elephant Butte created further urgency for a compact in the mid-1930s and precipitated the federal Rio Grande Joint Investigation. With data gathered by federal engineers, the engineering advisors for three states recognized that in the absence of additional water being imported into the Upper Rio Grande Basin the usable water supply was limited. They therefore devised two water delivery schedules that became the foundation for the compact – one for Lobatos, near the Colorado-New Mexico state line, and another for San Marcial, above Elephant Butte Reservoir. These schedules were intended to enable water resource development in Colorado and New Mexico above Elephant Butte Reservoir without compromising the Rio Grande Project and the supply of water to lands in Texas above Ft. Quitman.

The limited availability of usable water in the Upper Rio Grande Basin spawned the international and interstate problem of equitable distribution of the Rio Grande waters. The basin is an area of approximately 34,000 square miles that stretches from the headwaters of the Rio Grande in the San Juan Mountains in Colorado southward through the narrow Rio Grande Valley in New Mexico and then southeast to Fort Quitman, Texas. Historically, it has been divided into three smaller sections: the San Luis Valley in Colorado; the Middle Rio Grande Valley between the Colorado-New Mexico state line and San Marcial, New Mexico; and the Elephant Butte-Ft. Quitman section that encompasses the area between Elephant Butte Reservoir and Ft. Quitman (roughly 80 miles downstream from El Paso).

At nearly 2,000 miles long, draining approximately 175,000 square miles before debouching into the Gulf of Mexico, the Rio Grande is the principal river within the basin. Ft. Quitman has long been recognized as a natural dividing point on the river's course. Above Ft. Quitman, nearly all of the water supply for the Rio Grande originates in Colorado and New Mexico, and by the early 1930s the river in this stretch was devoted almost entirely to irrigated agriculture. Below Ft. Quitman, numerous arroyos and tributary streams originating in Mexico feed the river for the remainder of its course.[1]

Like most western rivers under natural conditions, the Rio Grande was irregular; sustained periods of minimal or no flow were punctuated by shorter periods of high flows and even flood. Lack of precipitation in the Upper Rio Grande Basin floor historically demanded the use of the river's waters for irrigation. Native Americans in the basin had irrigated from the Rio Grande, its lesser tributaries, and intermittent basin streams long before the Spanish encountered them in the mid-sixteenth century. They cultivated wheat, corn, fruit, and flowers, principally through the use of what the Spanish identified as "acequias," or community ditches. The most historically significant of these was the so-called "Acequia Madre" located in present-day Ciudad Juarez opposite El Paso, Texas. This large diversion, which could be more than four centuries old in origin, became the centerpiece of Spanish colonization in the area in the seventeenth century.[2]

Following the signing of the Treaty of Guadalupe Hidalgo in 1848 at the end of the Mexican-American War, American settlers in Colorado's San Luis Valley began irrigating from the river. It was not until the 1880s, however, that considerable development occurred on both sides of the international border established at the Rio Grande. Many of the canal systems that predated the federal Rio Grande Project were constructed during this decade. In the immediate vicinity of Juarez and El Paso, an estimated 550 cubic feet per second (cfs, or second feet) of water was diverted to support irrigated agriculture and burgeoning populations – some 15,000 acres and nearly 10,000 people on the American side, and 25,000 acres and 20,000 people on the Mexican

side. Demands on the river were reportedly still greater upstream. In the Territory of New Mexico nearly 183,000 acres used 5,600 cfs, and in Colorado, roughly 122,000 acres used 3,700 cfs.[3]

As upstream diversions increased, downstream American irrigators in the Mesilla and El Paso valleys and Mexican irrigators in the vicinity of Juarez began to complain of diminished river flows. They focused their ire on Colorado's San Luis Valley, near the Rio Grande's headwaters. The Mexican government took up their citizens' complaints, arguing to the US State Department that the diversions were an abrogation of the 1848 treaty. The dispute lingered over the next decade, and while Congress authorized the president in 1890 to negotiate a resolution with Mexico, the only achievement was the creation of the joint US and Mexican International Boundary Commission (predecessor to the present International Boundary and Water Commission) to address questions of the international boundaries formed by the Rio Grande and Colorado rivers.[4]

The Rio Grande Dam and Irrigation Company's proposed dam in New Mexico ultimately brought decisive action from the US. In early 1895, under the March 3, 1891 federal right-of-way act that granted ditch and canal companies and drainage and irrigation districts a right of way through federal (public domain) lands, the secretary of the interior authorized the company to develop a reservoir site near the mountain peak of Elephant Butte, more than 100 miles upstream from El Paso and Juarez. The company, financed largely by British capital, was led by Dr. Nathan Boyd. Boyd envisioned developing much of the narrow Rio Grande Valley running through New Mexico into small, irrigated farms. When the Mexican government learned of the proposed dam, it renewed its protest. The State Department was unwilling to embrace the view articulated by the attorney general that denied any US "duty or obligation" under the 1848 treaty or international law to see that Rio Grande water reached Mexican ditches. Together with the Mexican foreign minister, Secretary of State Richard Olney directed the boundary commission to investigate the problem further. The boundary commissioners endorsed construction of an "international dam" at El Paso to resolve the international dispute, and warned that Boyd's development imperiled this dam. US commissioner Anson Mills went further, recommending that further applications for rights-of-way to appropriate water on the public domain in the Upper Rio Grande Basin be denied. Olney relayed Mills' recommendation to the Interior Department, and on December 5, 1896, Secretary of the Interior D.R. Francis directed the commissioner of the General Land Office by letter "to suspend action on any and all applications for right of way through public lands for

the purpose of irrigation by using the waters of the Rio Grande River or any of its tributaries in the State of Colorado or in the Territory of New Mexico until further instructed…."[5]

This "embargo," as it came to be known, brought private irrigation development above Elephant Butte, particularly in Colorado, almost to a halt for three decades. The embargo was modified several times, prior to its revocation in 1925. These modifications permitted some rights of way that made possible the appropriation of nearly 115,000 af in Colorado by 1923. Nearly every modification, however, safeguarded the delivery of water to Mexico under the 1906 treaty and the Rio Grande reclamation project, authorized in 1905.[6]

Coloradoans chafed at the embargo's restrictions. San Luis Valley landowners were the most vocal in their condemnation. They insisted that their irrigation works did not impair downstream developments. Valley landowners and their state representatives argued that the embargo violated both the enabling act by which Colorado was admitted to the Union, and the 1891 right-of-way act.

Federal authorities into the 1920s rejected these arguments. They maintained that the enabling act reserved unto the federal government control of public lands within Colorado, and that the secretary of the interior enjoyed "discretion" under the 1891 act to approve or disapprove of right-of-way applications in the "public interest." Congressional authorization of the Rio Grande Project, they further argued, provided "that as a condition precedent to the approval of any application, it must appear clear that the Government project will not be injured thereby."[7]

As controversial as the embargo was within the Upper Rio Grande Basin, it nevertheless fostered settlement of the international dispute between the US and Mexico and development of the Rio Grande Project. In 1897, the federal government moved against Boyd and his company, seeking

to nullify the right-of-way for the private Elephant Butte Dam. Over the next 12 years, federal attorneys and company lawyers argued over whether the river was a navigable waterway; if the Rio Grande was navigable, as US lawyers argued, then the secretary of the interior could not issue a right-of-way under the 1891 act. Twice the US Supreme Court reversed findings made in trial court and affirmed by the New Mexico Territorial Supreme Court that favored the Rio Grande Dam and Irrigation Company, remanding the case back to the lower court. The US changed tactics for the third and final trial. Federal attorneys argued that as five years' time had elapsed for the company to begin construction with no work being done, the right-of-way had expired. Persuaded, the trial court found for the US in May 1903. Both the Territorial Supreme Court and the US Supreme Court subsequently affirmed the decision, effectively bringing the private effort to develop an Elephant Butte reservoir to end in 1909.[8]

The federal government's victory over the Rio Grande Dam and Irrigation Company coincided with a policy shift that finally brought forth a settlement with Mexico. The embargo had eased Mexican concerns, leading the US's southern neighbor to propose a treaty, but the US's own efforts to provide a physical solution to the international problem had lagged. Ongoing litigation with the private company contributed to delays, as did opposition in New Mexico. Several bills were introduced in Congress in the late 1890s and early 1900s that provided for the construction of an international dam at El Paso, and a system of distribution between the US and Mexico. Interests in New Mexico, however, reportedly opposed the idea of this dam, fearing that it would flood much of the Mesilla Valley and impede agricultural development.[9]

This was a view that the principal federal engineer responsible for the Rio Grande Project, Benjamin M. Hall, shared.[10] Passage of the National Reclamation Act of 1902 – also known as the Newlands Reclamation Act, or the Newlands Act for its sponsor Representative Francis Newlands of Nevada – established a new federal program to furnish water to arid regions of the American West. The act created the United States Reclamation Service (Reclamation), forerunner to the present Bureau of Reclamation. Reclamation initially focused on developing those Western

[8] Hamele, "The Embargo on the Upper Rio Grande," November 11, 1924, 18-19, 11, and Exhibit G, 55-56. 8-3 Rio Grande Distribution of Waters (Loose File), Box 1638, CCF 1907-36, RG 48, NARA II. The complicated legal fight between the United States and Boyd's Rio Grande Dam and Irrigation Company is discussed at length in Littlefield, *Conflict on the Rio Grande*, 56-78.

[9] Hamele, "The Embargo on the Upper Rio Grande," November 11, 1924, 19-20. 8-3 Rio Grande Distribution of Waters (Loose File), Box 1638, CCF 1907-36, RG 48, NARA II.

[10] Benjamin M. Hall, or B.M. Hall, earned a degree in engineering from the University of Georgia in 1876. He was a mathematics instructor at what is now North George College and State University, before finding work as an engineer on water and mining projects. Hall consulted with the USGS in 1896, and joined Reclamation soon after it was established. Hall was the supervising engineer on a number of federal reclamation projects in New Mexico, and after leaving Reclamation worked in Puerto Rico. Littlefield, *Conflict on the Rio Grande*, 97.

reservoir sites that had been identified by the "Irrigation Survey" of the United States Geological Survey (USGS) between 1889 and 1890. The Elephant Butte site that Boyd had intended to develop was among these. A more detailed federal investigation began in March 1903, as the final trial with Rio Grande Dam and Irrigation Company neared its conclusion, and involved assessing the possible irrigable acreage that could be served by a reservoir at Elephant Butte. By February 1904, borings for a federal dam at the location were complete. In June, after Mexico once again entreated the US for a settlement, Secretary of State John Hay suggested to Secretary of the Interior Ethan Hitchcock that the National Reclamation Act might offer a path to a settlement with Mexico. Planning for a federal reclamation project centered at Elephant Butte embraced the idea.[11]

Before the assembled delegates to the National Irrigation Congress in November 1904, Hall declared that 180,000 acres of land in the United States could be served by a dam opposite Engle, New Mexico, a third of a mile below Elephant Butte, while delivering water to Mexico. Hall's presentation was based upon a much larger study that he had made prior to the congress, "A Discussion of Past and Present Plans for Irrigation of the Rio Grande Valley." Both in his presentation to the congress and in that study, Hall asserted that a Reclamation dam near Elephant Butte could offer more than the "International Dam" proposed for the El Paso area; it would furnish valuable flood control benefits and supply more US lands with water. Hall's proposed reservoir would have a storage capacity of 2 million af and would yield 600,000 acre-feet (af) to serve "110,000 acres in New Mexico," "20,000…[in] Texas above El Paso," and "50,000…[in] El Paso Valley below El Paso." In order to serve the valley lands sufficiently, given the area's aridity, seasonal flooding, and the high silt content of the Rio Grande, Hall insisted upon building a reservoir

> as large as possible, and as deep as possible; having capacity for carrying a supply of water over from year to year to equalize the yearly inequalities, a surplus capacity for mud accumulations, and a surface for evaporation that is as small as possible in comparison with the quantity of water in storage.

As he emphasized in his presentation and study, "[a]ll of the water that comes down the river is needed for irrigation. We can not [*sic*] afford to waste any of it."[12]

[11] Hamele, "The Embargo on the Upper Rio Grande," November 11, 1924, 20-211. 8-3 Rio Grande Distribution of Waters (Loose File), Box 1638, CCF 1907-36, RG 48, NARA II; and Littlefield, *Conflict on the Rio Grande*, 94-97.

[12] Guy Elliott Mitchell, ed., *The Official Proceedings of the Twelfth National Irrigation Congress, Held at El Paso, Texas, Nov. 15-16-17-18, 1904* (Galveston, TX: Clarke & Courts, 1905), 215-216; B.M. Hall, Supervising Engineer, U.S. Reclamation Service, "A Discussion of Past and Present Plans for Irrigation of the Rio Grande Valley," November 1904, 7-8, and 57-58. ff. 46 Rio Grande Project. Penasco Rock Resv.

The delegates were pleased with Hall's proposal, calling it "an equitable distribution of the waters of the Rio Grande with due regard to the rights of New Mexico, Texas and Mexico," and Congress acted swiftly to make the project a reality. In 1905, it authorized the Rio Grande Project for New Mexico and Texas. Specifically, it extended the 1902 Newlands Act

> to the portion of the State of Texas bordering upon the Rio Grande which can be irrigated from a dam to be constructed near Engle, in the Territory of New Mexico, on the Rio Grande, to store the flood waters of that river, and if there shall be ascertained to be sufficient land in New Mexico and in Texas which can be supplied with the stored water at a cost which shall render the project feasible and return to the reclamation fund the cost of the enterprise, then the Secretary of the Interior may proceed with the work of constructing a dam on the Rio Grande as part of the general system of irrigation, should all other conditions as regards feasibility be found satisfactory.[13]

The following year, with the conclusion of successful negotiations with Mexico, the Senate ratified a treaty promising the US's southern neighbor 60,000 af of water a year from the Rio Grande.[14]

Federal reclamation authorities worked to develop the Rio Grande Project over the next several years. In 1906, Hall filed a notice of appropriation with the New Mexico territorial engineer for 730,000 af of water for the project. That same year, Reclamation entered into the first of several agreements with two water users associations, the Elephant Butte Water Users Association in New Mexico and the El Paso Valley Water Users Association in Texas, and their successors Elephant Butte Irrigation District (EBID) and El Paso County Water Improvement District No. 1 (EP #1), to furnish water from the project. Two years later, new project supervising engineer Louis C.

Site-Elephant Butte Resv. Site, 1904-1905, Box No. 792, Rio Grande 17-46, Entry 3, General Administrative and Project Records, 1902-1919 [hereafter Entry 3], Records of the Bureau of Reclamation, Record Group 115 [hereafter RG 115], National Archives at Denver [hereafter NARA Denver]; and Littlefield, *Conflict on the Rio Grande*, 100-102 and 108-109.

[13] Historian Douglas Littlefield argues that by extending the provisions of Newlands Act to the El Paso Valley in Texas – a non-"Reclamation" state – Congress "authorized the Reclamation Service to carry out the first true apportionment of any interstate stream." He goes on to connect this act to the later 1938 "interdistrict agreement" between Elephant Butte Irrigation District and El Paso County Water Improvement District No. 1, approved by the Interior Department to explain why no state-line delivery to Texas was established. See Littlefield, *Conflict on the Rio Grande*, 114-115, 203 and 207, and Opinion IV below.

[14] Mitchell, ed., *Official Proceedings*, 107; Hamele, "The Embargo on the Upper Rio Grande," November 11, 1924, 23-25. 8-3 Rio Grande Distribution of Waters (Loose File), Box 1638, CCF 1907-36, RG 48, NARA II; *An Act Relating to the construction of a dam and reservoir on the Rio Grande, in New Mexico, for the impounding of the flood waters of said river for purposes of irrigation*, February 25, 1905, chap. 798, 33 Stat. 814; and Littlefield, *Conflict on the Rio Grande*, 105-145.

Hill filed a supplemental notice for "[a]ll of the unappropriated water of the Rio Grande and its tributaries."[15]

Construction proceeded apace. Leasburg Diversion Dam and its canal, the first elements of the project system, were completed in 1908. Eight years later, Elephant Butte Dam was completed, and the remaining major irrigation works were constructed between 1914 and 1919. In the late 1910s, work began on a vast drainage system to manage rising groundwater levels and fulfill Hall's plan to utilize all of the waters of the Rio Grande, including return flow (see Opinion III). By the mid-1920s, while planning and construction of various elements would continue into the 1930s, the project was substantially completed.[16]

Although the embargo was intended to last until a resolution could be found to the diplomatic dispute with Mexico, federal officials eager to protect the water supply of the Rio Grande Project continued to supported it into the early 1920s. Successful conclusion of the Colorado River Compact, however, prompted Reclamation Director A.P. Davis to solicit the opinions of the Colorado attorney general and the general managers of EBID and EP #1 as to a modification of the embargo and possible negotiation of a compact in December 1922.[17]

In March 1923, citing recent criticism of the embargo by Coloradoans, Davis recommended to Secretary of the Interior Albert B. Fall that the embargo be modified such that Reclamation could "negotiate for the release of specific areas of public land for purposes of water storage under conditions that will best conserve and protect vested rights in all parts of the Rio Grande Basin."

Brook, President, Elephant Butte Irrigation District, Dec. 12, 1922.; and A.P. Davis, Director, to Mr. Roland Harwell, President, El Paso County Water Improvement Dist. #1, Dec. 12, 1922. ff. 032.02, Rio Grande Basin Water Rights: Rio Grande River Basin Embargo, Thru 1925, Box No. 925 Rio Grande Basin 032.02-- Lower Rio Grande 090., Project Files, 1919-1929, General Administrative and Project Records, 1919-1945, Entry 7 [hereafter Entry 7], RG 115, NARA Denver; and Littlefield, *Conflict on the Rio Grande*, 170-171.

The director predicated this recommendation on an analysis proffered by federal reclamation engineer Harold Conkling nearly four years earlier. In a June 1919 memorandum, Conkling argued that water developments in the San Luis and the Middle Rio Grande valleys would have a negligible impact on the Rio Grande Project downstream. In fact, he believed that with the construction of drainage works these developments could augment the water supply below Elephant Butte. Davis echoed this belief, expressing confidence that with Reclamation granted new authority, upstream projects could move forward without compromising the Rio Grande Project's water supply. Fall concurred, authorizing the modification in March 1923.[18]

The embargo came to an end entirely two years later. In September 1924, Davis's successor Elwood Mead expressed his support for the long-contemplated Vega-Sylvestre Reservoir in San Luis Valley. In April 1925, the Interior Department approved the reservoir. A little over a month later, Secretary of the Interior Hubert Work rescinded the embargo, reasoning that it was no longer necessary.[19]

Colorado and New Mexico had already moved forward with negotiating a compact, prior to Work's decision. In 1923, both states appointed commissioners to meet with a federal representative, and they initially sought to negotiate an agreement solely between themselves with the secretary of the interior's support and encouragement.[20] Concern for the possible

[20] According to Colorado Lieutenant Governor George Corlett's recollection, that encouragement came circa 1925, when at a conference with Work in Washington, D.C. The Secretary of the Interior urged Corlett to meet with New Mexico's commissioner Francis Wilson, who was also in D.C., and find "just one thing" upon which they agreed. Arrangements were made for the two men to meet at the Senate office building, and they ultimately sat down with Work and Reclamation representatives to discuss the possibility of an "outlet drain" for Colorado. Proceedings of the Rio Grande Compact Conference held at Santa Fe, New Mexico, December 10-11, 1934, 5-6. ff. Carpenter and Family [hereafter PDECF], Water Resources Archives

impact of water projects upstream from the Rio Grande Project, however, led Texas to push for inclusion. Following a preliminary "first" meeting of the Rio Grande Compact Commission in October 1924, in which El Paso attorney Major Richard F. Burges argued on Texas's behalf as an unofficial representative, the federal representative, Secretary of Commerce Herbert Hoover and the Colorado and New Mexico commissioners agreed to include Texas.[21] The parties further agreed that their negotiations should focus on the allocation of the waters of the Rio Grande above Fort Quitman, Texas as this was a natural dividing point in the river.[22]

Appointment of an official commissioner for Texas, New Mexico's withdrawal from compact negotiations following Work's rescission of the embargo, and the resignation of Hoover upon his election to the presidency delayed further talks among the three states until December 1928.

[hereafter WRA], Colorado State University, Fort Collins [hereafter CSU-FC], available online at http://hdl.handle.net/10217/41293, last accessed April 8, 2019.

[21] Richard Fenner Burges came from a prominent family of El Paso attorneys. After graduating from Texas Agricultural and Mechanical College (today Texas A&M University), he read law in Seguin, Texas. He joined the El Paso law practice of his oldest brother, William Henry Burges, Jr., in 1892. Burges was admitted to the bar two years later, and along with William and his middle brother Alfred Rust Burges (who joined Richard in his separate law practice in 1912) established the El Paso Bar Association in the early 1910s. Burges was the city attorney for El Paso between 1905 and 1907, where he drafted the City Charter and continued an anti-vice campaign began by William when he was city attorney. As a member of the Texas State Legislature between 1913 and 1915, Burges authored the Texas Forestry Act and the Texas Irrigation Code. He earned the military title of major for his service in France during World War I; Burges also earned a Croix de Guerre for his bravery on the battlefield. Returning to El Paso after the war, he was considered as a potential gubernatorial candidate but Burges declined. Instead he dedicated much of the rest of his life to representing El Paso, El Paso County, and adjacent Hudspeth County, particularly on matters related to the Rio Grande – as noted in the opinions offered here. From 1935 to 1940, Burges served as a special counsel to the Department of Justice on the Rio Grande Rectification Project (see footnote 169). See Laura Hollingsed, Biography, "Guide to MS 262 Burges-Perrenot Family Papers," C.L. Sonnichsen Special Collections Department, University of Texas at El Paso, available online at digitalcommons.utep.edu/cgi/viewcontent.cgi?article=1073&context=finding_aid, last accessed April 15, 2019.

[22] Pat M. Neff, Governor of Texas, to Honorable Herbert Hoover, Secretary of Commerce, Re: Commission to Divide Waters of the Rio Grande, September 20, 1924. Folder 3, Herbert Hoover, Sec. of Commerce (11.); First Meeting, Rio Grande River Compact Commission, Breadmoor Hotel, Colorado Springs, Colo., Sunday, October 26, 1924, 1-37. Folder 1. First Meeting Rio Grande Compact Commission. Oct. 26, 1924, Box 02-D.002, MS 0235 Elephant Butte Irrigation District Records, 1883-1981 [hereafter MS 0235], Rio Grande Historical Collections [hereafter RGHC], New Mexico State University Archives and Special Collections, Las Cruces [hereafter NMSU Spec. Coll]; and Littlefield, *Conflict on the Rio Grande*, 177-183.

As Burges put it, "It is a matter of fact, and it can be established to the satisfaction of any fair minded person, that the use of water of the Rio Grande above Fort Quitman does not at least materially affect the interests of the people below Del Rio, Texas, as there is no irrigation that is of any consequence, and I think no possible irrigation of any importance between Fort Quitman and Del Rio, Texas." First Meeting, Rio Grande River Compact Commission…October 26, 1924, 4.

Over the course of three meetings, from December 19 through December 21, New Mexico and Texas aligned in defending the Rio Grande Project against Colorado. New Mexico's commissioner Francis Wilson was adamant that a specific quantity of water for New Mexico be determined and delivered at the Colorado-New Mexico state line. Wilson also argued that the best development Colorado could make, and which would have little effect on projects downstream, would be to drain the so-called "Closed Basin" – lands in the San Luis Valley waterlogged by the river. Any dam or reservoir that would impound the existing surface flow of the stream, in his view, threatened the Rio Grande Project and its 1906 and 1908 water filings in New Mexico.[23]

Burges, speaking for Texas, argued that his state's claims to the waters of the Rio Grande derived largely from the Rio Grande Project filings and the allocation of water to lands in New Mexico and Texas within the project. He further pointed out that approximately 20,000 acres below the end of the project (roughly Fabens, Texas) down to Ft. Quitman was irrigated. These lands in Hudspeth County relied almost entirely upon return flow from the project, obtained under the provisions of a federal Warren Act contract (see Opinion III).[24]

Colorado sought the freedom to develop its San Luis Valley. Lieutenant Governor George M. Corlett was the principal voice for the state. He insisted downstream water users would not be harmed by the construction of upstream reservoirs and in fact, stood to benefit from return flows and reduced evaporation caused by the long transit time in stream flow to Elephant Butte. Corlett acknowledged the benefits of the drain suggested by Wilson, and although he did not abandon the idea of a San Luis reservoir he ultimately agreed to join with New Mexico and Texas to request federal support for a Closed Basin drainage project.[25]

Although Colorado marshaled data to convince New Mexico and Texas of its position, there was little else upon which the states agreed aside from the Closed Basin project. In February 1929, limited again by their states' respective schedules and needing more time to study the problem, Colorado, New Mexico, and Texas concluded a temporary compact. This agreement, in effect, was to maintain the status quo in the basin for a period of six years until June 1935. Neither Colorado (Article V) nor New Mexico (Article XII) was to "cause or suffer the water supply" of the

river "to be impaired by new or increased diversions or storage" – affording protection for the Rio Grande Project water supply – during this time. However, should the Closed Basin drain and State Line Reservoir be constructed prior to June 1935, "depletions" were permissible if "offset by increase of drainage return." The temporary compact further provided for the establishment of several stream-gaging stations to gather flow data (Article III), necessary to formulating a permanent compact and endorsed construction of the Closed Basin Drain and State Line Reservoir by the federal government (Article II).[26]

With the expiration of the temporary compact a mere six months away, Colorado commissioner M.C. Hinderlider, New Mexico commissioner Thomas McClure, Texas commissioner T.H. McGregor, and the new federal representative (and Reclamation assistant chief engineer) S.O. Harper re-opened talks on a permanent compact in December 1934. Little had changed for the three states; all remained committed to the positions they articulated back in 1928. Corlett once again insisted that Colorado have "parity" with New Mexico and Texas in the use of Rio Grande waters – which Harper understood to mean "equality as regards dependability of water supply with the lands under the Elephant Butte Reservoir in New Mexico and Texas." New Mexico and Texas representatives, however, demanded to know whether Colorado intended to accept federal monies then being offered by the President Franklin Roosevelt's New Deal administration for a Closed Basin drain study. Ralph Carr, legal advisor to Colorado, responded that certain obligations attached to this funding were objectionable, and he asked for New Mexico and Texas's support in addressing those objections. He also maintained that the commission's "problem" and "task" was "to make an equitable division of the waters of the Rio Grande." Colorado sought to "arrive at a permanent compact," and notwithstanding the issues surrounding the drain, Carr argued for the opportunity to "present the data which is needed to arrive at a solution…."[27]

Burges countered that until the drain was constructed it was impossible to estimate the quantity of additional water to be developed by storage for use in Colorado, and thus an equitable apportionment remained elusive. Texas, according to Burges, preferred to continue the present compact until the effective yield of the Closed Basin drain could be determined. Carr, however, believed that this was unnecessary, as the 1929 compact, in Harper's words, "concedes to

Colorado an additional amount of water equivalent to that developed by the drain…." At an impasse, but with each of the states informed as to the others positions, the commissioners decided to adjourn, study the questions in more detail, and reconvene in January 1935.[28]

The January meeting picked up where the December meeting had left off, with Colorado continuing to insist on parity with Texas and New Mexico. Corlett argued that construction of "the Outlet Drain" (i.e., the Closed Basin Drain) together "with the savings of avoidable waste from the Elephant Butte Project" would ensure sufficient water for Colorado's intended developments. By "avoidable waste," he meant the water released below Rio Grande Project lands in Texas. Corlett insisted that this waste had been controlled following the adoption of the temporary compact but since that time it had "crept into the operations of these projects, so that the releases at the Elephant Butte have now come back to approximately what they were before." Construction of the Closed Basin drain, together with control of "avoidable waste" on the Rio Grande Project would enable, he argued, "an annual uniform supply of water to the lands of Colorado on a parity with the supply now furnished to lands in New Mexico and Texas."[29]

As before, negotiation of the compact for Colorado was not contingent upon construction of the drain. Corlett believed that "with all of the excellent accumulated engineering data and advice" available to the commissioners that a compact could be devised, and to that end, Colorado's engineering advisor Royce J. Tipton took the floor.[30] Tipton elaborated on the argument first

[30] Born in Illinois in 1893, Royce Jay Tipton grew up in Colorado. After he graduated high school, he worked as an elementary school teacher before receiving practical training as an engineer with a mining company. Tipton entered the University of Colorado in 1915 to study civil engineering but before completing his degree he went overseas during World War I. Tipton never finished his academic studies, although in 1940 he was awarded "an Honorary Degree in Civil Engineering" by the university. Following his military service, Tipton worked as chief engineer for the San Luis Valley Land and Cattle Company, and in the early 1920s formed the first of several business partnerships and engineering consulting companies. In 1929, he became Colorado's engineering advisor in the Rio Grande Compact negotiations, and briefly assisted with Reclamation water supply studies for what became the Hoover Dam. His association with the Colorado State Engineer's office continued into the 1930s. Tipton's professional life took him abroad, and he partnered with Hill on a water supply projects in Pakistan and Egypt. Texas's engineering advisor recalled Tipton fondly in a 1968 deposition that Hill gave in an original action filed against Colorado by Texas and New Mexico, alleging violations of the 1938 Compact: "Mr. Royce Tipton was one of the outstanding engineer in this field… and I considered him of the of the ablest engineers in the field….I liked the man personally, I admired his ability…." "Memoir, Royce Jay Tipton, F. ASCE, Died December 23, 1967,"

advanced back in 1928 that the entire Rio Grande Basin stood to gain from the construction of reservoirs to serve the San Luis Valley. He presented technical data that he maintained demonstrated such works would assist in regulating the water supply and providing sufficient carryover storage from high to low water years in the valley, and by doing so return as much as 100,000 af to the stream to the benefit of downstream users in New Mexico and Texas.[31]

The rest of the commission, while intrigued by Tipton's presentation, felt that they had little time to consider it in detail. Extensive questioning by Burges (serving as Texas's acting commissioner at the request of the Governor James V. Allred), led to Colorado agreeing to make Tipton's work available to Texas and New Mexico for further review. In the meantime, the commissioners decided to recommend to their respective governors and legislatures a two-year extension of the temporary compact until June 1937.[32]

Before negotiations resumed, Texas filed suit against New Mexico and the Middle Rio Grande Conservancy District (MRGCD) in the US Supreme Court in October 1935. Texas alleged that by permitting diversions above Elephant Butte by MRGCD, diversions that diminished both the quantity and quality of water reaching Texas lands, New Mexico had abrogated the terms of the 1929 compact. Organized in August 1925 under the laws of New Mexico, the Middle Rio Grande Conservancy District aimed to reclaim and develop that portion of the basin above San Marcial, providing not only water but also flood protection to lands in the vicinity of Albuquerque. As the negotiations leading to the 1929 temporary compact were underway, MRGCD had formulated its plans and had contracted with Reclamation for additional technical support and study, leading to an assessment of "the water conditions of the Rio Grande." By the early 1930s, primarily with financial support from the federal Reconstruction Finance Corporation, the district had embarked on constructing El Vado, a proposed 190,000-af storage reservoir on the Rio Chama near the

Colorado-New Mexico state line, as well as half a dozen diversion dams on the Rio Grande, and several hundred miles of irrigation and drainage canals and levees.[33]

MRGCD's plans notwithstanding, New Mexico rejected Texas's allegations. The state asserted that diversions by Mexico in excess of that permitted under the 1906 treaty and inefficient operation of Elephant Butte Dam were to blame for the diminished water supply to lands in Texas. New Mexico further argued that the US's 1906 appropriation of water for the federal reservoir was not made in accordance with New Mexico law, in violation of the 1902 Newlands Act.[34]

State of New Mexico*, No. 12 Original, 1936 Term. *Statement by Special Master*, March 5, 1937. ff. Warren Charles, Correspondence re Texas vs. New Mexico / March, 1937, Box 4 Correspondence,

The Supreme Court granted leave to Texas to proceed with its suit in November, and appointed a special master, attorney Charles Warren, to take testimony in May 1936. Between November 1936 when Warren opened hearings and March 1937 when hearings concluded, nearly 40 hearings were held in Albuquerque, New Mexico, and El Paso, Texas, and in excess of 3,000 pages of evidence – including more than 260 exhibits, maps, charts, graphs, and witness testimony – were produced. Warren further personally inspected several hundred miles of the Rio Grande and the various irrigation and drainage system that served lands in New Mexico and Texas.[35]

Despite all of this, when the hearings ended the special master could not see a clear resolution. In his *Ad Interim Report* to the Supreme Court in March 1937, Warren indicated that he was "of opinion that findings of fact by me based on the evidence in its present shape would be unsatisfactory and might not result in an equitable adjustment of the situation." Essential legal issues (such as the absence of the US and Colorado as parties to the litigation) aside, the special master cited incomplete records and partial analyses of flow depletion and salinity levels as constituting an insufficient basis for findings of fact. Aware that the federal government through the National Resources Committee (NRC) was "investigating the whole problem of water supply and distribution in the Upper Rio Grande region," and at the request by counsel representing Texas, New Mexico, and MRGCD, to hold "further proceedings…in abeyance until the first day of October 1937," Warren recommended postponement of the case until January 1938. The high court approved the recommendation in April.[36]

The National Resources Committee referenced by Warren was a special working group of government officials and consultants within the Roosevelt Administration that aimed to foster development of the nation's natural resources through planned regional public works programs. In September 1935, a month prior to Texas filing suit against New Mexico and MRGCD, "spurred by the need for prompt action to avoid uncoordinated development of water utilization projects" in the Upper Rio Grande Basin, the group appointed a Board of Review to study the various water use problems and proposed projects in the basin. The board readily identified the potential for

the MRGCD to jeopardize the 1906 treaty with Mexico and prior federal investment in the Rio Grande Project. Other proposed federal water projects, such as the Conejos and Vega-Sylvestre dams and the so-called "State Line Reservoir" in Colorado, also presented potential conflicts with not only the Rio Grande Project and the MRGCD but also with the tristate compact under negotiation. Furthermore, the river basin was considered to be fully appropriated. New drafts on existing water resources without enhancing supply, the board ultimately concluded, would damage vested rights in the basin.[37]

In the interests of efficient, full, and equitable utilization of the basin's waters, the board recommended that no action be taken "to approve any application for a project involving the use of Rio Grande waters without securing from the National Resources Committee a prompt opinion on it from all relevant points of view." President Franklin D. Roosevelt, at the urging of Secretary of the Interior Harold Ickes, issued an executive order in September 1935 prohibiting federal officials from authorizing any water projects for the Rio Grande Basin without obtaining the approval of the NRC – in effect, restoring the embargo.[38]

In early October 1935, the NRC contacted Harper about the possibility of having representatives from the group meet with the Rio Grande Compact Commission to discuss how they might facilitate conclusion of a permanent compact by providing "needed basic data" that would foster "agreement on facts by the three states…." With the approval of Harper and the other compact commissioners, the NRC sent Harlan H. Barrows, a University of Chicago historical geographer and a member of the Board of Review, and Frank Adams, an agricultural economist with the NRC's Water Resources Committee, to meet with the commission in December.[39] At that

Roosevelt, To Federal agencies concerned with projects or allotments for water use in the Upper Rio Grande Valley above El Paso, September 23, 1935. File No. 8-3 (Pt. 7). Reclamation Bureau - Rio Grande Project - Rio Grande River - Distribution of Waters – General, February 6, 1933 to December 12, 1956, Box 1642, 8-3, Rio Grande, R, CCF 1907-1936, RG 48, NARA II.

[39] Harlan H. Barrows came to the University of Chicago as an undergraduate in 1903, earned a BA in geology, and later joined the university's Department of Geography – the first such academic department for the discipline in the United States. He went on to become a foundational figure in the study of historical geography, and garnered recognition and acclaim for his lectures. Barrows entered public service during World War I, as a member of the United States War Trade Board. In the early 1930s, he consulted on a number of US Department of the Interior-led, or -based initiatives, such as the Water Resources Committee of the National Resources Committee. See Biographical Note, "Guide to the Harlan H. Barrows Papers, circa 1880-1939,", University of Chicago Library, available online at

meeting, Barrows and Adams proposed a joint federal-state investigation of the water resources, uses, and needs throughout the Upper Rio Grande Basin, and the commissioners agreed. The investigation, it was determined, would include: 1) the water resources of the Rio Grande Basin "above Fort Quitman;" 2) the "past, present and prospective uses and consumption of water" in the basin within the United States; and 3) opportunities for conserving and enlarging the water supply to assist the commission "in reaching a satisfactory basis for the equitable apportionment of the waters of the Rio Grande Basin in the United States above Fort Quitman, as contemplated by such Rio Grande Compact."[40]

The commissioners embraced the offer of assistance, but were wary of the investigation coming to conclusions or making recommendations. Texas's new commissioner, attorney Frank B. Clayton (who also represented Texas in its suit against New Mexico and MGRCD) explicitly raised this concern, and the other state commissioners concurred.[41] In the final resolution authorizing the NRC to move forward, the Rio Grande Compact Commission pledged to assist in the joint

Much like Barrows, Frank Adams was a pioneer in his field. He earned degrees in economics from Stanford and the University of Nebraska in the early 1900s, and worked for the US Office of Experiment Stations, based in the Department of Agriculture, between his degrees. After a brief interlude working with his brother on a commercial venture, Adams re-joined with the Office of Experiment Stations in 1910 and was later appointed to lead the Division of Irrigation Investigations and Practices at the University of California's College of Agriculture. In the 1920s and through the 1940s, he consulted with Reclamation and was a key member of the National Resources Committee. See Biography, "Inventory of the Frank Adams papers, 1889-1962," Water Resources Collections and Archives, University of California, Riverside, available online at https://oac.cdlib.org/findaid/ark:/13030/tf9489p11x/entire_text/, last accessed April 8, 2019.

[40] Proceedings of the Rio Grande Compact, held in Santa Fe, New Mexico, December 2-3, 1935, 2-3 and 5-7. ff. 032.1 (2/3), Box 1326 Owyhee Proj. 222., Rio Grande Basin 032.1, Entry 7, RG 115, NARA Denver; and "Resolution Passed by Rio Grande Compact Commission at Santa Fe, New Mexico," December 3, 1935, 1-2. Folder 401-Rio Grande Compact Commission Resolutions, 1935-1937, Box 26, FAC, WRCA.

[41] A native of El Paso, born in 1902, Frank Britton Clayton attended Texas Western College (now the University of Texas at El Paso) and later enrolled at the University of Texas (at Austin) where he earned his law degree in 1925. He held fellowships at Yale and Harvard in 1927 and 1928, and taught at the University of Texas law school until 1930 when he entered private practice. Between 1933 and 1935, Clayton served as special counsel to the City of El Paso before becoming Texas's Rio Grande Compact Commissioner. As noted above, he represented the State of Texas in the original action against the State of New Mexico and the Middle Rio Grande Conservancy District; and as noted in Opinion IV, Clayton was counsel to Hudspeth County Conservation and Reclamation District No. 1. Following the ratification of the 1938 compact, he resigned his position as compact commission to become the city attorney for El Paso. In 1941, Clayton became counsel to the International Boundary and Water Commission. See Frank B. Clayton to Governor W. Lee O'Daniel, April 18, 1939. ff. Rio Grande Compact, Commissioner Appointments, 1938-9, 2001/138-143, W. Lee O'Daniel Governor's Papers, TSA; and "F.B. Clayton, Prominent Lawyer, Dies," *The El Paso Times*, December 2, 1951.

investigation, to secure matching state funds and services, and to share costs of the studies with the federal government. They also expressed their understanding that the cooperative investigation "shall be limited to the collection, correlation and presentation of factual data."[42]

After nearly two years of work, with the USGS, Reclamation, and the US Department of Agriculture's Bureau of Agricultural Engineering and Bureau of Plant Industry all contributing, an initial draft of the Rio Grande Joint Investigation report, or *JIR*, was available in August 1937.[43] Barrows, in presenting that draft to the commissioners when negotiations resumed in late September, expressed his belief that the report provided "a factual basis for an allocation of the waters of the river above Ft. Quitman that would be fair and just to each of the three states and to its citizens dependent upon the river."[44]

Although Texas's engineering advisors expressed reservations over the *JIR* (discussed in Opinion II), later accounts of the meetings between the engineering advisors for all three states and the US indicate that the report was an essential compilation of information for them. As Tipton reported to Hinderlider, "all the basic data pertaining to the problem were assembled and analyzed" in *JIR*. This data included "detailed studies" by the individual states as well as the federal investigation itself. From this, Tipton and his fellow engineers were able to ascertain "the discharge of the river at various points under present development in the basin," and "schedules of water delivery which would insure each section of the basin against injury by acts of water

uses in another section and yet would permit of the construction and operation of additional reservoirs above Elephant Butte Reservoir."[45]

Three decades after the permanent compact was signed, the recollections of Texas's engineering advisor Raymond A. Hill were similar.[46] Hill acknowledged that in the course of the federal investigation requests for "clarification" were made, "questions were raised as to the accuracy of some of the data," and "exceptions were taken to some of the findings." The *JIR* nevertheless assembled "all essential data as to the sources and quantities of water available for use in the several States, the needs for water in these States, and means for development and use of those supplies." Where it specifically came to development of delivery schedules that were at the heart of the compact, Hill stressed that the report brought together "all pertinent data." With this data provided to the commission, the engineering advisors crafted the technical basis for the compact.[47]

[45] R.J. Tipton, *Analysis of Report of Committee of Engineers to Rio Grande Compact Commissioner, Dated December 27, 1937* (February, 1938), 1-4. ff. 70, Box 44-70, MSS 312 Michael Creed Hinderlider Collection, 1897-1987 [hereafter MCHC 1897-1987], History Colorado, Denver [hereafter HC].

[46] Raymond A. Hill was a consulting engineer and partner with the Los Angeles-based engineering firm of Quinton, Code and Hill-Leeds and Bernard (after 1940, Leeds, Hill, Bernard and Jewett). The son of Louis C. Hill, the second supervising engineer for the Rio Grande Project, Raymond Hill graduated from the University of Michigan in 1914 with a Bachelor of Civil Engineering. He worked for Reclamation while in college on Strawberry Valley Project in Utah, the Green River Project in Colorado, and the Yuma Project in Arizona. Hill first became familiar with the Upper Rio Grande Basin when assisted in the investigation of the proposed high-line canal between Elephant Butte Reservoir and El Paso led by his father in the late 1910s. After a stint in the US Army Corps of Engineers during World War I, he returned to the University of Michigan and obtained, in his words, "the degree of Civil Engineer" in 1922. Hill and his firm were hired by EBID and EP#1 to investigate possible hydroelectric power development at the federal reservoir. In 1934, he studied possible canalization of the Rio Grande from Elephant Butte through El Paso, a study that became the basis for the Rio Grande Rectification Project (see discussion in footnote 169). In addition to serving as Texas's engineering advisor (which he did for nearly 40 years), Hill advised the International Boundary and Water Commission and served as consulting water engineer to the cities of Santa Barbara and San Diego. He also worked internationally on projects in Mexico and the Middle East. *State of Texas vs. State of New Mexico, et al*, *Plaintiff's Case in Chief*, Volumes III & IV [hereafter *Plaintiff's Case in Chief*, Vols.], 599a-603. Hill's recollections were prompted by a suit filed in US Supreme Court by Texas and New Mexico against Colorado for breach of the compact in the mid-1960s. For more, see Opinion V below.

Friedkin Papers, C.L. Sonnichsen Special

When the Rio Grande Compact Commission re-opened negotiations in September 1937 few of the attendees had had an opportunity to examine the report in advance, so the engineer-in-charge of the investigation, Harlowe M. Stafford, presented the *JIR*'s findings.[48] Calling attention to the report's immense size (1,700 mimeographed pages), he conceded that it was not easily summarized. At Harper's prodding, Stafford focused on those issues most critical to the commissioners. He emphasized that the investigation aimed to offer "factual data on the water supply, water utilization and water requirements, with the possibilities of augmenting supplies to the basin by transmountain diversion or conservation by storage." The quantity and quality of water, the federal engineer assured the commissioners, were central concerns. He described the efforts made by the various federal agencies involved to measure the water supply and assess water quality, and identified in which volumes specific information developed by these agencies could be found. Findings as to runoff, return flow, groundwater, irrigation development and irrigated acreage, and water uses and requirements within the Upper Rio Grande Basin were summarized in Volume I and, according to Stafford, assisted in the determination of the "diversion requirements of major units of the basin" – namely the San Luis Valley in Colorado, the Middle Rio Grande in New Mexico, and the lands between Elephant Butte Reservoir in New Mexico and Fort Quitman, Texas.[49]

Asked by Harper to identify the amount of irrigable acreage and current water uses in these areas for the benefit of those who had not yet seen the report, Stafford went to the tables in Volume I. The study had determined that 3 million af of water was produced in the basin – almost all of which came from sources in Colorado and New Mexico. Irrigated and "water consuming" acreage in the basin amounted to nearly 2 million acres, but less than 1 million was "actually irrigated with the balance taken up by areas temporarily out of crop and areas occupied by cities and towns and bare lands." The engineer noted that the "Total for the basin [was] 924,000" – "600,000 in the San Luis section; 153,000 in the Middle Rio Grande section, which includes acreage in tributary areas; and 171,000 in the Elephant Butte-Fort Quitman sections." Basin-wide stream flow depletion was 2.7 million af, which according to Stafford suggested there was "about 200,000" acre-feet of surplus flow on average during the 46-year study period (1890-1935)

Collections Department, University of Texas at El Paso [hereafter UTEP Spec Coll]. Additionally, this narrative was published posthumously in the *Natural Resources Journal* in 1974. See Raymond A. Hill, "Development of the Rio Grande Compact of 1938," *Natural Resources Journal* 14:2 (April 1974): 64-200.

[48] The NRC selected Stafford, then serving as Water Commissioner for the Sacramento and San Joaquin Valleys of California to lead the federal effort in January 1936. Barrows and Adams were to serve as "a Consulting Board," "an advisory group," to work with Stafford and liaise with the Rio Grande Compact Commission. Rio Grande Joint Investigation, January 10, 1936, Approved: January 11, 1936, by Frederic A. Delano, Vice Chairman, National Resources Committee, 4-5. Folder 390, Box 26, FAC, WRCA.

[49] Proceedings of the Meeting of the Rio Grande Compact Commission...September 27, to October 1, 1937, 6-8. Untitled folder 5, Box 2F463, RGCC-FBCP, UTA.

chosen by the investigation. This same 200,000 af was, he also noted, "about what now flows at Fort Quitman." Of this 2.7 million af, the San Luis Valley, "exclusive of the consumption in the closed basin," took 1,047,000 af; the Middle Rio Grande, 768,000 af; and the Elephant Butte-Ft. Quitman lands, 885,000 af. As to the diversion requirements for the various areas within the basin, Stafford presented the investigation's findings concisely:

> 650,000 acre-feet would be the diversion demand at Del Norte; in the Conejos area 230,000; Middle Rio Grande area 580,000 at Otowi Bridge; between Middle Rio Grande and San Marcial about 80,000, and Elephant Butte-Fort Quitman section 953,000 at San Marcial; or taking out the estimate of seepage and evaporation, 773,000 acre-feet demand on the reservoir. Those figures are set up on the basis of the irrigated acreage as follows: In the San Luis section 353,000 acres; Conejos, 80,000; Middle Rio Grande, 100,000; Elephant Butte-Fort Quitman section, 145,000 acres. That would not be total irrigated acreage, but the maximum for any one year.

Almost immediately following presentation of these figures, the commission adjourned at Clayton's suggestion. Texas's commissioner, citing an earlier proposal by former Colorado Governor A.T. Hannett, recommended that the individual commissioners withdraw to meet with their advisors and draft "written statements" outlining "the minimum conditions under which we would be willing to negotiate."[50]

When the commission reconvened the afternoon of September 28, Colorado commissioner M.C. Hinderlider explicitly used information contained in tables and charts presented in Volume I to support his state's longstanding view that there was sufficient water in the basin for the development of lands in Colorado "comparable to that which now exists in the Middle and Elephant Butte-Fort Quitman sections" without harming established developments in New Mexico and Texas. "As a matter of fact," he asserted, "the usable water supply for the Middle section would be improved by the construction and operation of the reservoirs required in the San Luis section."[51]

For their part, both New Mexico and Texas signaled their willingness to negotiate with each other and with Colorado. New Mexico was open to discussing "increased storage" in the basin for Colorado provided that "proper safeguards" for New Mexico's water users were instituted and a transmountain diversion to bring additional water into the basin was "made an accomplished fact coincident with the construction of such storage in Colorado." With regard to Texas, New Mexico indicated it was receptive to talks focusing on "the right to the use of water claimed by

[50] Proceedings of the Meeting of the Rio Grande Compact Commission...September 27, to October 1, 1937, 9. Untitled folder 5, Box 2F463, RGCC-FBCP, UTA.

citizens of Texas under the Elephant Butte Project on the basis of fixing a definite amount of water to which said project is entitled." It insisted that Mexican diversions had to "be strictly limited to treaty provision of 60,000 acre-feet per annum." Development of the Middle Rio Grande Conservancy District to its approximately 123,000 acres, moreover, had to be respected as did "[a]ll existing rights to the use of water in the Rio Grande Basin in New Mexico."[52]

Texas's negotiation position was the most succinct and direct of the three:

> Although the State of Texas feels that it should share in the benefits from new works for the augmentation of the water supply of the Rio Grande, it will not insist thereon, provided that the States of Colorado and New Mexico will release and deliver at San Marcial a supply of water sufficient to assure the release annually from Elephant Butte Reservoir of 800,000 acre-feet of the same average quality as during the past ten years, or the equivalent of this quantity if the quality of the supply is altered by any developments upstream.

The proceedings then adjourned for an "informal discussion" between the commissioners and their advisors regarding how the meeting might move forward. The commissioners decided to meet in executive session the following day with each commissioner limited to two advisors who could participate in discussions. Additional representatives from each state and the NRC attended, but only as observers. No record was made of this executive session.[53]

Substantive talks resumed on the third day, and quickly became technical in nature with the engineering advisors debating the relative merits of flow schedules and the quantity as well as the quality of water the downstream states (Texas, in particular) could expect should Colorado develop its own reservoirs upstream. For its part, Colorado offered a schedule of deliveries that would provide 750,000 af per year for the "mean required releases from Rio Grande Project storage." After considerable discussion, principally among the engineering advisors, the commissioners elected to adjourn to provide their advisors an opportunity to meet as a group, sift through the data, develop the "technical basis" for a compact, and report back to the full commission.[54]

The engineering advisors met twice following the October adjournment – the first time in Santa Fe from November 22 to 24, and the second in Los Angeles from December 15 to 27. On both

occasions the attendees were the same: Reclamation engineer E.B. Debler for the US, Tipton for Colorado, John Bliss for New Mexico, and Hill for Texas.[55] The Santa Fe meeting was dedicated to discussions about the factors influencing discharge of Rio Grande water at the Colorado-New Mexico state line and delivery of water to Elephant Butte Reservoir. The Los Angeles meetings dealt with these same issues in greater detail, developing explicit delivery schedules at certain control stations on the Rio Grande and its tributaries.

In Santa Fe in November, the engineers clung to their state's positions and were quite apart from each other. Tipton, as he had with the full commission meetings, opened the discussion. According to a memorandum prepared for Clayton by Hill following the meeting, in addition to insisting that Colorado receive credits for water prevented from being illegally diverted by Mexican interests, Colorado's engineering advisor stressed:

> a. Colorado can not [*sic*] consider anything less than present requirements, which means that depletion in the future will be at least as great as during the past few years.[56]
>
> b. The people in the San Luis valley are strongly opposed to any state line schedule that will restrict their use of water prior to the time that storage is provided.
>
> c. Even after storage is provided, they do not want any schedule that will give more water in dry years than actually did pass the state line.

Hill took all of this to mean that Colorado would not accept any restrictions on its use of water. He nevertheless believed that Colorado desired a compact and was willing to work toward "some reasonable schedule." Tipton, in fact, had developed such a schedule for a state-line delivery, "which could have been satisfied under natural conditions during the past eight or nine years." Colorado's engineering advisor was going to try to persuade San Luis Valley interests to accept

---

[55] A graduate of the Colorado Agricultural College (today Colorado State University) in 1925, John Bliss first worked to the Colorado State Engineer's office in land surveying. In 1926, he joined the New Mexico State Engineer's office and eventually rose to become the state engineer in 1946. He worked on several hydrographic investigations on streams in New Mexico, which included work in the Upper Rio Grande Basin, in Colorado's San Luis Valley, the Middle Rio Grande (above Elephant Butte), and as discussed in greater detail in Opinion III below, between Elephant Butte and El Paso. In addition to serving as engineering advisor to McClure, the New Mexico State Engineer, Bliss had substantial involvement in New Mexico's contributions to the federal Rio Grande Joint Investigation. *Defendant's Case in Chief*, Vols. X & XI, 2011. CB-F-171A thru CB-F-1716: Transcripts of TX V. NM, Box 4X219, RAHP, UTA; and "Past New Mexico State Engineers," New Mexico Office of the State Engineer / Interstate Stream Commission, available online at http://www.ose.state.nm.us/ProgramSupport/sepastEngineers.php, last accessed May 11, 2019.

[56] In his notes, Hill did not elaborate on what Tipton meant by "depletion."

this schedule. The other advisors, for their part, did not accept it outright but rather indicated that it "might be acceptable."[57]

Bliss, according to Hill, was apparently willing to accept deliveries to Elephant Butte based upon water actually stored in the reservoir in prior years. Yet, New Mexico's engineering advisor was apparently "very fearful of any fixed schedule, on account of uncertainty of physical conditions, particularly as to the amount of tributary inflow between Ottiwi [*sic*] and San Marcial." Hill thought that an agreeable schedule on the basis of prior years' inflow could be found "[i]f some formula can be developed that will protect them against under-deliveries through causes beyond their control."

As discussed in Opinion II, Hill addressed the issue of water quality with Bliss independently of the discussions with Debler and Tipton. Texas's engineering advisor believed that Bliss was sympathetic but unsure of how to proceed. Hill remained hopeful that he could convince Bliss "that some allowance be made for change in quality of water."[58]

For his part, Hill continued to advocate for 800,000 af for Texas via Elephant Butte. In the fact of skepticism from Tipton, Bliss, and Debler, Texas's engineering advisor argued that this quantity of water was necessary to assure downstream lands in Texas with a sufficient quality of water – what he called "equivalent service." Hill privately acknowledged to Clayton that the 800,000 af was open to dispute given recent releases from Elephant Butte and careful operation of the project:

> Unfortunately the project, with 1,500,000 acre feet in storage and more acres in crop than in any other year, or in several years, the release from Elephant Butte has been only about 730,000 acre feet, and will be less than 730,000 acre for the entire year 1937. This desire to save water in one year, when there was every reason for using larger amounts, has made and will make it very difficult to substantiate the 800,000 acre feet requirement, especially as we can look to some reduction in diversion, particularly on that to Mexico.
>
> The economy in use this year may cost the project 50,000 acre feet annually hereafter.[59]

Transmountain diversions were also discussed at the engineers' meeting. Debler was of the mind that new water from outside the basin was needed to provide a "permanent solution." Hill grudgingly accepted that if new water was brought into the basin for the benefit of existing lands, "the situation will be corrected automatically." In Hill's view, if a state paid for a water-

[57] Raymond A. Hill, Memo to Mr. Clayton: In re Meeting of Committee of Engineers, at Santa Fe, November 22 to 24, 1937, November 26, 1937, 1-2. [1937], Box 2F467, RGCC-FBCP, UTA.
[58] Hill, Memo to Mr. Clayton, November 26, 1937, 2. [1937], Box 2F467, RGCC-FBCP, UTA.
[59] Hill, Memo to Mr. Clayton, November 26, 1937, 2-3. [1937], Box 2F467, RGCC-FBCP, UTA. Notably, 730,000 af was the quantity of water first appropriated by Reclamation for the Rio Grande Project in 1906.

importation project, it should receive sole benefit of the water. If the federal government brought new water to the Rio Grande, however, each of the three states should receive equal amounts of that water. Tipton was strongly opposed to Texas receiving any new water, but he conceded "the equity of the provision" suggested by Hill.[60]

Despite the limited progress Hill described in his account of the November meetings, the engineering advisors arrived at what they believed was the technical basis for a compact by the end of the December meetings. Critically for Texas, Hill secured the concession of 800,000 af from the engineering advisors from Colorado and New Mexico. At that meeting, Bliss offered his own calculations of the project requirements for Elephant Butte. Allowing for delivery of water not only within the project and to Mexico but also to downstream lands in Hudspeth County, "unavoidable" project wastes and losses, "undivertable winter flow," and water necessary to achieve a "salt balance" down to Ft. Quitman, the engineer projected 750,000 af from Elephant Butte. This was the same figure developed by Tipton and offered by Colorado at the September-October compact proceedings.[61]

Yet, both Tipton and Bliss ultimately accepted 800,000 af. Tipton was persuaded, as he later explained to Hinderlider, that this "amount [was] not far different from the proposal made by Colorado [at the compact proceedings], and not far different from the conclusions of the engineers for the N.R.C. [i.e., the Rio Grande Joint Investigation]." "These engineers," he pointed out,

> arrived at two demands on Elephant Butte by two methods of analysis, one demand being 773,000 acre-feet and one being 736,000 acre-feet. The 773,000 acre-foot demand was recommended. Both were based on a delivery of 60,000 acre-feet to Mexico. It was estimated by N.R.C. engineers that the diversions to Mexico in 1930-1936 inclusive above the Tornillo Canal heading averaged 130,000 acre-feet per year. Therefore, if these diversions were reduced to 60,000 acre-feet there would result a saving of 70,000 acre-feet, and the normal release from Elephant Butte Reservoir would become 800,000 acre-feet, minus two-thirds of 70,000, or about 753,000 acre-feet. This is almost exactly the average between the two demands worked out by the engineers of the N.R.C. and practically the same as the 750,000 acre-feet suggested by Colorado in October, 1937, which was based upon a diversion to Mexico of 60,000.

This reasoning appears to have held true for Bliss as well. On December 22, as the engineering advisors prepared to draft their recommendations, he informed McClure by letter that all had

[60] Hill, Memo to Mr. Clayton, November 26, 1937, 3. [1937], Box 2F467, RGCC-FBCP, UTA.

[61] [Raymond Hill], "TEXAS COMPACT: John Bliss Estimate of Project Requirements at Elephant Butte," 12/17/37. CB-F-137-34, Box 4X215, RAHP, UTA; and "John Bliss Estimate of Project Requirements at Elephant Butte," typescript, n.d. CB-F-137-34, Box 4X215, RAHP, UTA.

agreed that "the Elephant Butte Project [would]…be limited to annual releases of 800,000 acre feet reduced by two-thirds of the savings to be made by limiting Mexico."[62]

In the resulting "Report of Committee of Engineers to the Rio Grande Compact Commissioners," dated December 27, 1937, the engineering advisors noted that they had "avoided discussion of the relative rights of water users in the three States." Instead, they "were guided…by the general policy – expressed at the meeting of the Compact Commission in October – that present uses of water in each of the three States must be protected in the formulation the Compact," as "the usable water supply is no more than sufficient to satisfy such needs." The engineers further recognized that "precise determination of past conditions and close estimates of future changes" were "not possible," so they recommended "review of these matters" by the commission "after five years and for adjustments within the intent of the Compact."[63]

For the purposes of their discussion on how to distribute equitably the existing water among the three states, the engineers recognized the three natural divisions of the Upper Rio Grande Basin:

1. San Luis Valley – "the drainage area above the Lobatos gaging station on the Rio Grande near the Colorado-New Mexico State Line;"
2. "The Middle Rio Grande from Lobatos to Elephant Butte Reservoir…;"
3. "The balance of the Rio Grande Basin from Elephant Butte and Fort Quitman, including the Juarez Valley in Mexico."

The main issue with respect to Colorado was to adopt a state-line delivery schedule to New Mexico. The engineers noted that there was a "consistent relationship…between the combined inflow of the major streams flowing into San Luis Valley and the outflow of the Rio Grande at Lobatos." Construction of upstream storage reservoirs would disrupt this relationship so the engineers offered "separate schedules [of water delivery] for the Conejos and Rio Grande stream systems." These schedules would "automatically" compensate for "variations in discharge of contributing streams…particularly, if storage reservoirs are constructed." "The obligation of Colorado to deliver water in the Rio Grande at the Colorado-New Mexico State Line" the engineers observed, "would be the sum of the quantities set forth" in the schedules provided, subject to certain permissible departures. Use of these schedules would permit "appropriate

[63] Hill, Memo to Mr. Clayton, November 26, 1937, 3. [1937], Box 2F467, RGCC-FBCP, UTA; "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission, Held at Santa Fe, New Mexico, March 3rd to March 18th, inc., 1938, Appendix No. 1, 40. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

adjustments…[to] made for any trans-mountain diversions, for any change in location in gaging stations, and for any new or increased depletion of natural run-off at gaging stations above Lobatos."[64]

With regard to New Mexico's obligation to Texas, the engineers observed that "wide variations in the discharge of tributary streams" rendered the "amount of water in the Rio Grande above the principal agricultural areas of New Mexico and inflow into Elephant Butte Reservoir" inconsistent and unpredictable. After careful study, they agreed that a "reasonable relationship" existed "between the discharge of Rio Grande at Otowi Bridge and the inflow to Elephant Butte Reservoir," excluding the months of July, August, and September. Removing these three months from the calculations, the remaining data could be used to adopt a proper schedule of deliveries at Otowi Bridge to obtain the appropriate supply of water at Elephant Butte. The curve then required some adjustment "to compensate for increased salinity of the Elephant Butte supply." The New Mexico's obligation to deliver water into Elephant Butte Reservoir was subject to several factors: a system of accrued credits and debits on annual scheduled deliveries; "appropriate adjustments…for any change in points of measurement"; "any new and increased depletion in New Mexico of the natural runoff measured at Otowi Bridge"; and "any trans-mountain diversions between Lobatos and Elephant Butte."[65]

The engineers set an average of 800,000 af per year as the "normal release" from Elephant Butte Reservoir – the quantity for which Hill and Clayton had argued. This release was subject to "any gain and loss in usable water resulting from the operation of any reservoir below Elephant Butte." As both Tipton and Bliss indicated to their commissioners, it would also be "reduced or increased by two-thirds of any change in aggregate diversions and loss to Mexico between Courchesne gaging station and the lowest point of diversion to lands of the Rio Grande Project." The suggested index used to determine the amount of change was "the average annual diversion and loss to Mexico from 1928 to 1937." Should "normal release…[be] modified by any change in the amount of diversions and loss to Mexico," Colorado and New Mexico had to "share equally" with

[64] "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 1, 40-42. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

[65] "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 1, 42-44. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

their "accrued credits or debits…adjusted annually by an amount equal to one-third of such change in diversions and loss to Mexico."[66]

Although the engineers recognized that natural variations in discharge at their selected control stations and additional storage of flood waters in upstream reservoirs would require appropriate adjustments to delivery schedules, they established definite limitations on accrued debits and credits. Colorado's annual or accrued debit was capped at 100,000 acre-feet, except as caused by storage in reservoirs constructed above Lobatos after 1937. New Mexico's allowable accrued debit was capped at 200,000 acre-feet, except as caused by storage in reservoirs in New Mexico. However, in both states accrued debit caused by such storage could not exceed the amount of water held in storage in such reservoirs. If in any year the total accrued debits of Colorado and New Mexico exceeded "the difference between the total capacity of [Rio Grande] Project storage and the amount of usable water then in storage, such debit shall be reduced proportionally to an aggregate amount equal to the minimum unfilled capacity in that year." If there was unusable spill from Elephant Butte, all accrued debits of Colorado and New Mexico for that year would be cancelled, "excepting debits caused by storage in reservoirs prior to the time of spill."[67]

Accruals in excess of the limits established for Colorado and New Mexico, respectively, could be applied to offset debits caused by storage in reservoirs. In computing accrued credits or debits, annual credits in excess of 150,000 acre-feet were to be taken as equal to that amount. If unusable spill occurred at Elephant Butte Reservoir, the aggregate credits of Colorado and New Mexico would be reduced by the amount of such spill in proportion to each state's respective credits at the time of the spill. "[N]o credits…[would] be considered in a year of spill."[68]

The report also proposed specific protections for the Rio Grande Project water supply. "[W]henever there [was] less than 400,000 acre-feet of water in storage available for use in the Rio Grande Project," neither Colorado nor New Mexico would be allowed to increase storage in any reservoir built after 1929 in the Upper Rio Grande Basin. Furthermore, if the same minimum stage was reached on January 1 of any year, Colorado and New Mexico had to "release on

[66] "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 1, 45 and 47. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

[67] "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 1, 45-46. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

[68] "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 1, 46. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

demand, at the greatest rate practicable, water from reservoirs in the amount equal to the total debit of each which was caused by storage of water in reservoirs."[69]

In addition to adjusting the curve for New Mexico's deliveries into Elephant Butte to compensate for increased salinity in the reservoir, the engineers also recommended a limitation on the salinity at the Colorado-New Mexico state line. It was still unclear whether or not Colorado's "Closed Basin Drain" would be constructed and what effect the drain would have on the salt content of the Rio Grande downstream. Therefore, the engineers suggested that if any works were constructed after 1937 to deliver water from the Closed Basin Drain into the Rio Grande, Colorado would only be credited for the water so delivered if "the proportion of sodium ions is less than 45% of the total positive ions in that water."[70]

Concluding their report, the engineers offered their recommendation for the basis of a compact. They noted that "no material expansion of the irrigated area in the Rio Grande Basin above Fort Quitman" was feasible without transfers of water from outside the basin. Acknowledging that "[g]ood use could be made of this [imported] water," they nevertheless determined that the "allocation of any supply so obtained constituted a matter of policy beyond our province." Therefore, "no recommendation [was] made" on this issue. Three other recommendations were:

1. "…that the normal release from Elephant Butte Reservoir be deemed to be 800,000 acre-feet per annum, adjusted for gains or loss of usable water resulting from the operation of any reservoir below Elephant Butte," and "that this normal release be reduced or increased by two-thirds of any change in aggregate diversions and loss to Mexico."
2. "…that deliveries by New Mexico into Elephant Butte Reservoir be made in accordance with the schedule based on the flow at Otowi Bridge and the usable supply at Elephant Butte, subject to proper limitations on departures" (as outlined in the table in the report, "Deliveries Into Elephant Butte Reservoir Exclusive of July, August, and September").
3. "…that deliveries by Colorado be the sum of the amounts set forth in the schedules for the Conejos stream system and for the Rio Grande system, exclusive of Conejos River, both subject to proper limitations on departures."

[69] "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 1, 46-47. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.
[70] For more on the water quality requirements at the Colorado-New Mexico state line, see footnote 120 below.

Inclusion of the delivery schedules and other provisions of the report, in the opinion of the engineering advisers, would result in both "the maximum practicable use of the waters of the Rio Grande, and would minimize unusable spill at Elephant Butte."[71]

Confident that progress was being made toward an interstate compact, Texas filed a motion in December for a continuance of the *Texas v. New Mexico* hearings, which Warren subsequently granted. A month later, Clayton forwarded a copy of the report of the committee of engineers to the special master. Texas's commissioner confessed that the report "means more to an engineer than to a lawyer," but after having Hill explain the approach and conclusions, he and the other attorneys for Texas had been convinced that it represented "a reasonably fair compromise of the views of the three States and provides a fairly workable basis for a permanent compact."[72]

Although all of the engineering advisors signed off on the December 1937 report and recommended its adoption by the compact commission, McClure objected to the report in late January 1938. Even before the report was completed, he had reservations. When the New Mexico state engineer and compact commissioner learned the general outlines of the report on December 22 from Bliss, McClure confidentially told his advisor that the 800,000 af release "will not be agreeable."[73]

The New Mexico commissioner's opposition hardened in the wake of a detailed analysis of the December 1937 report prepared by MRGCD consulting engineer H.C. Neuffer. After reviewing the engineering advisors' report in January, Neuffer forwarded a six-page memorandum to Bliss critical of the work. In his transmittal letter he suggested re-consideration "of the schedules of delivery at San Marcial or Elephant Butte," and recommended that "the figures upon which the curves" of the "usable supply at Elephant Butte" be obtained as he was having difficulty deriving those curves based upon the data he had on hand.[74]

[71] "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 1, 47. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver. Water quality is also discussed in Opinion II below.

[72] Charles Warren to Frank Clayton, December 21, 1937; and Frank B. Clayton to Charles Warren, January 27, 1938. [1938], Box 2F467, RGCC-FBCP, UTA.

[73] Bliss to [McClure], December 22, 1937; and T.M. McClure to John H. Bliss, telegram, 1937 Dec 24 AM 10 27. Rio Grande Compact – July 7, 1937 to June 30, 1938, 26th Fiscal Year, NM_0015692 – NM_00156929 and NM_00156927.

[74] Two weeks after this letter, and after receiving his own from Neuffer, McClure contacted Hill to obtain "the data used in corrected the Elephant Butte storage figures and thereby arriving at your [Hill's] Usable Supply table." Thomas M. McClure, Engineer, to Mr. Raymond A. Hill, January 14, 1938. Rio Grande Compact – July 7, 1937 to June 30, 1938, 26th Fiscal Year, NM_00156897.

Neuffer and the district's "chief objection," as Bliss privately informed Tipton, was the report's recommended "normal release" of 800,000 af from Elephant Butte. According to New Mexico's engineering advisor, "The Middle Valley people have set their mind upon a much smaller figure as ample Project release annually." Indeed, Neuffer argued that figure "need not be in excess of 700,000 acre feet per annum." The MRGCD consulting engineer pointed in his memorandum that over the past decade, 1927 to 1936, 781,000 af on average had been released from the reservoir – a figure inclusive "of excessive quantities of water delivered to Mexico, avoidable project wastes, and savings which can be made after the channel rectification is completed."[75] He calculated that as little as 686,000 af could satisfy "Project use above El Paso," "Mexican Treaty Requirements plus river loss to riverside drain in Mexico," "Unavoidable project wastes below Riverside heading," "Winter discharge of Project drains in New Mexico not redivertable," and "Net project diversions below El Paso." In Neuffer's mind, 700,000 af "would be liberal allowance" for Elephant Butte Reservoir. The engineer nonetheless conceded the necessity for negotiation, and expressed his openness to 750,000 af "as the very maximum figure without injury to New Mexico or the Middle Valley" – the same figure suggested by Tipton and Bliss prior to the December 1937 report.[76]

---

[75] For more on this channel rectification program, see footnote 169 below.

[76] H.C. Neuffer, Consulting Engineer, to Mr. John H. Bliss, State Engineer's Office, Re: Report of Committee of Engineers to Rio Grande Compact Commissioners, December 27, 1937, January 7th, 1938. NM_00054005; H.C. Neuffer, Memorandum, Subject: Report of Committee of Engineers to Rio Grande Compact Commissioners, December 27, 1937, np [1-3, and 6]; JHB, Engineer, to Mr. R.J. Tipton, Consulting Engineer, January 14th, 1938. Rio Grande Compact – July 7, 1937 to June 30, 1938, 26th Fiscal Year, NM_00156900 – NM_00156902, NM_00156905, and NM_00156892 – NM_00156894.

The other objections included adjustments to be made for Caballo; accounting for losses to Mexico; the tally of 2,638,860 af for the "maximum storage for the Rio Grande Project"; language in the December 27, 1937 report concerning "unusable spill"; "the arbitrary figure of 400,000 acre feet storage in Project reservoirs, below which all storage debits of the upper basin states could be called for by the Project"; and the relation between Colorado-New Mexico state line deliveries and Otowi. Independently, Bliss expressed second thoughts as to the exclusion of the months of July, August, and September, in the Otowi-Elephant Butte index – although Neuffer had "no serious objection" to this. See Neuffer, Memorandum, December 27, 1937, np [1-6]; and JHB to Tipton, January 14th, 1938. Rio Grande Compact – July 7, 1937 to June 30, 1938, 26th Fiscal Year, NM_00156900 – NM_00156905, and NM_00156892 – NM_00156894.

On the issue of Elephant Butte releases, Tipton wrote back a few days later that he was "inclined to agree with" Bliss, and that it was "a matter which will have to be thoroughly discussed by the Compact Commissioner." Tipton himself was "going to give more thought to" the issue. Tipton also clarified some matters relating to the 400,000 af figure, and expressed interest in developing "a State Line-Otowi relationship." As to the exclusion of the three months from the Otowi-Elephant Butte index, the Colorado engineer admitted that he "did not follow in sufficient detail your [Bliss], and Mr. Hill's work in connection with setting up the Otowi-Elephant Butte relationship to express an opinion…." R.J. Tipton, to Mr. John H.

Two weeks after writing Bliss, Neufer urged McClure to reject the engineering advisors' report. The MRGCD consulting engineer had thus far been unable to verify portions of the report because "of the availability of the data used by the Committee in working out the relationship of the flow of the Rio Grande at various stations." Moreover, he argued that "[t]here are…certain other items which we feel, if agreed upon, would result in permanent damage to the Middle Rio Grande Conservancy District and other water users in New Mexico above the Elephant Butte Dam." Neuffer did not specify what those are items were in his letter, but they were likely the same as he raised in the memorandum forwarded to Bliss. The MRGCD consulting engineer further offered the services of the district to the engineering advisors.[77]

McClure formally objected to the "Report of the Committee of Engineers" in a January 25, 1938 letter to Harper. The New Mexico state engineer indicated that he had given the report "additional consideration," and was now "in thorough accord with the position taken by Mr. Neuffer." McClure had also discussed the work "with others in authority representing the State of New Mexico," and all were of the same mind to reject it. He dismissed the report as "too vague and indefinite in some respects," lacking a sufficiency of data to support "the relationship of flow at various stations." The "basis for the water supply to the State of Texas," furthermore, was in McClure's "judgment and in the judgment of others in authority in New Mexico…so far out of reason that it could not be considered as a basis for negotiations." Most damningly, the New Mexico state engineer asserted that "the engineers in their recommendation plainly exceeded their authority." Rather than "reporting accurate basic data," which McClure understood to be their charge, they offered "a compromise of basic data." Echoing Neuffer, he called "for the engineers to reassemble at the earliest possible moment and give this matter further study."[78]

New Mexico's view of the December 1937 report was in stark contrast to Texas's and Colorado's. Two days after McClure's letter to Harper, which was circulated to the other commissioners, Clayton praised the work of the engineers to the Rio Grande Compact Commission chair. He thought their report offered "a fairly workable basis for the equitable apportionment of the waters of the Rio Grande, without permitting further encroachments upon Texas' already inadequate supply." Texas's commissioner neither accepted McClure's characterization of the

Bliss, January 18, 1938. Rio Grande Compact – July 7, 1937 to June 30, 1938, 26th Fiscal Year, NM_00156881 – NM_00156882.

[77] [H.C. Neuffer] to Mr. Thomas M. McClure, State Engineer, January 13, 1938; and Thomas M. McClure, State Engineer, to Mr. S.O. Harper, Chairman, Rio Grande Compact Commission, January 25th, 1938. ff. 032.1 Rio Grande Basin Corres. re Compact between States of Colorado; New Mexico & Texas re Rio Grande Basin Water Rights, Jan. 1938 thru May 1939, Box No. 936 Rio Grande Basin 023._246., Entry 7, RG 115, NARA Denver.

[78] McClure to Harper, January 25th, 1938. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

work nor believed that the engineers had exceeded their authority. As to the assertion that "the basis for water supply to the State of Texas" was unreasonable, Clayton countered

> It seems to me and to those interested with me in the protection of Texas' water supply that the report contains no recommendations for the benefit of Texas than what she is plainly entitled to. In fact, it makes concessions to the upper States about which we are somewhat dubious. But in the interests of an amicable settlement of our common problems, we are willing to accept the report as a basis for further negotiation…. [T]he engineering representatives of all three States and of the United States, as well, apparently reached the conclusion, after considerable research and negotiation, that the basis suggested in the report will do no more than preserve the status quo as far as the water supply is concerned, while, at the same time, permitting New Mexico and Colorado to proceed with certain desired developments.

He further pointed out

> in passing that the commissioner for New Mexico seems to lose sight of the fact that there is a very extensive section of his own State lying below the Elephant Butte dam, and that its large vested interests are likewise entitled to representation and protection, along with the Middle Rio Grande Conservancy District.

Texas was "unwilling to recede from…the minimum requirements for the protection of Texas' water supply in the report," but was ready "to proceed with negotiations towards a permanent compact, based upon the report of the committee of engineers."[79]

---

[79] Frank B. Clayton, Rio Grande Compact Commissioner for Texas, to Mr. S.O. Harper, Chairman, Rio Grande Compact Commission, January 27, 1938. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

Hill also took exception to McClure's objections in two separate letters to Clayton in early February. In the first, he admitted he was "somewhat amused by McClure's position," in that the New Mexico's compact commissioner "relies more upon the judgment of Neuffer than that of his own deputy." He supported Clayton's position that another meeting of the engineers was unnecessary and the compact commission was the best venue for further deliberation. Raymond A. Hill to Mr. Frank B. Clayton, February 3, 1938. Box 2F466, RGCC-FBCP, UTA.

The tone of Hill's second letter, sent less than a week after the first, was angrier. Noting that Clayton had admonished McClure for failing to recognize the interests of New Mexican lands within the Rio Grande Project (Elephant Butte Irrigation District), Texas's engineering advisor insisted "that the time has come when the State of Texas should cease being the direct representative of an irrigation district situated in New Mexico." He argued that as long as Texas advocated for the water rights of all lands under the Rio Grande Project, New Mexico officials would identify more strongly with the interests of the Middle Rio Grande Conservancy District. Hill suggested that "pressure" be brought to bear on McClure to defend all of New Mexico's interests, and that Texas demand a schedule of deliveries measured at Courchesne for its lands only. Such a schedule would provide roughly 500,000 af for Texas:

(a) for all water diverted or lost to Mexico;

(b) for all consumptive requirements below El Paso;

Hinderlider was similarly critical of McClure. Writing to Harper in early February, he insisted that "Mr. McClure should not unqualifiedly accept the views of Mr. Neuffer," and he strongly opposed including the MRGCD engineers in the discussions. The Colorado commissioner objected further to what he saw as local interests influencing state authorities, insisting "that it will be impossible to reach an interstate agreement so long as every individual group of water users is permitted to inject and insist upon individual points of view." Colorado sought "parity with the two lower states, in the development of her water resources in the San Luis Valley," and Hinderlider believed that the engineers' report "could be accepted in principle as a basis of further discussions and negotiations by the Compact Commission." He suggested that McClure "specifically and definitely point out the items in said report to which he takes exception, and indicate the particular points upon which he desires further information." On this basis, the commission as a whole could determine if the engineers needed to meet again prior to the commissioners.[80]

Because of McClure's letter and the subsequent correspondence from Clayton and Hinderlider, Harper suggested the commission meet on March 3 in Santa Fe. When proceedings re-opened both Clayton and Hinderlider expressed their support of the engineering advisors' report even as McClure rose to repudiate it. Altogether New Mexico's commissioner proposed nine separate specific changes to the report. Before the commission, however, McClure stressed that the two most important issues were: 1) the indexing between Otowi and Elephant Butte "usable [supply]," and 2) use of 800,000 af as the "basis of releases from the Elephant Butte Reservoir." He argued that the engineers offered no "actual factual data" to support the Otowi-Elephant Butte indexing relationship and the release schedules for the reservoir. The 800,000 af was, moreover, "far in excess of past and present average releases and [was] far in excess of their project needs." As evidence of the report's deficiencies, McClure asserted that his office had

---

(c) for drainage outflow in sufficient amount to give a salt balance and provide equivalent service;

(d) for operating waste; and

(e) for water undivertible in the winter and in excess of irrigation demands during the irrigation season.

Hill recognized that this idea had been discussed and rejected previously, but he was of the opinion "that the situation is sufficiently changed to warrant such a demand from Texas." Raymond A. Hill to Mr. Frank B. Clayton, February 8, 1938. Box 2F466, RGCC-FBCP, UTA. As discussed in Opinion IV, such an arrangement was untenable owing to the nature of the Rio Grande Project. No historical evidence, moreover, has come to light that Hill's suggestion was seriously entertained by Clayton or discussed at the subsequent (and last) compact commission meetings in March 1938. See also Littlefield, *Conflict on the Rio Grande*, 202-203.

[80] M.C. Hinderlider, Commissioner for Colorado, to S.O. Harper, Chairman, Rio Grande Compact Commission, February 4, 1938. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

analyzed the indexing stations used in the report and found the Otowi-Elephant Butte indexing in the report inaccurate.[81]

Clayton preferred the commissioners to work out these issues, calling upon the engineering advisors or NRC representatives for clarification as necessary. Harper, Hinderlider, and the engineers themselves, however, were persuaded that the engineers should formally assess the merits of New Mexico's objections. In a presentation the following day (March 4), the engineers indicated their willingness to re-consider their report on the basis of nearly all the issues raised by McClure.[82] With regard to the two key objections – use of an Otowi-Elephant Butte index and the 800,000 af to be released from the reservoir – they agreed "to give further consideration" to New Mexico's proposal for an Otowi-San Marcial index, and to examine "any data in support" of New Mexico's claim that "800,000 acre-feet of water exceeds both past uses and requirements below Elephant Butte," data hitherto unavailable to them. The commissioners concluded that the engineering advisors should meet again to revise their report, with Clayton insisting that New Mexico "furnish the data and other figures on which they predicate their demands" and the commission proceed with negotiations while awaiting a revised report.[83]

That revision took a week to complete. The engineers worked in isolation, joined only by Neuffer who acted as a "witness."[84] A "Memo of Suggested Changes to be Made in the Engineering

[81] S. O. Harper, Chairman, Rio Grande Compact Commission, to Mr. M.C. Hinderlider, Rio Grande Compact Commissioner for Colorado, Mr. Thomas M. McClure, Rio Grande Compact Commissioner for New Mexico, and Mr. Frank B. Clayton, Rio Grande Compact Commissioner for Texas, February 12, 1938. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver; and Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, 1, 3, 5 and 9. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

[82] On two issues the engineering advisors were unwilling to concede to further review. Collectively, they concluded that New Mexico's request "to be relieved of responsibility for Indian or other operations beyond its control" was "a matter…of policy for determination by the Compact Commission." The group further dismissed New Mexico's assertion that their December 1937 report had engaged in a "judicial interpretation" of the Mexican treaty. They were nevertheless open to examining data that New Mexico might have with regard to fixing the figure of present-day use by New Mexico. Proceedings of the Meeting of the Rio Grande Compact Commission...March 3rd to March 18th, inc., 1938, 11-15. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

[83] Proceedings of the Meeting of the Rio Grande Compact Commission...March 3rd to March 18th, inc., 1938, 7-15, and Appendix No. 6, 56-57. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

[84] Neuffer's attendance was prompted by a suggestion by one of McClure's legal advisors, former New Mexico governor Arthur T. Hannett in a stated bid to "save a lot of time." Edwin Mechem, EBID's counsel and a legal advisor to Clayton, immediately objected to what he saw as MRGCD engineering consultant being "substituted for the State's [New Mexico's] expert." Mechem asserted that EBID's interests were greater and that "Mr. Neuffer doesn't represent us." Hannett countered that his suggestion was not to replace Bliss, but simply to include Neuffer. It was a "practical matter," because MRGCD's support for the compact was essential to the compact's ratification by New Mexico's legislature. "For that reason the

Advisors' Report," prepared by Bliss coming out of the March 3 meeting, indicates that altogether 11 revisions were to be made or considered. The most notable of these were the substitution of "an "Otowi-San Marcial relation" for the engineers' recommended "Otowi-Elephant Butte Supply relation," and the reduction in the proposed 800,000 af average "Normal Release from Elephant Butte" per year to 775,000 af. This was close to the figure that the federal Rio Grande Joint Investigation had determined as the demand on the reservoir for the Elephant Butte-Ft. Quitman section of the basin, and 25,000 af more than Tipton and Bliss had calculated ahead and during the engineering advisors' meetings.[85]

Dated March 9 but presented the following day, the revised engineers' report reflected the two key changes sought by New Mexico. An Otowi-San Marcial index (excluding the months of July, August, and September) replaced the original Otowi-Elephant Butte index, and the recommended figure for "normal release from Elephant Butte" was reduced. However, that reduction was not from 800,000 af annually to 775,000 af as suggested by Bliss's "Memo." Instead the normal release was proposed to be "an average of 790,000 acre-feet per annum, adjusted for any gain or loss of usable water resulting from the operation of any reservoir below Elephant Butte."[86]

As discussed above, Hill had been adamant that 800,000 af was critical to serving lands in Texas with a sufficient quantity and quality of water, and it was a position that Clayton strongly supported before the rest of the commission. Nonetheless, the revised report recommended a lesser figure under pressure from interest in New Mexico. The reason for Texas's concession may very well lie in the problem Hill had identified back in November 1937: the fact that in recent years the Rio Grande Project had utilized closer to 730,000 af. Thirty years after the compact had been signed, Hill gave sworn testimony in a deposition for the *Texas and New Mexico v. Colorado*

---

engineering expert of that district," he asserted, "has got at least to have the opportunity to check our figures before we bind ourselves, and that's all we ask." At Hinderlider's suggestion, Neuffer was therefore designated a "witness" rather than a direct participant in the engineering discussions with the commissioners agreeing that his contributions would be at the discretion of the engineers. Proceedings of the Meeting of the Rio Grande Compact Commission...March 3rd to March 18th, inc., 1938, 18-20. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

[85] J.H. Bliss, Memo of Suggested Changes to be Made in Engineering Advisors' Report, March 3, 1937. . Rio Grande Compact – July 7, 1937 to June 30, 1938, 26th Fiscal Year, NM_00156842-NM_00156843. The date, "March 3, 1937," on the face of this document is likely a typographic error. The memo's content makes clear that it was drafted either just before or just after the March 3, 1938 compact meeting, in light of McClure's objections to the December 27, 1937 engineering advisors' report. Additionally, this particular copy of the memo (NM_00156842) appears in sequence of chronologically organized documents between other documents from 1938.

[86] Proceedings of the Meeting of the Rio Grande Compact Commission...March 3rd to March 18th, inc., 1938, 61, 62, and 65. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

suit before the US Supreme Court in 1968 that succinctly explained the 790,000 af figure adopted by the commission and later ratified in the 1938 Compact:

> The 790,000 acre-feet that was arrived at as the normal release, so defined in the Compact, included the water which was obligated to be delivered to Mexico under the Treaty of 1906, the 60,000 acre-feet in the Acequia Madre. So that the allotment on the downstream side of Elephant Butte was really seven hundred thirty for uses in the United States and sixty for uses in Mexico, and the provision that was incorporated that if they used more than sixty in Mexico, it came out of the seven hundred thirty….[87]

Following Debler's presentation and submittal of the written report, the commission recessed until March 11 to give the compact commissioners an opportunity to review the proposed changes to the December 1937 engineering advisors' report. When the commission reconvened, it almost immediately went into a closed session to permit an "informal discussion, off the record" so the commissioners could "speak freely" on points in the report that required "further clarification or change." The precise substance of this discussion is unknown; it went unrecorded by the commission secretary. The recorded proceedings merely indicate that the commission as whole sought "additional information" about the report.

A formal written clarification report was submitted by the engineers on March 11, and before the commission Debler and Hill addressed two specific issues: "the stage of project storage when the upstream reservoirs ceased storing," and the meaning of "average" with regard to the proposed 790,000 af releases from Elephant Butte annually. For the first, Debler explained that the group had settled on 400,000 af as the minimum level of project storage to serve lands below Elephant Butte. As the clarification report went on to detail, if there was less than 400,000 af of usable storage in the reservoir then neither of the upper states could continue storing water in any reservoirs built after 1929. The "intent" (in Debler's words) or "principle" (in Hill's), was that the states would share proportionately in diminished stored water.[88]

As for the second issue, according to Debler, use of the term "average" reflected the engineers' understanding that releases could be greater or lesser from year to year. McClure was concerned about the potential impact of years of releases greater than 790,000 af. Debler assured McClure that the system of debits and credits would protect the upper states from significant depletion. He also made plain that so long as the United States operated the reservoir, it would "bear down

[87] Deposition of Raymond A. Hill. Taken December 4, 1968, 18. ff. Texas & New Mex. v. Colo., w. 66-1061 Texas vs. Colorado, Box 1989 41-240, LF-TAG, TSA.
[88] Proceedings of the Meeting of the Rio Grande Compact Commission...March 3rd to March 18th, inc., 1938, 25-27, and Appendix No. 8, 66. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

awfully hard so those boys down there [i.e., the waterusers] don't short themselves in low periods as they have in the past."[89]

Following this presentation, the commissioners' focus shifted to the drafting of the compact. They accepted these revisions and appointed a "Drafting Committee" to put the final document together. The legal advisors to the commissioners comprised this committee: Corlett and Carr for Colorado; former New Mexico governor Arthur Hannett and Fred E. Wilson for New Mexico; and Burges and EBID attorney Edwin Mechem for Texas. No federal representative was available to attend, so the attorneys for the state commissioners worked out a draft. The full commission recessed for nearly a week, from March 11 to March 17, as the legal committee deliberated. "Several closed and informal meetings of the Commission," according to the recorded commission proceedings, "were held." At these meetings "controversial questions were discussed with the Drafting Committee and the engineering advisors and differences were resolved" confidentially with "[n]o record of these meetings…kept."[90]

The engineers reviewed at least one draft of the compact dated March 16. A memorandum signed by all of the engineering advisors and Neuffer and dated that same day suggested some changes. They recommended, for instance, the inclusion of a paragraph compelling the Commission to undertake "special studies" of the flow at San Acacia, San Marcial, and below Elephant Butte should "the necessity arise" for "an equivalent schedule." The engineers also suggested "[a]mplifying" paragraph 15 of the draft compact like so:

> During the month of January of any year the Commissioner for Texas may demand of Colorado and New Mexico, and the Commissioner for New Mexico may demand of Colorado, the release of water from storage reservoirs constructed after 1929 to the amount of the accrued debits of Colorado and New Mexico, respectively, and such release . . .

"In the next to the last line" of this paragraph, they further called for the addition of the phrase "of 790,000 acre-feet" to modify the term "release."[91]

On March 17, 1938, the Drafting Committee submitted their final compact draft to the commissioners who accepted it unanimously the following day. Although no provision was made in the final document for the "special studies" suggested by the engineers, Article IV required that "[c]oncurrent records…be kept of the flow of the Rio Grande at San Marcial, near San Acacia,

[91] Proceedings of the Meeting of the Rio Grande Compact Commission...March 3rd to March 18th, inc., 1938, Appendix No. 9, 68-70. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

and of the release from Elephant Butte Reservoir, to the end that the records at these stations may be correlated." The final draft also incorporated the language suggested by the engineers for paragraph 15 as Article VIII.[92]

The state compact commissioners, Clayton, Hinderlider, and McClure, soon after forwarded the document to their respective governors, and in the case of Harper, to the secretary of the interior. In his November 1938 transmittal letter to Governor W. Lee O'Daniel, Clayton expressed his opinion that the "compact represents a fair and equitable settlement of the controversies that have raged almost continuously for over forty years between the three States." "As far as Texas is concerned," the commissioner wrote, "it in effect prevents further encroachments on the waters of the Rio Grande by the upper basin States.""[93]

Letters by Hinderlider, McClure, and Harper all evoked the same optimism, even as each touted the individual benefits of the compact of their respective states or for the United States. Hinderlider "believed" that the "interstate River Compact or Agreement…equitably allocates the waters of the Rio Grande Basin originating above Fort Quitman, Texas, between the States of Colorado, New Mexico, and Texas." For Colorado specifically, he informed Governor Teller Ammons a few days after Clayton wrote O'Daniel, the "permanent compact…fully protects present and future uses of waters in the San Luis Valley, and the San Juan Basin in Colorado against exportations of water out of that basin for use in the Rio Grande Basin in New Mexico, except upon the conditions stated in the Compact." That protection further extended, according to Hinderlider, to "the rights of the water users under federal reclamation projects in New Mexico and Texas," as well as to "Indian tribes, and to the Republic of Mexico under existing treaty obligations."[94]

McClure used almost identical language to Hinderlider in his letter to New Mexico Governor John E. Miles in January 1939. "The Compact," he wrote, "fully protects present and future uses of the waters of the Rio Grande stream system in New Mexico." He envisioned an end to the controversies over the use of the Rio Grande waters with the compact, "particularly the suit

Hinderlider, Commissioner for Colorado, to His Excellency, Governor Teller Ammons, State Capitol, Denver, Colorado, November 15, 1938, in *Rio Grande Basin Compact* [and Analysis Thereof by M.C. Hinderlider in Address to Colorado Legislature and to Gov. Teller Ammons on Nov. 15-1938], 5-9. ff. 58 Rio Grande Basin Compact, Box 44-70, MSS 312, MCHC 1897-1987, HC.

between the States of New Mexico and Texas now pending in the Supreme Court of the United States."[95]

Likewise, writing to Secretary of the Interior Harold Ickes, days following the conclusion of the compact negotiations in March 1938, Harper was unequivocal: "The Compact, if ratified, will end over forty years of controversy and dispute among the States, and it is the unanimous opinion of the Commissioners and their advisors that it provides an eminently fair and equitable solution of this troublesome problem." Harper believed that U.S. "interests" were "fully safeguarded" in the compact, in part as a result of the "inclusion, in the State allocations, of all water to which Federal irrigation projects are entitled."[96]

Although some Texans below Ft. Quitman expressed concerns for the compact (discussed in Opinion IV), all three states and the United States ratified the agreement in 1939.[97] As the statements of the compact commissioners indicate, all those representatives believed that the compact equitably apportioned the waters of the Rio Grande above Ft. Quitman after several decades of controversy. That apportionment protected the Rio Grande Project in New Mexico and Texas, which also served lands down to Ft. Quitman, and gave Colorado and New Mexico above Elephant Butte the freedom to pursue new water projects. The water delivery schedules devised by the engineering advisors for the three states were the basis for that apportionment, and reflected the understanding among the engineers that in the absence of a transfer of additional water into the Upper Rio Grande Basin the Rio Grande was fully appropriated.

Miles Papers, NMSA; and United States of America, *Congressional Record: Proceedings and Debates of the 76th Congress, First Session*, Volume 84-Part 6, May 19, 1939, to June 9, 1939 (pages 5771 to 6948) (GPO, 1939), 6589.

Opinion II: The quantity of water apportioned to Texas by the 1938 Rio Grande Compact included flows to address water quality concerns for Rio Grande project lands in Texas.

As noted in Opinion I, the quantity of water to be apportioned to Texas by the 1938 Rio Grande Compact was inextricably linked to the quality of water. The loudest voice for water quality belonged to Texas's engineering advisor Raymond A. Hill. Hill was vociferous in his advocacy of flows to mitigate the salinity of irrigation water reaching downstream lands in Texas. In the *Texas v. New Mexico* original action, in the compact proceedings, and before his fellow engineering advisors, he was adamant that an 800,000 af release from Elephant Butte was essential to achieving a "salt balance." Broadly speaking, Hill argued that Texas required more water than it could use consumptively to ensure that little or no additional alkali salts were deposited as a result of irrigation on downstream lands to the detriment of those lands. The 800,000 af figure reflected his calculations of what was necessary to achieve what he called, "equivalent service." Neither of Hill's counterparts in Colorado and New Mexico, Royce Tipton and John Bliss, readily agreed that such a large release from Elephant Butte was justified. The federal Rio Grande Joint Investigation, which aimed to provide the requisite technical data to craft a compact, similarly did not assess a sufficient quantity of water to achieve Hill's equivalent service. With the completion of the federal investigation and the resumption of negotiations in late 1937, Texas's engineering advisor redoubled his efforts to convince his fellow advisors that 800,000 af was the appropriate amount – and he succeeded. The December 1937 engineering advisors' report recommended 800,000 af as the "normal release" from Elephant Butte. Although this figure was reduced to 790,000 af after New Mexico's compact commissioner Thomas McClure objected (reflecting the concerns of upstream interests in New Mexico), Texas's acceptance of this reduction and the compact indicates that 790,000 af was inclusive of the flows necessary to achieve Hill's "equivalent service."

Salinity was a known issue within the stretch of the Rio Grande between Elephant Butte Reservoir and Ft. Quitman. Beginning in the 1920s, the Bureau of Reclamation (Reclamation), the US Department of Agriculture (USDA), and the International Boundary Commission (predecessor to today's International Boundary and Water Commission), responsible for overseeing the provisions of the 1906 treaty with Mexico, had made various measurements and analyses of water quality and salt concentration in the river and at riverside drains. In 1929-1930 and in 1933-1934, Rio Grande Project drainage waters were the subject of close study. According to project superintendent L.R. Fiock, in 1933 alone water from the reservoir carried 600,000 tons of dissolved salts. As noted below and discussed in Opinion IV, Reclamation purposefully released additional water from Elephant Butte to compensate for increased salinity at the lowest end of the project, which further benefitted lands downstream to Ft. Quitman.[98]

The issue of water quality with regard to the quantity of Rio Grande water to be apportioned to Texas by a compact, however, was not clearly articulated until Texas filed suit against New Mexico and the Middle Rio Grande Conservancy District (MRGCD) in the US Supreme Court in October 1935. Texas alleged that New Mexico "violated the [1929] Compact by impairing the water supply in the Elephant Butte Reservoir through excessive diversions and through injurious increase of the salt contents of the water," and "that such excessive diversions and increase of salt contents were in violation of the rights of Texas waters users." As discussed in Opinion I, New Mexico denied this claim and instead asserted that illegal Mexican diversions and inefficient operation of Elephant Butte were to blame.[99]

Quantity and quality of water reaching lands in Texas went hand-in-hand, as Frank Clayton, attorney for Texas and the state's Rio Grande Compact commissioner, explained to Special Master Charles Warren near the outset of the hearings in November 1936. Clayton, citing Article XII of the 1929 compact that the water supply for Elephant Butte "shall not…be impaired by new or increased diversions or storage on the upper Rio Grande," argued that "the increased diversion in the Middle Rio Grande District has impaired both as to quality and quantity." Compensation for the diminished quality, the attorney insisted, "required an increased quantity in order to give equivalent service."[100]

Although Fiock testified that Reclamation released water "for the purpose of washing out salts," characterizing this practice as "both beneficial and necessary," much of the testimony and evidence for Texas's argument was offered by Hill and his associate (later partner) J.Q. Jewett.[101]

[101] John Q. Jewett earned his Bachelor of Science in Civil Engineering from the University of Colorado in 1920, and like Hill, later received "the degree of Civil Engineer." He was an instructor at the university during the 1922 and 1923 academic years. After the University of Colorado, Jewett joined the Yaqui Valley Irrigation Project in Mexico as an "office engineer," rising the position of "assistant to the Chief Engineer."

Using a demonstrative exhibit, Hill endeavored to explain to Warren the dynamic between irrigation, drainage, and increased salt concentration in the waters of the Rio Grande as it moved downstream. The illustration from which the engineer spoke compared a typical cross-section of the Rio Grande Valley as it would appear in “a state of nature” to that same cross-section “after irrigation and drainage.” Hill noted that part of the water from the irrigation canal passed out to the land, carrying with it salts in solution. Some of that water was lost into the atmosphere as vapor, and carried no salts. Part of the water consumed by crops, the excess over the consumptive use, passed into the ground and found its way to the drainage system. Only part of this water reached the drain, but in a well-designed irrigation system, no salts can be allowed to accumulate, Hill pointed out. If it did, the land would become unfit for cultivation over time. In a successful drainage system, the engineer emphasized, there had to be a continuous movement of salt from the canal to the drain – i.e., as much salt must reach the drain as left the canal. Therefore, water in the drain would necessarily have a higher salt concentration than the water in the delivery canal. These drains necessarily connected and discharged back into the river, with the result of increased salinity as in the Rio Grande as the river flowed downstream.[102]

Jewett pointed out in his testimony that this was in fact the case for land in Texas. Water quality analyses, he argued, indicated that there had been an accumulation of salts between Courchesne, Texas (immediately upstream from El Paso) and Ft. Quitman in every year from 1930-1935, inclusive, a period of consistent record. The accumulation varied from 141,000 tons in 1931-1932 to 345,000 tons in 1934. The total salt accumulation during the entire six-year period, 1930-1935, was nearly 1.3 million tons. The purpose of Jewett’s testimony, Clayton told the special master, was “to show whether we are increasing the concentration of [salt in] the soil through too sparing use of the water.” Or, put in another way, “how much water is necessary to be used to maintain a balance.” Jewett indicated that the evidence pointed to a substantial salt balance between Elephant Butte and Courchesne, lands largely in New Mexico, but a salt balance between Courchesne and Ft. Quitman, lands in Texas, was “not being maintained by a very wide margin.” If the same area was to be irrigated under the same conditions and the same amount

---

In 1926, Jewett joined Quinton, Code & Hill, Leeds & Barnard. He assisted in the water supply-hydroelectric power study the firm made of Elephant Butte Dam in the 1920s, and in the 1930s, oversaw the company’s work on water supply studies of the federal Salt River Project in Arizona. *Plaintiff’s Case in Chief*, Vols. I, II, 215-216. CB-F-171A thru CB-F-1716: Transcripts of TX v. NM, Vol. 1-16, Box 4X219, RAHP, UTA

[102] *Plaintiff’s Case in Chief*, Vo. I, II, 409-416; and Vol. III, IV, 603-615. CB-F-171A thru CB-F-1716: Transcripts of TX v. NM, Vol. 1-16, 4X219, RAHP, UTA.

of water consumed, the only way to produce a more favorable salt balance, the engineer testified, would be to "increase the supply at the head of the valley."[103]

To accomplish this, Hill testified that 800,000 af was the necessary release of water for lands below Elephant Butte. This was the "maximum amount which can be properly withdrawn" from the reservoir, according to the engineer, based upon recorded releases from the reservoir over the past decade. Hill calculated that gross consumptive use between the reservoir and Ft. Quitman over the previous decade (1925-1935) had amounted to 675,000 af: 300,000 af from Elephant Butte to Courchesne, and 375,000 af from Courchesne to Ft. Quitman (including land in Mexico). The engineer further estimated that the "average total consumption" between Elephant Butte and Ft. Quitman "under present conditions of distribution of crops" at 3 af per acre (af/a), and in his judgment, 50,000 af of unavoidable operating waste was a "reasonable allowance" for the Rio Grande Project. Beyond these figures, Hill argued that an additional 145,000 af was necessary to maintain a "salt balance" for the lands between Courchesne and Ft. Quitman. Cumulatively, these figures were in excess of 800,000 af by 70,000 af. This led to additional testimony by Hill ascribing the additional water use to Mexican diversions above the 60,000 af prescribed by the 1906 treaty.[104]

An undated memorandum, "Equivalent Service Under Present Conditions (Hill)," located in Clayton's papers at the Dolph Briscoe Center University for American History at The University of Texas at Austin sheds additional light on the salt balance Hill believed necessary. According to this memorandum – which may be Clayton's summary of a larger analysis prepared by Hill or which may have been prepared for Clayton by Hill – "[t]he "average concentration of water available for diversion to the El Paso Valley [as] 50% greater than the concentration of water available for diversion to the valleys above El Paso at the present time." To achieve equivalent service in the valley, therefore, "the farm duty should be about 1.5 greater than for the other valleys [above El Paso, i.e., Palomas, Rincon, and Mesilla]." "However," the memorandum acknowledged, "this excess is evidently not available even under present conditions."[105]

New Mexico challenged this analysis. John Bliss, New Mexico's engineering advisor and an expert witness called by the state, in particular offered an alternative view. He acknowledged that the further downstream water travelled from Elephant Butte, the higher the concentration of salts. However, Bliss argued that project "officials dilute the entire flow of the river to produce a

satisfactory quality" at the lowest end of the project – the "Tornillo unit." As much as 50,000 af, New Mexico's engineer calculated, was passed out of the project to achieve this balance at Tornillo. In fact, passing this much water, Bliss further observed, resulted in lands outside the project, in Hudspeth County above Ft. Quitman receiving as much 38,000 af of reservoir water.[106]

As discussed in Opinion I, after nearly five months of testimony and argument, Warren was unable to arrive at suitable findings of fact for the Supreme Court. The amount of data presented and analyzed in testimony was considerable. The special master nevertheless found the evidence regarding the salt content of Rio Grande water "limited" and "unsatisfactory." At the urging of counsel for Texas, New Mexico, and MRGCD, he recommended in March 1937 that the case be stayed, in part until the federal Rio Grande Joint Investigation completed its studies of the water resources of the Upper Rio Grande Basin.[107]

Water quality was a critical concern for Texas in the federal investigation, but Colorado and New Mexico were initially hesitant to examine the issue of salinity. The Middle Rio Grande Conservancy District was especially opposed. Federal engineers, however, concurred with Texas as to the necessity of the work, as did representatives from Colorado following an organizational meeting of the Rio Grande Joint Investigation held in Santa Fe in late April and early May 1936. The USDA Bureau of Plant Industry and its principal agriculturalist, C.S. Scofield, were charged with the study of water quality in the basin as part of the federal investigation. Although Texas did not contribute to that investigation as Colorado and New Mexico did, Hill endeavored to relay what he believed was the appropriate consideration of "equivalent service" to the federal investigators.[108] In particular, he provided Scofield with the mathematical formula for "service

[106] *Defendant's Case in Chief*, Vols. X & XI, 2011. CB-F-171A thru CB-F-1716: Transcripts of TX V. NM, Box 4X219, RAHP, UTA.
[107] *Ad Interim Report of the Special Master*, received Mar. 26, 1937, 7-13. ff. RG 267, Entry 26, TX v NM #10, Box 401, Entry 26, RG 267, NAB.
[108] At a series of meetings in Santa Fe in early February 1936, Barrows, Adams, the state engineering advisors, and compact commissioners worked out the plans for the joint investigation – including the work to be done and the various costs of work. Meeting with C. C. Hezmalhalch, deputy state engineer for Colorado, McClure, Clayton, and W.A. Laflin (an engineer working with Clayton's engineering advisor Raymond Hill), Barrows and Adams asked the states to collectively contribute upwards of $55,000 either "in cash or acceptable services." Hezmalhalch indicated that Colorado was willing to provide a third of this amount, "how much, if any…in services to be worked out later." McClure likewise pledged a third for New Mexico "in money or services," but indicated that it "would take a good deal of scratching about to do this." Clayton agreed that an equal division of the cost among the three states was "entirely fair and equitable," but he was unable even after speaking with Gov. Allred to commit Texas to any amount of money. He pledged to "'do his damnedest'" to convince the Texas legislature to "make an emergency appropriation for the purposes of the Rio Grande Compact Commission for the balance of the fiscal year ending Aug. 31, 1937," but subsequent events suggest that he was unable to secure a financial contribution from Texas. Only the Colorado State Engineering Department and the Office of the New

equivalence" that was used in the Bureau of Plant Industry's study for which the federal engineer expressed his indebtedness.[109]

Hill's contribution notwithstanding, the draft *JIR* distributed in mid-August 1937 failed, in his mind and Jewett's, to recommend the necessary for equivalent service. Writing to Texas's compact commissioner Frank Clayton not long after securing a copy of the report, Hill remarked that he was "becoming discouraged at the progress possible." He observed that much of the "discussion of water supply [was] limited to records taken prior to the instigation of the Rio Grande Joint Investigation," and reflected "the opinions" of federal engineers.[110]

In September, in advance of the next round of compact proceedings, Jewett elaborated on the concerns Hill alluded to in his letter to Clayton. The engineer prepared a thorough critique of the draft summary report of *JIR* (which he called Volume I, and which is identified in the final released copy as Part I). Jewett, in particular, took the study to task for failing to appreciate the scope of

Mexico State Engineer are credited in the final report as "Cooperating Agencies" from the three states. Acknowledgments are also given to "the contributions and assistance" of the MRGCD, the San Luis Valley-based Rio Grande Water Users Association, the "Rio Grande Reclamation Project," but to no Texas state agency or local organization. Hill, in his 1968 report on the development of the compact did note that "the engineering advisor to each of the Rio Grande Compact commissioners worked closely with those carrying out the Joint Investigation" – and that certainly seems to be the case where it came to the salinity issue, as discussed below. See Typed notes, Conference in U.S.G.S. office, Santa Fe, 2-4-36, 2-5-36, and 2-6-36. [109] Even before the federal investigation, on the eve of the hearings before Special Master Warren, Hill was in communication with Scofield. During the spring and summer of 1936, he solicited the federal investigator for information and shared his views on the problem. See, for example, Raymond A. Hill to Mr. C.S. Scofield, Division of Western Irrigation, Bureau of Plant Industry, U.S. Department of Agriculture, April 16, 1936; Raymond A. Hill to Mr. C.S. Scofield, Bureau of Plant Industry, U.S. Department of Agriculture, May 12, 1936; C.S. Scofield, Principal Agriculturalist in Charge to Mr. Raymond A. Hill, June 3, 1936. ff. Elephant Butte-El Paso Dists. General Correspondence G352 1935, Box 4X190, RAHP, UTA; and *JIR*, 464.

Hill also explained how he developed this equation for equivalent service in a letter to the investigation's engineer-in-charge, Harlowe M. Stafford, in May 1937. Raymond A. Hill to Mr. Harlowe Stafford, Engineer in Charge, Rio Grande Joint Investigation, May 18, 1937. [1937], Box 2F467, RGCC-FBCP, UTA.

[110] Proceedings of the Meeting of the Rio Grande Compact Commission…September 27, to October 1, 1937, 1. Unnamed folder 5, Box 2F463; and Raymond A. Hill to Mr. Frank B. Clayton, August 20, 1937. ff. Correspondence Business and Legal, 1935-1938, Pamphlets, 1935-1938, Box 2F464, RGCC-FBCP, UTA.

water quality issues confronting downstream lands in Texas. These lands included not only those project lands at the furthest end of the Rio Grande Project, "the Tornillo unit," but also beyond, down to Ft. Quitman, "in the Hudspeth District." Jewett acknowledged that the report observed that "more abundant applications [of irrigation water] are needed to prevent the accumulation of salt in the soil and resultant deleterious effect upon plant growth" in these areas of the basin. Yet, the engineer pointed out, the report failed to recognize "that the concentration of salts in irrigation water may affect the production of crops regardless of whether or not there be an accumulation of salts in the soil." No "consideration," moreover, "[is] given to the possibility that any other portions of the Rio Grande Valley below Elephant Butte [i.e., other than Tornillo or Hudspeth] may be affected either by concentrations of the irrigation water or by accumulation of salts within the area."[111]

Jewett maintained that the draft summary report gave short shrift to "equivalent service" despite Scofield's own use of Hill's formula. In his assessment of the work of the federal investigators, he stressed that "nowhere in Volume I or studies of water supply by R.G.J.I. is any consideration given to the outflow of Rio Grande which should be maintained either from Rio Grande Project or from the basin at Fort Quitman to preserve the irrigated areas in a productive condition by removal of salts." The engineer further remarked, "[n]o consideration is given to the question as to whether there has been a sufficient outflow from the El Paso District above Fabens to preserve a salt balance in that district in the past three years." "[L]iberal allowance for water to the Tornillo District" – on the order of 19,000 af – appeared to the engineer as "an excuse for not giving further consideration to salinity control."[112]

Bringing his appraisal to a conclusion, Jewett expressed the view that Texas and its needs hardly seem to matter to the federal investigators. The "general implication," he wrote,

> is that proposed storage development on Rio Grande in Colorado and New Mexico will benefit developed lands, and probably new lands in Colorado, and will improve the water supply to lands in New Mexico above Elephant Butte. The further general implication is that the lands below Elephant Butte would suffer shortages during drouth [sic] period anyway, and that probably the shortages would not be much worse if conditions in Colorado and New Mexico were to be improved.
>
> It seems to the writer that the answer to the voluminous report of R.G.J.I. can be stated very simply. The purpose of the proposed development on the Upper Rio Grande, principally construction of storage reservoirs, is to regulate the water supply in Colorado and New Mexico to meet as closely as possible the irrigation demands in those areas, and secondarily to conserve the water supply for the purpose of avoiding shortages in

[111] J.Q. Jewett, "Notes and Comments on Volume I of Report of Rio Grande Joint Investigation," September 1937, 41. CB-F-137-11, Box 4X215, RAHP, UTA.

> developed areas, or for the purpose of irrigating new lands. Such being the purpose of the proposed development, it follows directly that the effect upon the lands below Elephant Butte will be an impairment of their water supply in either quantity or quality, or both. This inevitable action of cause and effect cannot be stopped by estimates and opinions, by fortuitous 46-year averages [the years 1890-1935 were used as the basis for calculating water supply], or by an unsound grouping of statistics.[113]

It was within this context, this critical assessment by Texas's engineers that the water quality needs of lands in Texas above Ft. Quitman were not adequately addressed by the federal investigation, that Clayton offered Texas's sole demand when the Rio Grande Compact Commission reconvened in September 1937:

> …that the State of Colorado and New Mexico will release and deliver at San Marcial a supply of water sufficient to assure the release annually from Elephant Butte Reservoir of 800,000 acre-feet of the same average quality as during the past ten years, or the equivalent of this quantity if the quality of the supply is altered by any developments upstream.[114]

Texas's concerns for water quality were thus not limited to developments immediately above Elephant Butte in New Mexico; those concerns extended to the water supply that Colorado proposed to develop from draining the so-called "Closed Basin" in San Luis Valley. When the subject was raised during the September-October 1937 meeting, "[s]peaking for the people at the lower end of the [El Paso] valley," Hill observed that this water was "of a highly undesirable quality [87 percent sodium content]…." Consequently, if it were "added to the Rio Grande it would be necessary for dilution at the lower end to offset it, and we much prefer that it not be dumped into the river."[115]

Federal investigators, Jewett's criticism of the *JIR* notwithstanding, were sympathetic to Texas's desire for an improved quality of water. NRC representative Harlan Barrows echoed Hill's position when called upon by commission chair S.O. Harper to offer his views at that same meeting. After praising the group for tackling the problem of the equitable distribution of the waters of the Rio Grande, Barrows surveyed various possibilities for development of each of the sections of the Upper Rio Grande Basin. The lower end, he believed, unquestionably required a higher-quality water:

> Going to the lower valley, - shall I say for the sake of brevity the El Paso District, meaning the whole lower end, - what does it need if it is to realize, so far as conditions of water

> and land are concerned, its potentialities? Of course, it needs an adequate supply of water, a reliable supply and a supply of good quality…. Hudspeth has poor water and it ought to have good water.[116]

When the development of the technical basis for the compact moved to the respective states' engineering advisors, as discussed in Opinion I above, Hill continued to insist that 800,000 af was the necessary release from Elephant Butte to meet the needs of the project in New Mexico and Texas down to Ft. Quitman. He expressly urged his fellow engineering advisors, Royce Tipton of Colorado, Bliss and E.B. Debler for the United States, to adopt "the 800,000-acre-feet requirements" for the benefit of Texas during their November 1937 meetings. Tipton and Bliss, Hill noted in a memorandum to Clayton, expressly opposed this quantity. "I showed them," the engineer explained

> …by different methods of calculation that this amount [800,000 af] would be needed for equivalent service to lands below El Paso, in the Rio Grande project, or to maintain a salt balance in the El Paso area. In fact, it worked out about the same either way. If the salt balance is maintained, then equivalent service is given, and vice versa.[117]

According to Hill, New Mexico in particular did "not want to accept responsibility of furnishing Texas any additional water for salinity control in case the quality of water should change adversely." A letter to Texas's engineering advisor prepared by Bliss for McClure less than a week before the November meetings summed up the upstream state's position:

> New Mexico believes that the quality of water available to Texas under present conditions is influenced by so many factors in Colorado, New Mexico and Texas, many of which are uncontrollable and for many of which New Mexico can in no way be responsible, that she is not justified in assuming the responsibility of furnishing Texas additional water for salinity control in case that quality should change adversely.[118]

Hill was not dissuaded. Away from Debler and Tipton at the November meeting, he discussed with Bliss increased water deliveries to address rising salinity levels in the Rio Grande below Elephant Butte. As noted in Opinion I above, Hill believed that New Mexico engineer sympathized with Texas's position on this issue "but does not know how to measure the effect upon the water supply produced by an irrigation development above Elephant Butte." Texas's engineering

Hill, JAH:EM, cc: Mr. Royce J. Tipton, November 16, 1937, 3. Rio Grande Compact – July 7, 1937 to June 30, 1938, 26th Fiscal Year, NM_00156944.

advisor remained hopeful that he could convince Bliss "that some allowance be made for change in quality of water."[119]

As discussed in Opinion I, Hill succeeded by the end of the December meetings. When the group reconvened in Los Angeles, Bliss had prepared his own estimate of the demand on Elephant Butte Reservoir. Out of a total of 750,000 af, the New Mexico engineering advisor had made an allowance of 19,000 af for "Salt Balance & Service Equivalents" – the same amount that the *JIR* made, as Jewett had noted. At the end of the meetings, Bliss and Tipton had both conceded the 800,000 af figure to Hill.[120] The December 1937 "Report of the Committee of Engineers" subsequently adopted the figure as an average for the "Normal Release from Elephant Butte."[121]

---

[119] Hill, Memo to Mr. Clayton, November 26, 1937, 2. [1937], Box 2F467, RGCC-FBCP, UTA.

[120] Hill also sought a water-quality guarantee from Colorado for deliveries made at the Colorado-New Mexico state line, and here he was less successful. Hill's own notes of the engineering advisors' meetings do not disclose much information on this issue, but Tipton discussed the matter in his February 1938 *Analysis of Report of Committee of Engineers to Rio Grande Compact Commissioner, Dated December 27, 1937*. According to the Colorado engineer,

> Due to the fears of Texas with respect to the quality of water below Courchesne, this item was a very controversial one during the meetings of the engineering committee. The Texas representative [Hill] insisted that so far as Colorado was concerned, credits at the stateline should be reduced by one acre-foot for each three ton increase in salt at the stateline over 80,000 tons per annum. Such a provision would have prevented further development in the [San Luis] Valley since Colorado cannot put into effect the proposed plan of reservoir operation without increasing the salt content at the stateline. The proposed provision by the Texas member of the Committee, therefore, was not made a part of the agreement. It was provided, however, that no credit should be claimed by Colorado for water imported from the "Dead Area" which had sodium ions in excess of 45% of the total positive ions. This would prevent the receiving by Colorado of credit for water brought to the river from the sump area proper, but would not prevent its receiving credit for water developed west of the sump, or from water developed from such creeks as Saguache, San Luis, Sand, and east side creeks.

This provision, as noted in Opinion I above, was recommended in the report, and it was ultimately incorporated into the 1938 Compact as part of Article III. Tipton, *Analysis*, 10-1. ff. 70, Box 44-70, MCHC 1897-1987, HC; and "Rio Grande Compact," in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 11, 77. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

Rio Grande Compact – July 7, 1937 to June 30, 1938, 26th Fiscal Year, NM_0015692 – NM_00156929; and "Report of Committee of Engineers to Rio Grande Compact Commissioners," December 27, 1937, in Proceedings of the Meeting of the Rio Grande Compact Commission…March 3rd to March 18th, inc., 1938, Appendix No. 1, 45 and 47. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

Although the 800,000 af figure was later reduced to 790,000 af following objections raised by New Mexico (as discussed in Opinion I above), historical evidence exists that this slightly smaller figure nevertheless encompassed the flows that Hill argued was necessary for "equivalent service." Article XI of the 1938 Compact, for example, states in pertinent part, "New Mexico and Texas agree that upon the effective date of this Compact all controversies between said States relative to the quantity or quality of the water of the Rio Grande are composed and settled…."[122] Such a statement, given Texas's position on the quality of Rio Grande water during the compact negotiations of the late 1930s, is indicative that the 790,000 af figure was sufficient.

Clayton joining with McClure and Hinderlider in signing the compact in March 1938, and later advocating for ratification is further evidence. In a pamphlet "To Water Users Under The Rio Grande Compact" that included a copy of the compact, released soon after the negotiations, Texas's commissioner stressed that the compact "seeks primarily to protect vested uses of water above Fort Quitman, and guard them against future impairment, both as to quantity and quality." Clayton delivered a similar message to water users outside the geographical confines of the compact in May 1938 (addressed in Opinion IV). At a meeting of the Lower Rio Grande Water Users Association, he expressed his conviction that Texas had obtained "every drop of water originating in Colorado and New Mexico that she was entitled to" above Ft. Quitman – a declaration that given his earlier statement would appear to be inclusive of the flows to ensure a sufficient quality of water. To Texas Governor W. Lee O'Daniel in November 1938, Clayton indicated the "engineers, attorneys, and other technical experts" for Texas were similarly convinced. In their collective "judgment," the commissioner confidently predicted to the governor, the compact would "restore a feeling of security to the water users in Texas above Fort Quitman…."[123] Indeed, as noted above (and discussed in Opinion IV below), water users between the end of the Rio Grande Project and Ft. Quitman relied upon unused waters released through the project. These waters possessed a higher quality owing to Rio Grande Project operations intended to ensure a sufficient quality of water throughout the project.

That the quality of the water of the Rio Grande reaching its lands was a central concern for the State of Texas in the negotiations leading to the 1938 compact is clear. The state had singular demand by 1937: the annual release of 800,000 af from Elephant Butte Reservoir "of the same average quality as during the past ten years, or the equivalent of this quantity if the quality of the supply is altered by any developments upstream." Texas's engineering advisor Raymond Hill advocated for this figure, and sought to convince federal engineers and the engineering advisors for Colorado and New Mexico of the necessity of additional flows to Texas above what the state's present consumptive use suggested. The other engineers agreed that lands downstream required an improved quality, but until late 1937 were unconvinced of Hill's projection. Hill managed to persuade them, and while Texas ultimately agreed to a slightly lesser figure of 790,000 af, the state's commitment to the final compact strongly indicates that this quantity of water was inclusive of the flows to ensure water of sufficient quality for downstream lands.

Opinion III: The Rio Grande Project water supply, circa 1938, included not only the surface flow of the Rio Grande captured in Elephant Butte Reservoir, but also all water tributary to the project including groundwater as well as return flows.

At the outset of the federal reclamation program established by the 1902 Newlands Act, federal lawyers and engineers embraced a broad conception of what constituted the water supply for federal projects primarily out of concerns for adequacy. The United States Reclamation Service's principal legal officer Morris Bien argued that while the Newlands Act obligated the United States to recognize state and territorial water laws concerning the appropriation of water, the federal government held dominion over public lands and unappropriated waters. The scale of proposed reclamation projects, moreover, demanded that the US have unique freedom as an appropriator, that the water supply for projects be protected from adverse claims. This latter idea found expression in New Mexico territorial water laws in 1905 and 1907 that drew upon a draft water code prepared by Bien. Legal arguments aside, Rio Grande Project supervising engineer Benjamin M. Hall envisioned the project in 1904 as utilizing all of the waters of the Rio Grande – the surface flow within the river's channel, tributary flows to the river, and groundwater – so as to serve lands in New Mexico and Texas adequately. At the recommendation of Reclamation attorneys, Hall's 1906 filing for 730,000 af was supplemented in 1908 with a filling for "[a]ll the unappropriated water of the Rio Grande and its tributaries." By the early 1910s, federal reclamation authorities were claiming "waste, seepage, spring, and percolating water arising within the project" as well as "return flows," water released from the Elephant Butte Reservoir that was diverted, used on project lands, and returned to the river channel for further use downstream. As Rio Grande Compact negotiations moved forward in the 1920s and 1930s, federal and state engineers alike recognized that surface flows, water tributary to the project including groundwater, and return flows constituted the water supply for the Rio Grande Project.

The 1902 Newlands Act, or National Reclamation Act, that created the Reclamation Service (or Reclamation, predecessor to the present Bureau of Reclamation) was not the first attempt by the US to provide for the irrigation of arid western lands. The act replaced the 1894 Federal Desert Lands Act, better known as the Carey Act after its sponsor Senator Joseph M. Carey of Wyoming. The Carey Act sought to foster private-state irrigation projects. It authorized the General Land Office, working in concert with individual western state governments, to award upwards of 1 million acres of the public domain to each semi-arid western state. The states were to administer the sale of this land, see that it was irrigated and developed into no larger than 160-acre farms sold to actual settlers only, with irrigation systems being built and operated either by individual states or by private enterprises that sold water to irrigators owning farms within the project. Project plans were to be submitted to the secretary of the interior. Although the Interior Department set aside nearly 4 million acres of the public domain for use by the states, outside of Idaho and Wyoming, the program had few demonstrably successful projects. Most western states did not possess the necessary administrative and financial resources to fulfill the Carey Act's promise and speculative investors often had insufficient capital to carry their irrigation projects to completion. By 1902 nearly 90% of the private irrigation companies developing Carey Act projects were nearing bankruptcy, and arid land development continued to lag further behind the number of acres set aside under the Carey Act. With the failure of the Carey Act, western proponents of irrigation, led by Senator Francis Warren of Wyoming, turned to the federal government, recommending federal construction of dams and reservoirs, leaving to the states the building of water distribution systems with allocation of water in accordance with state water right laws. When Congress failed to approve Warren's bill, Representative Francis Newlands of Nevada introduced a bill in 1901 providing for the federal government itself to construct irrigation projects in western states and territories.[124]

Some western representatives were hesitant of Newland's proposed legislation, fearing centralized authority and concerned that railroad and other more highly capitalized interests would benefit. Following extensive legislative negotiations involving President Theodore Roosevelt and debates over competing bills that proposed more modest programs and measures, Congress enacted the National Reclamation Act, or Newlands Act in June 1902. The act provided for the federal government, through the secretary of the interior, to withdraw un-entered and unoccupied public lands in 16 western states and territories: Arizona, California, Colorado, Idaho, Kansas, Montana, Nebraska, Nevada, New Mexico, North Dakota, Oklahoma, Oregon, South Dakota, Utah, Washington, and Wyoming. Upon these lands, Reclamation was to build dams, canals, and other irrigation works for the benefit of small family farmers settling on irrigable land within the designated reclamation project area.[125]

Appropriation of water was central to the newly-created federal reclamation program. To varying degrees, state and territorial law by the early 1900s required that claims to the use of water were to be recorded by filing notices of appropriation that would be perfected by applying the water

Rowley, *The Bureau of Reclamation: Origins and Growth to 1945*, Bureau of Reclamation, United States Department of the Interior, vol. 1 (GPO, 2006), 100-101.

so claimed to beneficial use. Such law also provided for adjudication of existing rights and prescribed methods for the determination, regulation, and control of the rights to water in the future. Some states, such as California, looked to the judiciary to settle claims of appropriators, while others like Wyoming relied upon a state board or a state engineer to adjudicate claims before the courts became involved.[126]

Reclamation supervising engineer and principal legal officer Morris Bien saw the US as having a unique status relative to all other appropriators, especially with regard to its reclamation projects.[127] At the first conference of Reclamation engineers and officials in Ogden, Utah, in September 1903, he articulated a position that shaped not only Reclamation's early approach to its projects, but also state and territorial water law in the early 20th century. Bien asserted that "[t]he control of the Federal Government over the public lands and the nonnavigable waters is that of a proprietor…." Put another way, as he did in a February 1904 memorandum prepared "in connection with the motion of U.S. to intervene in the case of Kansas v. Colorado" – an interstate dispute over the waters of the Arkansas River – the federal government was the "sole proprietor" of the public domain and was consequently "in sole control of the waters on such lands." Prior acts of Congress, specifically the 1891 right-of-way act and the 1897 organic act (which provided for the establishment of federal forest reserves), as well as the Newlands Act, "merely…recognize the system of state control, regulation, and recording" of water appropriation.

Bien found support in recent case law, most notably the US Supreme Court's ruling in favor of the federal government against the Rio Grande Dam and Irrigation Company. In the Rio Grande

Newell, Chief Engineer, comp., Department of the Interior, United States Geological Survey, Water Supply and Irrigation Paper No. 93 (Washington: GPO, 1904), 233; Morris Bien, "Proposed State Code of Water Laws," in *Proceedings of Second Conference of Engineers of the Reclamation Service with Accompanying Papers*, F.H. Newell, Chief Engineer, comp., Department of the Interior, United States Geological Survey Water Supply and Irrigation Paper No. 146. (Washington: GPO, 1905), 29-30, and Morris Bien, Supervising Engineer, U.S. Reclamation Service, to Mr. Samuel C. Wiel, November 1, 1905, in Samuel C. Wiel, *Water Rights in the Western States* (San Francisco: Bancroft-Whitney Company, 1905), vi-ix. This development is also traced in Dunbar, *Forging New Rights*, 73-132.

[127] Morris Bien was a University of California, Berkeley-trained engineer who later earned a law degree from Columbian University (predecessor to George Washington University in Washington, DC). In 1903, at the request of Reclamation Chief Engineer F.H. Newell, he came to the Reclamation Service from the General Land Office in 1903. Over the next 20 years, he led Reclamation's Land and Legal Division. His "expansive view of the authority and prerogatives of the Reclamation Service," laid out here with specific reference to the Rio Grande Project, is discussed more broadly in William Rowley's official history of the Bureau of Reclamation. See Rowley, *Bureau of Reclamation*, 147-151.

Dam and Irrigation Company case, the high court identified "'two limitations'" to state control of waters "'within its dominion.'" The Reclamation official highlighted the first:

> in the absence of specific authority from Congress a state cannot by its legislation destroy the right of the United States, as the owner of lands bordering on a stream, to the continued flow of its waters; so far at least as may be necessary for the beneficial uses of the government property.

This sentence, Bien maintained,

> indicates clearly that the United States has the right to the continued flow of the waters that have not already been appropriated, for there has been no specific authority granted to the States to infringe upon this right, Congress having merely authorized the acquirement of rights by prior appropriation, and the States having undertaken to regulate this right of appropriation.

A "similar view was expressed" in *Gutierrez v. the Albuquerque Land and Irrigation Company* (188 U.S. 545) concerning "the utilization of water for irrigation purposes in the Territory of New Mexico." Whether a state or territory was concerned, Bien saw "no reason why the same view should not be held…." He also pointed out that in *Howell v. Johnson* (89 Fed. Rep. 556), a dispute over the waters of Sage Creek, an interstate stream flowing from Montana to Wyoming, the US Circuit Court of Appeals "held in a similar way as to the rights of the Federal government over the unappropriated waters on the public domain."[128]

In 1904, following meetings with commissioners from Oregon and Washington seeking a "code of irrigation law," Bien was asked to "prepare a draft" of his own. Bien's draft reflected his views of federal dominion over public lands and waters, and made special provision for developing federal reclamation projects. As he explained to the second Reclamation conference in November 1904,

> In order that the State may obtain the full benefit of this work and prevent serious interference with and perhaps the entire abandonment of the projects to be investigated, it is provided that the water supply for such projects shall be reserved from general appropriation until the investigations of the Reclamation Service shall determine the precise amount required for the project, the remainder being then released from such reservation.

---

[128] Bien, "Relation of Federal and State Laws to Irrigation," 233-234; and Morris Bien, "Memorandum Concerning the Origin of the Right of Appropriation of the Public Domain," February 6, 1904, 1-5. ff. 762. Legal Discussions -General. Thru December 31, 1907., Box 223 760F- -762, Entry 3, RG 115, NARA Denver. Bien also discussed the Rio Grande Dam and Irrigation Company case and *Howell v. Johnson* in "Relation of Federal and State Laws to Irrigation," 234-236.

The "theory" behind this was

> that the State regulates the appropriation of water, exercising this power and holding the land in trust for the public, and that when the interest of the public are so directly involved as in these large irrigation projects, and when further, there is no element of individual speculation and profit in the construction the works, which are for the purpose of establishing the maximum number of homes on the land, it is the duty of every State to which the reclamation act is applicable to assist with every resource under its control.[129]

Bien insisted that the water supply for federal projects be protected against adverse claims by other appropriators. When Idaho Commissioner of Reclamation D.W. Ross "object[ed] to the proposition providing for the withholding of water for appropriation after the filing of the claim for it by the Reclamation Service," the supervising engineer argued in January 1904 letter to F.H. Newell, Reclamation's chief engineer, that Ross "fails to perceive…that a project might be completed and fail because of interference with water rights." Reclamation, Bien believed, would in "nearly every project…develop the whole water resources of the stream." It would "build better and must do more preliminary work on that account," and thus could not "compete with private parties as to time of completion…." Instead, with this "safety against speculative water filings," the federal government would "act in good faith and promptly release any claim to water which it does not propose to use."[130]

Elements of Bien's draft water code were ultimately reflected in the New Mexico territorial water laws under which Reclamation made its filings for the Rio Grande Project in 1906 and 1908. In 1905, the states of Colorado, Idaho, Montana, Nebraska, Nevada, North Dakota, Oregon, South Dakota, Utah, Washington, and Wyoming and the territories of Oklahoma and New Mexico all adopted new water codes. Each state and territory, as Bien noted to his colleagues at the second Reclamation conference in El Paso, made provision "for cooperation with the work of the United States in the construction of reclamation projects." In some instances, this cooperation extended to the "Necessary water supply" along the lines that he had proposed in his draft code.[131]

This was certainly true for New Mexico. Section 22 of its new water code stated:

> Whenever the proper officers of the United States authorized by law to construct irrigation works, shall notify the territorial irrigation engineer that the United States intends to utilize certain specified waters, the waters so described, and unappropriated at the date of such notice, shall not be subject to further appropriations under the laws of New Mexico, and no adverse claims to the use of such waters, initiated subsequent to the date of such notice, shall be recognized under the laws of the territory, except as to

> such amount of the water described in such notice as may be formally released in writing by an officer of the United States thereunto duly authorized.

Section 22, as Reclamation "assistant examiner," or attorney B.E. Stoutemyer later observed, did "not affirmatively provide that the U.S. shall acquire any rights by filing the notice described [in this section] but provides that after this notice is given, no other person shall acquire any right," which presumably may have been adverse to the federal government's.[132]

As noted in Opinion I, on January 23, 1906, pursuant to the 1905 code, B.M. Hall, the engineer supervising Reclamation's proposed reclamation projects in New Mexico, formally notified New Mexico Territorial Engineer David L. White through Reclamation's chief engineer of Reclamation's intent to construct the Rio Grande Project. The proposed project would "utilize…a volume of water equivalent to 730,000 acre feet per year requiring a maximum diversion or storage of 2,000,000 miner's inches. This water would "be diverted or stored from the Rio Grande River," in a 2 million acre-foot storage reservoir at Elephant Butte, "and diversion dams below at Palomas, Rincon, Mesilla and El Paso Valleys in New Mexico and Texas." Hall "requested" that these "waters…be withheld from further appropriation and that rights and interests of the United States" as contemplated in the 1905 territorial statute "be otherwise protected."[133]

Hall found this filing "unsatisfactory.". It was prepared on the basis of a form provided by the chief engineer, and was used not only for the Rio Grande Project but also for filings for four other proposed storage projects in New Mexico. In forwarding these for approval, Hall lamented that he "would have greatly preferred filing on <u>the entire unappropriated flow</u> [original emphasis] in each case."[134]

White, New Mexico Territorial Engineer, to B. M. Hall, Supervising Engineer, U.S. Reclamation Service, February 16, 1906. ff. 41, Box 6, Entry 3, RG 115, NARA Denver.

[134] B.M. Hall to Chief Engineer, Jan. 23, 1906; and Acting Chief Engineer to B. M. Hall, January 29, 1906. ff. 41, Box 6, Entry 3, RG 115, NARA Denver. The other projects were Hondo, Urton Lake, Carlsbad, and Las Vegas

Hall's preference was in keeping with the conception of the project's water supply that he articulated at the same Reclamation conference at which Bien discussed his water code. "The 180,000 acres of land to be irrigated" by the project, Hall informed his colleagues, "are in a long, narrow valley, and the return water from the irrigation of the upper valley can be rediverted on lands lower down the valley." The "Engle Dam," as the engineer called it,

> will hold back all of the floods and distribute them over the irrigation period of ten months. The water will be let out as needed and there will be no more disastrous floods below the dam. The river bed will never be dry at any time of year, as the return water from such a large irrigated area will form constant springs along the whole course of the river. Lastly, the supply of ground water for pumping will be greater and more constant than it now is, as the water entering the ground from the irrigated lands will form a constant supply.[135]

As noted above, Hall emphasized in both his study and in his presentation to the National Irrigation Congress that "[a]ll of the water that comes down the river is needed for irrigation. We can not [*sic*] afford to waste any of it."[136]

Responding to a question from a delegate regarding his proposal at the congress, Hall suggested that the water coming down the Rio Grande channel was a mix of surface and subsurface flows, and that Elephant Butte Dam would aggregate and control these waters for the beneficial use of downstream lands:

> Question – As I understand it, you propose to bring that water [from the dam] down the river channel, is that true, Mr. Hall?
>
> Mr. Hall – The water that you get now in the river, that is underneath the river bed and in the valley lands comes from the rains on the high lands and from floods down the river, and from the water that is flowing in the river at certain periods. The under gravel gets saturated. We estimate that when we get in that storage dam, that instead of injuring that condition we will better it. You will still get all of the rainfall that comes down below the dam; of course you will have the floods originated below the dam – they will not be disastrous floods – but you will at all times have a wet river bed, and considerable water flowing in it, while at present you have a river bed that is dry for five months – and longer this year – and I suppose the conditions ought to be better because of the percolation from the river bed more or less and there is always a flow from the rain-fall on the mesa.[137]

137 Mitchell, ed., *Official Proceedings*, 219.

The work of Charles Slichter, a hydrologist consulting with USGS, informed Hall's response. Interested in learning more about the potential water supply to be derived from groundwater sources, particularly in the Mesilla Valley, the Reclamation engineer had contacted Slichter in July 1904, before the National Irrigation Congress meeting. Hall observed in a letter to the hydrologist that valley irrigators who pumped groundwater had found a "plentiful quantity of water at a short distance from the surface." Pumps with a capacity of 1,000 gallons per minute could operate "continuously for weeks without lowering the water plane." The water table might be drawn down as much as seven feet, observed Hall, but returned to its former level "within a few minutes after the pump stops." He therefore sought to know:

> 1st:- How much water per square mile can be pumped continuously from the ground at lowest season, without lowering the water table?
>
> 2nd:- What were the sources of supply of this underground water? Does the water all come down the river bed, or is there a large quantity coming from beneath the mesa country on each side?
>
> 3rd:- If there is a continuous under-flow along the river bed, what is its volume in cubic feet per second, during the time that the river is dry, so far as surface flow is concerned?
>
> 4th:- The river bed of the Rio Grande consists of coarse sand to a depth of 70 to 100 feet and more. Just above El Paso the bed rock is limestone and there is a narrow pass where the bluffs are only 400 feet apart at the river level, and the bed rock is at a depth of about 100 feet. If a submerged concrete dam or weir were constructed here with its crest at the level of the river bed surface, how much underflow would be brought to the surface by such a structure?

These were not idle questions for Hall. As he stressed to Slichter,

> In order to irrigate the rich lands of the Rio Grande Valley in the Territory of New Mexico alone it will probably be necessary to use all of the floods and all of the underground water than can possibly be made available, and no time is to be lost in determining this vital question of underflow.[138]

The hydrologist began his work the following month, and by October, a month before the National Irrigation Congress, he had completed his pumping plant tests. Slichter found a direct connection between the river and the ground water in the Mesilla Valley, as he told the assembled delegates following Hall's presentation:

> I will not take up your time with any further matters except one point I observed in the Mesilla Valley, near Mesilla Park and Las Cruces, where we succeeded in measuring the amount of water lost by the river and contributed to the gravels. I think we have

[138] B. M. Hall, supervising engineer, to Charles E. Slichter, July 9, 1904. Folder 432 Rio Grande – Power Development – Slichters Reports as to Water Supply, Box 819 Rio Grande 430A – 458A, Entry 3, RG 115, NARA Denver.

> established that the source of the water that is used by the pumping plants is the river itself; that the origin of the ground waters or the supply of ground waters which are used by the pumping plant, is the water contributed to the river itself or lost by the river.[139]

Slichter made this same point when he published his work as USGS Water-Supply and Irrigation Paper No. 141, *Observations on the Ground Water of Rio Grande Valley* in 1905. According to his "observations of the test wells" in the Mesilla Valley,

> the ground waters in the Mesilla Valley originate in the flood waters of the river. During times of low water the river bed is so thoroughly covered with mud that probably only a small amount of water escapes in the sand and gravels of the valley. During the period of flood, when the scour is deep, the contributions of the river to the underflow reach a maximum, as at that time the greatest amount of water is available for this purpose.[140]

Federal reclamation plans for the Rio Grande Project thus from the outset anticipated utilizing all of the waters hydrologically connected to the river for the benefit of lands in New Mexico and Texas.

New Mexico's adoption of a more comprehensive irrigation code in 1907 opened an opportunity to expand federal claims to Rio Grande waters as Hall had wished. Stoutemyer had a direct role in shaping this new water code, especially with respect to "the work of the Reclamation Service," as he later informed Hall.[141] The new code further drew upon aspects of Bien's draft code. Section 40 of the 1907 act was virtually identical to Section 22 of the prior 1905 act, and the new law greatly expanded the authority of the territorial engineer. That office was soon filled by the appointment of Vernon L. Sullivan, who Stoutemyer noted to Bien in April was "well known to the Reclamation Service." Under Sullivan, the office placed greater emphasis on the public interest, ascertaining the validity of old claims to water rights, determining the quantity of

[139] Charles S. Slichter to F. H. Newell, USGS Chief Engineer, October 25, 1904. Folder 432, Box 819, Entry 3, RG 115, NARA Denver; Mitchell, *Official Proceedings*, 218; and Charles S. Slichter, *Observations on the Ground Water of Rio Grande Valley*, Department of the Interior, United States Geological Survey Water-Supply and Irrigation Paper No. 141 (GPO, 1905), 1.

[140] Slichter, *Observations*, 27. Slichter further noted "that a small portion of the underflow reaches the river valley from the mesa and foothills to the north and east of Las Cruces."

[141] Stoutemyer had met with the New Mexico territorial governor and attorney general to "outline a plan" for the "proposed Irrigation Code" in 1907. He later met with various members of the territorial assembly and local attorneys to discuss "some features of the bill, particularly as to the territorial engineer and his work…." Stoutemyer believed that the new law would "be satisfactory to the Reclamation Service," and that it was "a great improvement over the present [1905] law." See B.E. Stoutemyer, Assistant Examiner, to Mr. B.M. Hall, Supervising Engineer, El Paso, Texas, Proposed Irrigation Code in New Mexico, March 4, 1907. ff. 110-E9, Legislation, Irrigation Laws; Water Codes; Etc., New Mexico, Transfer Case, Box 92 110E-7- -110E-12, Entry 3, RG 115, NARA Denver. See also Clark, *Water in New Mexico*, 118-122.

unappropriated water in the public streams of the territory, setting reasonable timetables for completion of large projects initiated prior to the adoption of the new water code.[142]

In early November 1907, Stoutemyer wrote to Reclamation district engineer W.M. Reed, recommending a "supplemental" filing for the Rio Grande Project under the revised territorial water code. After reviewing copies of the various notices of water appropriations made for projects in the Office of the Territorial Engineer, the assistant examiner believed re-filing Reclamation's notice of water right appropriation for Elephant Butte Reservoir and the Rio Grande Project was prudent. Stoutemyer was concerned about the highly variable flow of the Rio Grande from year to year, a flow that could be as small as 200,000 af to upwards of 2 million af per year. Hall's 1906 filing for 730,000 af could thus become a significant limitation on project operations. If Reclamation desired "all the flow of the river," then Stoutemyer favored amending the notice of appropriation to read "all the unappropriated water of the Rio Grande and its tributaries," or if a definite number of acre-feet was required to "make it large enough to cover the entire flow of the largest year." He cautioned that the filing must be made in a manner that did not forfeit any of the government's existing rights under the 1906 notice, and recommended the inclusion of language that "clearly expressed" Reclamation's "intention to preserve our rights under the former notice…." Stoutemyer noted there were a number of water right applications in the Rio Grande drainage pending in the territorial engineer's office and undoubtedly more would be filed before the federal dam was completed.[143] Filing for all the unappropriated waters

No. 120; Approved March 19, 1907, *1907 Acts of the Legislative Assembly of the Territory of New Mexico, Thirty-Seventh Session* (Santa Fe: New Mexican Printing Company, 1907), 71-95; B. F. Stoutemeyer to Morris Bien, April 2, 1907. ff. 110-E9, Box 92, Entry 3, RG 115, NARA Denver; and Clark, *Water in New Mexico*, 118-123.

[143] B.E. Stoutemyer, Assistant Examiner, to Mr. W. M. Reed, District Engineer, U.S.R.S., re Appropriation Notices in New Mexico, Nov. 8, 1907. ff. 41, Box 6, Entry 3, RG 115, NARA Denver.

Several applications for water rights on the Rio Grande and its tributaries that had the potential to adversely affect the Rio Grande Project were filed in late 1907. Stoutemyer responded with formal protests against each application. One application was for a partially constructed irrigation project with two failed dams on the Rio Puerco that flowed into the Rio Grande near Albuquerque. Some $80,000 had been invested in the project, but no water had been applied to irrigate the land within the project. A second project was designed to divert water from the Rio Grande into the old La Union Community Acequia. This was a small project but its location was bothersome as it was located between Elephant Butte Reservoir and the Texas state line. The third, and largest, project was an application by the Red River Land & Water Company in Taos, New Mexico for development of a large irrigation project involving the La Plata River. Reclamation filed formal protests with the territorial engineer against the three applications, but later withdrew its protest against the Red River Land & Water Company as Reclamation's La Plata River project had been abandoned. B.E. Stoutemyer, assistant examiner, to W. M. Reed, district engineer, U.S. Reclamation Service, December 20, 1907; Morris Bien, Acting Director, to B. E. Stoutemyer, of the Rio Grande could check adverse competition by taking advantage of Section 28 of the 1907 law which declared that "If in the opinion of the territorial engineer there is no unappropriated water available, he shall reject the application."[144]

Reed forwarded Stoutemyer's recommendation to the Reclamation director and Bien, serving as acting director, responded in late November. He agreed that the 1906 filing for "a volume of water equivalent to 730,000 acre feet per year" under the 1905 act was an insufficient quantity of water and should be expanded to include a supplemental filing for "all unappropriated water of the Rio Grande and its tributaries" under the 1907 act while "reserving all rights under notice of January 23, 1906." The director's office was nonetheless of the opinion that Reclamation's 1906 filing was legally sufficient without further action. Bien specifically cited Section 22 of the 1905 act as constituting

> a waiver by the Territory or a release to the Federal Government of all territorial rights over unappropriated waters upon the completion of certain acts by agents of the United States. By Section 22 of Chapter 102 of 1905, and the notice filed in pursuance thereof, the Territorial Legislature has relinquished claim to the waters of the Rio Grande in favor of the Federal Government, and there remains to be done only the filing of amendment of the notice as suggested.[145]

As noted in Opinion I above, on April 14, 1908, Louis C. Hill, Hall's successor as supervising engineer of the Rio Grande Project, filed a "supplemental notice" with Sullivan, pursuant to Section 40 of Chapter 49 of the laws of the 37th New Mexico territorial assembly enacted in 1907. The filing declared that the United States intended to utilize "[a]ll the unappropriated water of the Rio Grande and its tributaries" to be diverted or stored at a storage dam located 9 miles west of Engle, New Mexico, with a capacity of 2 million af and at diversion dams below in Palomas, Mesilla and El Paso valleys in New Mexico and Texas. Hill requested that these waters be withheld from further appropriation and that the rights of the United States be protected.[146]

By the 1910s, however, Sullivan had embraced the idea that a large proportion of water diverted upstream would return to the Rio Grande – the "'return water theory,'" in the words of one Reclamation official – and thereby cause no material damage to the federal project. It was a stance that inclined the territorial engineer toward approval of most other filings for water on

[144] Expressly reserving all of the unappropriated water in excess of 730,000 af per year would also tie the hands of an unfriendly territorial engineer who might favor private enterprises, Stoutemyer noted. Stoutemyer to Reed, Nov. 8, 1907. ff. 41, Box 6, Entry 3, RG 115, NARA Denver.

[145] W.M. Reed, District Engineer, to The Director, U.S. Reclamation Service, November 15, 1907; Acting Director [Morris Bien] to Reed, November 29, 1907. ff. 41, Box 6, Entry 3, RG 115, NARA Denver.

[146] Supervising Engineer to Sullivan, April 14, 1908. ff. 41-D, Box 9, Entry 3, RG 115, NARA Denver.

the Rio Grande and its tributaries. After carefully examining the issue, Reclamation and the Interior Department came out against such applications. Federal authorities believed that these filings would have an adverse effect on the water supply for Elephant Butte Reservoir. They asserted that approval would set a "precedent for the general allowance of such claims and the ultimate destruction of the Rio Grande Project," abrogating treaty obligations to Mexico and contracts with water users dependent on the project water supply. These arguments, coupled with the Rio Grande "embargo" and the temporary 1929 compact, were sufficient to preclude significant developments upstream from Elephant Butte until the advent of the Middle Rio Grande Conservancy District's proposed project.[147]

Around this same time, Reclamation began asserting the right to "waste, seepage, spring, percolating water," as well as "return flows" from project operations. As noted above, in proposing the Rio Grande Project in 1904, Hall had suggested that the project would make use of "return water." Bien's 1905 draft water code had also provided for the appropriation "of seepage water…in the same manner as other waters…provided that the seepage can be traced to such works beyond reasonable doubt." The 1905 New Mexico territorial water law did not adopt such a provision, but Section 53 of the 1907 law did. There is no indication from the historical record reviewed that a formal filing for "seepage water" from the Rio Grande Project was made by either Reclamation or another party, pursuant to Section 53.[148]

Federal authorities nevertheless saw such waters as an essential element of the overall supply for the Rio Grande Project as it developed into the 1930s. In 1912, four years prior to the completion of Elephant Butte Reservoir, a board of US Army engineers reporting on the progress of the project to Congress recognized that "losses in the distribution system," estimated at 20

[148] Bien, "Proposed State Code of Water Laws," 33; and Chapter 49, Section 53, *1907 Acts of the Legislative Assembly of the Territory of New Mexico*, 89. Section 53 stated:

> In the case of the seepage of water from any constructed works, the owner of such works shall have the first right to use thereof upon filing an application with the territorial engineer as in the case of an original appropriation, but if such owner shall not file said application within one year after the completion of such works, or the appearance upon the surface of such seepage water, any party desiring to use the same shall make application to the territorial engineer, as in the case of unappropriated water, and such party shall pay to the owner of such works reasonable charge for the storage or carriage of such water in such works; Provided, That the appearance of such seepage water can be traced beyond reasonable doubt to the storage or carriage of water in such works.

percent, would occur as a result of "transit between the reservoir and the diversion dams." However, such "losses in transit," these engineers maintained would "be partly offset by the return seepage in upper parts of the valley, which will be available for diversion lower down."[149]

The following year, in April 1913, Reclamation chief engineer A.P. Davis prepared for the new secretary of the interior a report on the Rio Grande Project and its water supply, "Water Supply of Rio Grande, from Official Records, 1912," that again emphasized the importance of return flows:

> In the irrigation development of a large river system, such as the Rio Grande, it is undoubtedly wise to use a considerable proportion of the water in the upper valleys soon after it leaves the mountains and before it has had much opportunity to evaporate. As more tributaries reach the river, the additional water supply justifies other diversions lower down, which can also utilize return seepage from the upper valleys.[150]

The *Twelfth Annual Report of the Reclamation Service for 1912-1913*, released in 1914, offered this explicit statement with regard to the Rio Grande Project: "The United States claims all waste, seepage, spring, and percolating water arising within the project, and proposes to use such water in connection therewith." Such claims for other Reclamation projects were asserted in the *Twelfth Annual Report* as well.[151]

Subsequent Reclamation annual reports repeated this claim within the context of the project's "Irrigation Plan." The 1914-1915 report, for instance, described the Rio Grande Project as 19.7 percent complete exclusive of storage and 50 per cent complete including the storage works at Elephant Butte Dam. The project at that time served 47,160 acres. No stored water was yet available to project lands in 1914, only direct diversions, but the following year stored water was. The report indicated that the project would increasingly rely on water now being stored at Elephant Butte Reservoir. Its "Irrigation Plan" nonetheless included a claim to "all waste, seepage, spring, and percolating water arising within the project and proposes to use such water

[151] *Twelfth Annual Report of the Reclamation Service, 1912-1913* (GPO, 1914), 176. The plan for Colorado's "Uncompahgre Valley project," for instance, included "utilization of all the waste, seepage, spring, percolating, and return water arising within the project in the irrigation of lands in the Uncompahgre Valley." The irrigation plan for the Minidoka Project in Idaho used the exact same language as used for the Rio Grande Project. Newell, *Twelfth Annual Report*, 78 and 95.

in connection therewith." Three years later, in its 1917-1918 annual report, Reclamation again described its "Irrigation Plan," which was estimated as 40 per cent complete excluding Elephant Butte Dam and 66.4 per cent including the dam. The project at that time was serving about 90,000 acres. As in the 1914-1915 report, Reclamation asserted "claims [to] all waste, seepage, spring, and percolating water arising within the project…."[152]

In June 1919, Reclamation engineers Harold Conkling and Erdman Debler produced the first comprehensive assessment of the operations of the Rio Grande Project since the completion of Elephant Butte Dam, an assessment that emphasized the importance of "return flows." Conkling and Debler noted that given the long irrigation season in the basin (from February to November) "conditions are favorable for a reuse of almost the entire return flow." This return flow, according to the engineers, "consist[ed] of the transportation loss from canals and deep percolation from irrigated areas." Such waters were often captured in project drains, and brought back to the river channel. The engineers maintained that unlike with most projects, such return flow did not pose much of a problem "because of immediate rediversion by canal headings below," and in fact the lowest units of the project – San Elizario Island and the Tornillo District – could "probably use the entire return from the El Paso Valley." Although the amount of return flow from drains was then "uncertain," Conkling and Debler estimated 1.5 af/a per year. They further anticipated that other than the return flow from the Tornillo unit (which would be lost to the project because Tornillo was the lowest unit) and return flow during the winter (which would be lost because of lack of use) return flow would be fully utilized on project lands.[153]

Conkling prepared a separate memorandum report on the water supply for the San Luis Valley in Colorado, the Middle Rio Grande Valley in New Mexico, and the Rio Grande Project in New Mexico and Texas later that same month. He once again stressed that "on each…project conditions are favorable for re-use of return flow by the acreage on the lower end." With specific reference to the Rio Grande Project, the engineer reiterated the analysis he and Debler offered in their larger report. Conkling assumed 4.32 af/a for the diversion duty for the project, and

[153] Harold Conkling, Engineer, and Erdman Debler, Asst. Engr., Water Supply for and Possible Developments on Irrigation and Drainage Projects on the Rio Grande River Above El Paso, Texas, June-1919, 105, 111-112. ff. 302.31, New Mexico. Report dated June 1919 by Conkling and Debler on Water Supply for and Possible Developments on Irrigation and Drainage Projects on the Rio Grande River Above El Paso, Texas, transmitted by letter July 15, 1919, Box 262 302.28--302.31 A. NV-NM, Entry 7, RG 115, NARA Denver.

believed that given the basin's 10-month irrigation season, "almost all of the return flow may be utilized on the project if this duty can be obtained."[154]

The engineer took further note of the potential impact of non-federal groundwater development on project lands. He observed that the project was then assumed to serve 155,000 acres ("as estimated by the project office") but could be extended "privately [i.e., not by federal authorities] by pumping from ground water under assumed unirrigable acreage of 29,000 acres." "An additional draft of 70,000 acre feet annually," Conkling pointed out, would significantly worsen two prior years of shortages "without adverse effect in other years." Whether such expansion was advisable, he left to the "attitude of the government toward the question of allowing such possible shortages."[155]

Conkling's observations highlight the interrelationship of surface, subsurface, and return flows upon which the Rio Grande Project and many other federal projects had come to rely. The claim to waters other than surface flow was, as Assistant Attorney General William D. Riter wrote to John F. Truesdell, Special Assistant to the Attorney General, in July 1921, a "matter of policy…for the Secretary of the Interior to decide." In Riter's view, as evidenced by the assertions made over the years in "annual reports and otherwise," the Interior Department had "announced the intention of reclaiming seepage and waste waters of government projects for further use thereon." At the time of Riter's writing, Truesdell was apparently uncertain of the efficacy of this position. While acknowledging that the question was not entirely settled from a legal perspective, Riter noted that both the Justice Department's Public Land Division and US Solicitor General Alexander Campbell King gave "careful consideration" to the issue. Both believed that the federal government was on firm ground, provided that it took the position

> that when the Government makes an appropriation of water for a reclamation project, it is for the project as a whole, and not for particular farms comprising parts of the project; and the fact that a portion of the water, after serving to irrigate one farm escapes by seepage and finds its way to a piece of private land which happens to be inclosed [*sic*] by the project lands, is no evidence of an intent on the part of the Government to abandon that water, and does not in law amount to an abandonment; but the Government may recapture it and apply it to other parts of the same project.

[154] Memorandum, From: Engineer Harold Conkling, To: Chief of Construction, Subject: Water Supply – Rio Grande River, June 18, 1919 [hereafter Conkling Memorandum…June 18, 1919, 2 and 17. ff. 302.31, New Mexico. Surveys and Investigations. THRU 1929, Box 262, Entry 7 RG 115, NARA Denver. This report led to the modification of the Rio Grande "embargo" in 1923, as discussed in Opinion I.

[155] Conkling Memorandum, June 18, 1919, 17-19. ff. 302.31, New Mexico. Surveys and Investigations. THRU 1929, Box 262, Entry 7, RG 115, NARA Denver.

Riter later informed Reclamation chief counsel Ottamar Hamele, who steadfastly insisted upon the federal government's claim to these waters, "that the two Departments [Justice and Interior] are in accord."[156]

The federal government's assertions of ownership over waters returning to or arising on project lands further won judicial approval in federal and state courts in the early 1920s. In the case of *United States v. Ramshorn Ditch Co.*, which concerned waters initially diverted for the North Platte River Project in Nebraska, the federal Circuit Court of Appeals in November 1920 reportedly "sustained the right of the Government to reclaim seepage waters from a part of the reclamation project and use them again upon other lands of the same project." The federal district court in Idaho likewise sustained "the right of the Government to recapture and again use seepage waters" for lands in the Boise Project in Idaho in *New York Canal Co. (Ltd.) v. Bond and Weinkauf*. US attorneys made similar arguments in 1921 for the recapture and reuse of water previously diverted to serve lands in the Shoshone Project in Wyoming in *United States v. Ide et al.*, and *The Lincoln Land Co. et al. v. Weymouth et al.*[157]

Within the Rio Grande Project itself, Elephant Butte Irrigation District recognized the importance of what its president H.H. Brook termed "Drainage return flow." Brook, writing project superintendent L.R. Fiock to express concerns about the proposed inclusion of downstream lands in Hudspeth County into the project (discussed in Opinion IV below), observed that the "water supply of these arises from two sources":

> (1) The formally acquired unappropriated natural flow, flood and torrential waters of the Rio Grande including the ancient natural flow rights of the landowners of the present project and stored in the Elephant Butte Dam…
>
> (2) Drainage return flow artificially created by the expenditure of large sums by the United States under contract with the landowners giving a first lien on their land to secure repayment and which artificially created water supply, according to the law of the West, belongs to the landowners creating it to be used or disposed of by the United States as trustee for the benefit of the said land and water right owners.

Brook further asserted in his letter that "the right to drainage and seep water was reserved in the water right filings" for the project.[158]

Persistent interest in the issue of return flow into the late 1920s prompted Reclamation Commissioner Elwood Mead to suggest that an article be drafted for the agency's *New Reclamation Era* publication, whose readership included farmers and water users on federal reclamation projects. This article would discuss "the utilization of the return flow of water in connection with various irrigation projects." E.B. Debler, who had co-authored with Harold Conkling the 1919 study that identified the central importance of return flows to the Rio Grande Project, drafted the piece for the August 1927 issue.[159]

In "Return Flow and Its Problems on Reclamation Projects," Debler emphasized both the necessity of return flow while acknowledging the somewhat legally ambiguous status of such water. By way of introduction, he offered a detailed and inclusive definition of "return flow," that seemed to embrace not only previously diverted surface flow that made its way back to the stream within the project but also water underlying project lands:

> When water is applied to the earth's surface naturally through rains and snow or artificially by irrigation it is disposed of in a number of ways. A part passes away immediately or very soon as surface run-off or evaporation from the surface of the snow, ground, or from the exposed surfaces of plants which catch the moisture. Another part enters the ground is in part returned to the surface by capillary action to replace water evaporated from the surface. Some is taken up through the roots of plants and evaporated in the growth processes of the plant or stored in the plant structure and hauled away as a plant product. The remainder passes beyond the limit of capillary action and joins the mass of water existing under the ground surface, there generally to form part of a moving stream seeking a lower level, and reappearing in the form of seepage, springs, or artesian flow, the particular name popularly applied being dependent on the concentration of flow and the pressure with which it reaches the surface. The reappearance of these waters may be but a few hundred feet from the source thereof, or it may be several hundred miles, depending entirely on the ground structure and topography.

Return flow in "arid regions" was thus

[159] Memorandum, From: Commissioner [Elwood Mead], To: Chief Engineer, Denver, Colorado, Subject: Article for the New Reclamation Era on Return Flow, February 4, 1927. ff. 030.1, Box 33, Entry 7, RG 115, NARA Denver.

> the increase therein due to the application of irrigation water. This includes waters lost by seepage from canals and reservoirs, as well as waters applied by the irrigator to his land. Such return flow is in these places particularly prominent, as the return flow from precipitation prior to irrigation development is usually so small that the stream in its passage through the region actually loses a part of the water it brings from its mountain sources, at times drying up completely. With irrigation development such conditions are materially changed and living stream often result therefrom.[160]

Return flow was "heavily concentrated in the irrigation season," with "large irrigation areas underlain to great depths with permeable deposits" experiencing nearly continuous return flow. Debler estimated that 60 percent of the water diverted for irrigating crops became return flow "and reenters streams for further use unless intercepted." In some areas with diversions of up to 15 af /a return flow could be as much as 90 percent, and in other areas, concrete-lined canals and "favorable soils" could reduce return flow to 25 percent of the water diverted.[161]

Regardless of the amount, the engineer stressed the importance of return flow to federal reclamation projects. He argued that

> return flow augments the irrigation water available in the late summer after the stream flow, due to melting snows, has declined to less than the irrigation requirements of lands dependent thereon, and in that way serves a similar purpose as do storage reservoirs, but with the advantage that there is no loss from evaporation. In practice the effect has been to materially improve water rights on the lower portions of stream systems due to irrigation development on the upper reaches. In some cases the irrigation systems that have produced such return flow have been able to benefit in that less water is thereafter necessary to be passed down the stream to care for prior rights.

Debler pointed out that return flow was vital to the water supply for both federal projects and beyond.[162] For Texas specifically, he noted Hudspeth County water users (discussed in Opinion IV) who were not part of the Rio Grande Project were nonetheless "entirely dependent on return flow and waste water from project lands" upstream in the El Paso Valley. The El Paso Valley,

[161] Debler, "Return Flow and Its Problems on Reclamation Projects," *New Reclamation Era* (August, 1927), 124. ff. 030.1, Box 33, General Files, 1919-1929, Entry 7, RG 115, NARA Denver.
[162] According to Debler, both the Notus Division of the Boise Project in Idaho and the "west extension division" of the Umatilla Project relied upon return flows from upstream project diversions. On the North Platte Project in Wyoming and Nebraska, utilization of return flow likewise enabled more efficient use of stored water.

which was within the project, "in turn uses return flow from Mesilla Valley in New Mexico and Texas."[163]

The importance of return flows to established reclamation projects aside, Debler observed that state law was neither entirely decided nor altogether antagonistic to the issue. Early water codes in western states were "generally…framed before return flow became a recognized factor in irrigation supply" and consequently were "in a rather unsatisfactory shape" with "decisions…in conflict." "The general tendency, however," according to the engineer, "is to regard return flow in all of its forms recoverable by the agent producing it until it enters a stream which in its natural condition supplied irrigation diversions, when it becomes a part of such stream and subject to appropriation therefrom as are other waters of the same stream."[164]

As the states of Colorado, New Mexico, and Texas moved forward with negotiations for a compact, federal and state engineers alike recognized that the Rio Grande project water supply encompassed a range of surface and return flows, both of which influenced and were influenced by waters lying beneath the surface of project lands. As early as 1924, Reclamation measured the groundwater in the Mesilla Valley, in the later words of the Rio Grande Joint Investigation report, or *JIR*, "chiefly to derive the annual increment or decrement of ground water as a necessary factor in computing the annual consumptive use of water in the valley by the inflow-outflow method."[165]

In an internal Reclamation report on silt issues prepared by Rio Grande Project Superintendent L. R. Fiock for Reclamation's Chief Engineer in July 1931 (at the latter's request), the superintendent yet again emphasized the importance of return flows in his discussion of project operations. Fiock observed that the reservoir retained the "entire flow or discharge of the Rio Grande reaching [it]," and fully controlled and regulated releases "to meet irrigation demand requirements." According to the project superintendent,

> The water as released is drawn from the river at the various diversion throughout the project. Part of the amount diverted at each respective diversion point is compensated for by waste return and drainage recovered flow which mingling with the remaining released reservoir water as it passes through each succeeding project division is available for rediversion at the diversion points on farther down.[166]

[165] *JIR*, 62.
[166] L.R. Fiock, "Effect of the Operation of Elephant Butte Reservoir on the River through Rio Grande," 1-2, enclosed with Memorandum, From Superintendent [signed L.R. Fiock], To Chief Engineer, Denver,

This was especially true for lands below El Paso in Texas (as Debler had previously suggested):

> The flow required at El Paso to meet the normal irrigation requirements from April 1st to September 1st is from 800 to 1,000 second feet, this has required from 300 to 500 second feet in the river below Mesilla Dam, the difference being made up of waste return and drain recovery in the valley above between Mesilla Dam and El Paso….[167]

The surface flow of the Rio Grande captured by Elephant Butte and the return flow from diversions – i.e., "waste return and drain recovery" – also fed and relied upon the groundwater underlying the project, as New Mexico engineer John Bliss found in the mid-1930s. Conkling's observations about the potential impact of private groundwater pumping within the project notwithstanding, there were few investigations of groundwater below Elephant Butte prior to Bliss's study in 1935-1936. Slichter's study of the Mesilla Valley in 1904 had indicated a hydrological connection between the river and the valley's groundwater, but it was made prior to the construction of the Rio Grande Project. Reclamation had made "[m]easurements" in 1917 and 1918, however, as Bliss pointed out, "the data were obtained prior to drainage construction and are not applicable to present day conditions." In 1928, E.L. Barrows, working for the New Mexico State Engineer's Office, made "a preliminary seepage determination" for the stretch between Elephant Butte Reservoir and the Leasburg Diversion Dam, yet a planned follow-up study ultimately was not undertaken. Later that same year, a study of river hydrographs by Middle Rio Grande Conservancy District Designing Engineer R.G. Hosea found no "evidence of an invisible underground flow tributary to the river." He instead noted instead that "it is apparent that when the reservoir is not releasing water during the winter months, the Ft. Quitman flow is just about equal to the total drainage water from the project."[168]

Bliss's investigation, by contrast, identified "a direct relation of seepage to ground water and irrigation": at certain critical points between Elephant Butte and El Paso, underflow fed the groundwater table, providing basin lands with additional water that was recovered by project

drains and returned to the river channel for use on lands downstream. Bliss's study, presented to New Mexico State Engineer and Rio Grande Compact Commissioner Thomas McClure in February 1936 as "Report on Investigation of Invisible Gains and Losses in the Channel of the Rio Grande from Elephant Butte to El Paso" grew out of a suggestion for such an investigation made by Fiock in fall 1935. "[D]etermination of invisible gains and losses in the bed of the Rio Grande," as Bliss noted in his report, were "an important item in the study of the use and distribution of the waters of the river" yet "few such data are available below Elephant Butte Reservoir." Fiock had proposed that such an investigation be made prior to the construction of Caballo Dam; Caballo was a critical feature of international efforts to rectify the river's channel downstream from Elephant Butte, and pursuing a study before the dam was built would permit "work in the canyon above Percha Dam."[169] With the cooperation and assistance of USGS, Reclamation, and

---

[169] Caballo Dam, which today regulates the flow of the Rio Grande for flood control purposes, compensates for the loss of storage space in Elephant Butte due to silting, and generates hydroelectric power, came about as a result of international efforts to rectify the channel of the Rio Grande. The treaty of Guadalupe Hidalgo had established the river as the boundary between the two nations. Periodic high flow events since the treaty's ratification, however, altered the river's course, damaging land and property on both sides of the river and confusing the precise location of the border. Completion of Elephant Butte Dam in May 1916 brought greater control over the river, but the Rio Grande continued to meander into the 1920s. See Department of the Interior, *Fifteenth Annual Report of the Reclamation Service 1915-1916* (GPO, 1916), 324; and History and Development of the International Boundary and Water Commission, United States and Mexico, El Paso, Texas, April 1952, Revised April 1954, 45-49. Item 41, Box 1, MS042 International Boundary & Water Commission Records [MS042], UTEP Spec Coll.

A major flood in 1925 prompted the US and Mexico to enact a treaty eight years later that committed to the nations to stabilizing the river channel through the Rio Grande Rectification Project. A chief feature of this project was "the construction of [a] flood retention dam at Caballo, New Mexico" to enhance river regulation and prevent further meanders. Between 1934 and 1936, under pressure from local interests that had long sought a hydroelectric power facility at Elephant Butte as well as additional water for Rio Grande Project lands, the USBR in conjunction with the International Boundary Commission committed to building an 85-foot high and 4,250-foot long dam at Caballo. The proposed dam, according to the Interior Department:

> will, through flood control, become a highly important feature of the International Boundary Commission's plan for rectification of the Rio Grande in El Paso and Hudspeth counties, Texas, and it will provide an afterbay for the Elephant Butte Dam of the Bureau of Reclamation. Elephant Butte Dam stores water for the Rio Grande Federal Reclamation project in New Mexico and Texas. Provision of an afterbay will provide additional storage for project lands and will make it possible to install hydroelectric generation equipment at Elephant Butt Dam in the future.

Caballo was substantially completed in September 1938. History and Development of the International Boundary and Water Commission, United States and Mexico, El Paso, Texas, April 1952, Revised April 1954, 45-49. Item 41, Box 1, MS042, UTEP Spec Coll; Chronology – Caballo Dam Construction, February 1, 1933-November 30, 1935, December 16, 1935. ff. B-8.2.4.2, Conservation, Power, Diversion & Drainage Projects, Caballo Dam, 5 of 6. August 1935 thru March 1937, Box 5, Accession Number 076-69A-0928, Records of the International Boundary and Water Commission, Record Group 76 [hereafter RG 76], National Archives and Records Administration at Fort Worth, Texas [hereafter NARA Ft. Worth]; and the International Boundary Commission, Bliss embarked on the study in early January 1936 so as "to allow ground water and bank storage to reach a minimum" before water was released for the 1936 irrigation season."[170]

Bliss initially intended to examine that stretch of the Upper Rio Grande Basin between Elephant Butte and Ft. Quitman. Field work was to consist of two parties each making "complete series of measurements," guided by Reclamation engineers. Reclamation also installed temporary recording gages at Percha and Leasburg diversion dams, and brought into service the "operation station at Mesilla Dam…during the investigation." The methodology was like so:

> River stations were selected at frequent intervals to localize channel gains and losses in order to determine their probable sources or causes. No diversions were being made in any of the canals during the period of the investigation. To speed the work, all drain flows were measured but once, which was felt to be sufficient as these discharges vary but slightly.

Conditions during the investigation, however, forced alterations. The ongoing channelization program limited Bliss's work to the area between Elephant Butte and Courchesne, and unexpected rains soon after surveys began forced a "remeasurement of the entire river" – a "third series" of measurements starting February 1. High winds further affected this third series, "caus[ing] considerable variation in the discharge" as well as "preclude[ing] any reliable additional measurements." Despite these issues, survey work was completed by February 7, and the three sets of measurements were tabulated and averaged. Discharges were ascertained "by comparison of the three series, those apparently in error being discarded," and a "few measurements were corrected for change in river stage due to rain." Other corrections were made for the rising river stage below Elephant Butte and evaporation.[171]

Whatever the limitations of the study, Bliss felt confident enough in the work to make several significant observations about the complicated dynamics of underflow, groundwater, irrigation, and gains and losses in the Rio Grande that affected the project. He noted, for instance, that there was a "consistent increase in the canyon from the [Elephant Butte] Dam to the Dona Ana-

Sierra Country line," which Bliss ascribed "chiefly to underflow from the large intermittent streams entering [the Rio Grande channel] from the west."[172]

In the Rincon and Mesilla valleys, there were further fluctuations. "[W]ater lost in the Rincon Valley," the engineer asserted, "feeds the ground water of the surrounding lands and is recovered largely by the [project] drains." In the valley's Selden Canyon, Bliss identified a "small increase" attributable to "several short arroyos and from seeps in the vicinity of Radium Springs." In the Mesilla Valley, losses were greater "particularly in the section between Picacaho Flume and Mesquite, through which the large Del Rio Drain parallels the river at a short distance." Yet, "above Vinton bridge where the rivers enters a canalized section," he found an "increase." Bliss hypothesized that this was caused either by "underflow in the old river channels on the west side of the valley entering the present channel above the bridge," or "that the cut, which traverses an apparently undisturbed deposit of caliche and heavy clay, is effective in bringing a considerable underflow to the surface in this section."[173]

For the Mesilla Valley losses, Bliss made a further analysis of the data gathered. Taking a closer look at the drain measurements, the engineer noted that "much" of the Del Rio Drain flow was "drawn directly from the river channel through underflow." This was less true of the Montoya Drain and the "the Chamberine which drains the old river channels on the west side of the valley below Las Cruces."[174]

Attempting to develop curves for his study in comparison to others previously made, Bliss acknowledged that the data sets all differed from each other and those differences were not fully explainable. "It is impossible to account for the eccentricities of the curves prior to the present one, as little is known of the conditions of flow, irrigation, etc., at the time the measurements were made," he wrote. Bliss nevertheless argued that the curves demonstrated "a direct relation of seepage to ground water and irrigation." He proposed further study of "seepage during the non-irrigation period" so as to compare "against gains and losses found during the summer at a period when river and canal flows can be kept in a stable condition."[175]

This "direct relation of seepage to ground water and irrigation" was not addressed in the testimony given in the original action between Texas and New Mexico in the mid-1930s. However, Bliss, Fiock, and Texas engineers Raymond Hill and J.Q. Jewett all gave testimony acknowledging that the Rio Grande Project relied upon return flows. These were the flows that Bliss's study suggested intercepted groundwater, found their way to drains that fed the river

channel below Elephant Butte, and would have served, either wholly or in part, downstream lands in Texas.

Fiock was among the first to affirm the importance of all the waters arising on the Rio Grande Project before Special Master Charles Warren. Confirming Warren's understanding that "nearly double" the amount of water released from Elephant Butte Dam was needed to satisfy irrigation demands on the project, for instance, the project superintendent stated, "That is nearly, approximately the proportion, although we [federal Rio Grande Project officials and staff] do recover and redistribute water over and over down through the project."[176]

Fiock reiterated this point later when asked by Texas's attorney Frank Clayton, "Now, in the upper reaches of the river, the sand traps, or sluice ways, go back into the river and the water is rediverted below, is that correct?":

> With successive operating diversion points, and operating divisions down the river, as the Rio Grande Project has, that water is available and is counted on as part of the supply for the succeeding diversion below.[177]

The project superintendent not only testified that water released from Elephant Butte was used multiple times – such water variously identified by Fiock as "return flow from drainage," "drain water," "drain flow," or "drain runoff" – but also reported the same officially, outside of the courtroom. From one project operations report, dated November 7, 1934, New Mexico's attorney George Hannett read:

> …the demand for water was high due to continued dry warm weather. There was eight thousand five hundred twenty-eight acre feet delivered with a release of nineteen hundred acre feet from storage. In 1933 all water used for satisfying irrigation demands was return flow from drainage, which was rediverted into various canals as demands required.

When asked if he could recall making this report, the federal Reclamation official replied: "I don't recall the exact words, but that is the nature of our reports." [178]

Later still, under cross examination, when asked "How do you deliver water down from the dam, the Elephant Butte Dam, to serve the Tornillo canal for mixing for this Tornillo area?" Fiock responded:

> After being released from Elephant Butte reservoir, which is a hundred fifty miles above the heading of the Tornillo canal, it passes down the Rio Grande, which is utilized as a main carrier canal. In passing through the main Rio Grande Project, water is diverted at the successive diversion dams, and the drain discharge from the successive operating divisions of the Project discharges at the other end, lower end respectively of each division; and, each time one of the operating divisions is passed, then there is that much higher percent of drain water, so that when the water has arrived at Fabens, it has, some of it, been diverted and used, and is returned through the drains, as much as four times. A certain percent of it, of course, flows right on through, directly through the channel of the river.[179]

Under further questioning from Warren about the measurement of drain flow within the project, Fiock explained

> The drain flow over the Rio Grande Project constitutes a very important element in the irrigation supply, and must be taken account of in computing the release of water for irrigation from the reservoir, so we [Rio Grande Project staff] measure those drains frequently, that is once a week we meter the drains.[180]

The project superintendent stressed again the importance of such water to the overall project water supply when the special master asked him about the reported 1934 reservoir release, which was substantially larger than in prior years. Fiock noted that project staff had estimated the delivery at farms in the project to be 1.5 af/a and thus twice that amount had been released to ensure this delivery. "There are other things," he cautioned "to take into consideration" in making releases. One of these was the "drain runoff," which was "to make up part of the irrigation supply."[181]

Fiock was not alone in his conception of what constituted the water supply for the Rio Grande Project. Two other expert witnesses for the State of Texas similarly asserted the critical value of re-diverted water (to paraphrase Fiock). J.Q. Jewett testified that in his calculations "reservoir water" was "all the water reaching Courchesne station except the estimated tributary flow" – in other words, "a mixture of drain water and water released from Elephant Butte reservoir." When

asked a clarifying question as to whether this "reservoir water" was in fact the "reservoir release no matter how many times it has been used in the meanwhile," Jewett replied in the affirmative.[182]

Texas's engineering advisor Raymond Hill likewise acknowledged the project's reliance upon what Clayton called "drain waters," and expressed concerns for the practice owing the diminishing quality of the water as it moved downstream (see Opinion II above):

> [Clayton]: "The testimony adduced in the trial of this case has shown that drain waters in the valleys below Elephant Butte dam to Fort Quitman has been used and re-used progressively as you proceed down the stream. What is your conclusion, Mr. Hill, as to whether that is a proper use of those waters?"
>
> [Hill]: "As a general principal [*sic*], the use of drainage waters at the successive points of diversion from Elephant Butte down through the valleys is proper; however it is my judgment that the process has been carried to an extreme in the case of the Rio Grande Project, or in other words there has been too great a use of the drainage waters and that additional dilution of these waters would have been better, and taken over a longer period of time some greater dilution of those waters will be necessary in order to insure continued production of a profitable nature."[183]

New Mexico's own experts did not offer direct testimony on the issue of return flow. Bliss nevertheless acknowledged under cross-examination from Clayton that "drain water" was utilized on the lands below Elephant Butte:

> [Clayton]: "You mean to say that drain water that enters the river in the Rincon and Mesilla Valleys is not used?"
>
> [Bliss]: "It is altered – Yes."
>
> [Clayton]: "It is rediverted down below?"
>
> [Bliss]: "Yes"
>
> [Clayton]: "And used for irrigation?"
>
> [Bliss]: "Yes"[184]

The subsequent federal Rio Grande Joint Investigation likewise took note of the importance of return flows to the Rio Grande Project and lands beyond, as discussed in Opinion IV. With regard to groundwater, the *JIR* focused largely on the San Luis and Middle Rio Grande valleys.

Nonetheless, observations made in the report suggest federal engineers were aware of the relationship between surface and subsurface flows and groundwater in the basin. For the Middle Rio Grande, for instance, "Ground water in the Middle Valley" was identified as having several sources," including "seepage from canals" and "seepage from irrigated lands." For the basin overall, the *JIR* made three critical observations that underscore the complicated relationship between surface water and groundwater:

1) "extensive development of ground water for irrigation would add no new water to the Upper Rio Grande Basin…",
2) "recharge of the ground-water basins would necessarily involve a draft on surface supplies which are now utilized otherwise"; and
3) "The chief element to be considered in such a development [of groundwater] would be the redistribution of the availability and use of present supplies and the resulting effect upon the water supply of lower major units [i.e., the Rio Grande Project and beyond to Ft. Quitman]"[185]

The compact negotiations of the 1930s neither engaged with the issue of groundwater on Rio Grande Project lands nor the specific nature of the project water supply. However, as discussed above, both engineering advisors for New Mexico and Texas, Bliss and Hill, and the federal engineering advisor, Debler, were familiar with the project, its diverse water supply, and the hydrology of the Elephant Butte-Ft. Quitman section. The commissioners themselves believed the compact protected the project with the federal representative S.O. Harper insisting that the compact garnered "all water to which Federal irrigation projects are entitled." This was water that as a matter of longstanding Reclamation policy and practice included surface, subsurface, tributary, and return flows – waters arising on project lands.[186]

Reclamation's broad conception of the Rio Grande Project water supply arose from the impulse to assure sufficient water for the project. Reclamation authorities leveraged New Mexico territorial law, which recognized a unique standing for the United States with regard to reclamation projects, to protect and support the project's development. The project's aim from the outset was to utilize as much of the Rio Grande's flow, surface and subsurface, for the benefit of lands in New Mexico and Texas. In due course, Reclamation recognized that water released from Elephant Butte and diverted to project lands could be and necessarily must be reused. Such waters – characterized as "return flow," "seepage," "waste water," and "drain water" – were

[186] S.O. Harper, Chairman, Rio Grande Compact Commission, to The Honorable, The Secretary of the Interior, Washington, D.C., Re: Rio Grande Compact, March 26, 1938, 2. ff. 032.1, Box No. 936, Entry 7, RG 115, NARA Denver.

captured in project drains. These waters, as New Mexico's engineering advisor John Bliss later found and explained to New Mexico State Engineer and Rio Grande Compact Commissioner Thomas McClure, intercepted basin groundwaters, joined with tributary flows before re-entering the river's channel, and ultimately supplied lands downstream within the project and (as discussed in Opinion IV) below the project. The engineers most involved in developing the compact thus knew and understood that the Rio Grande Project's water supply included more than the surface flow stored in Elephant Butte. Waters arising on project lands, including groundwater, tributary flows, and return flows, however defined, were as essential as storage waters to the project.

Opinion IV: Delivery of water by New Mexico to San Marcial, under the terms of the 1938 Rio Grande Compact, constituted the delivery of water to serve lands in Texas within the Rio Grande Project as well as downstream to Fort Quitman.

As discussed in Opinion III above, water released from Elephant Butte Reservoir and water arising on the Rio Grande Project was used and re-used throughout the project. Reclamation and other federal, state, and local authorities considered such waters part and parcel of the project's water supply. By the 1920s, these waters had also become important to several thousand acres of Rio Grande bottomlands that stretched downstream from the end of the project through Hudspeth County to Fort Quitman, an area historically known as the "Fort Hancock district." Under a Warren Act contract, in exchange for relinquishing claims to Rio Grande flow, Hudspeth county landowners – organized as Hudspeth County Conservation and Reclamation District No. 1 in 1923 – obtained the use of waters captured by Elephant Butte, used on project lands, and ultimately passed out of the project. This extra-project water supply figured into the technical studies leading to the 1938 compact, and thus formed part of the 790,000 af "normal release" from the federally-controlled Elephant Butte Reservoir that was apportioned to Texas for lands above Ft. Quitman by the compact. In an acknowledgement of federal control over the Rio Grande between Elephant Butte and Ft. Quitman, encompassing lands both within and without the Rio Grande Project, the compact commissioners eschewed a state-line delivery by New Mexico for Texas and instead made the delivery point for the Rio Grande water apportioned to Texas at San Marcial, above the federal reservoir.

Reclamation plans for the Rio Grande Project initially did not consider land beyond the El Paso Valley. As discussed in Opinion I above, the project's first supervising engineer, B.M. Hall, conceived of a project to water arid lands in southern New Mexico and the El Paso Valley in Texas. Reclamation subsequently executed contracts for the delivery of water to two local water users' associations, and later their successors, Elephant Butte Irrigation District (EBID) in New Mexico and El Paso County Water Improvement District No. 1 (EP #1). Reclamation's *Twelfth Annual Report* for 1912-1913 also plainly described that the project was to serve lands in the Palomas, Rincon, and Mesilla valleys in New Mexico, and the El Paso Valley in Texas.[187]

Nevertheless, as construction of the federal project advanced in the late 1910s, individual Hudspeth County landowners began diverting water that flowed down the Rio Grande from the project. Reclamation, in response, executed annual rental contracts with these water users to deliver water into the Rio Grande "at the end of the project limits where four private and community ditches have their heads." This was done, as project superintendent L.R. Fiock later

---

[187] *Twelfth Annual Report*, 176.

explained, "under the theory that it was project developed water" – that is, having originated out of the project's water supply, as surface flow, drainage water, or return flow.[188]

By the early 1920s, according to one Reclamation estimate, this surplus water irrigated more than 10,000 acres downstream of the project, and area landowners sought to obtain a still greater supply. In April 1923, they met with Reclamation director A.P. Davis during his visit to the El Paso Valley to discuss extension of the project's Tornillo Canal to serve their lands. The current Hudspeth-area diversion works were insufficient for taking water from the Rio Grande unless there was "a very large excess flow." Davis, although concerned that additional project releases would encourage Mexican diversions on the opposite side of the river that would diminish the project water supply, was sympathetic to the Hudspeth landowners. Observing that their irrigated lands were "mainly in large holdings" and there was "no organization…thru which to act," the director suggested the formation of a separate "irrigation district" and subdivision of agricultural holdings so as to conform with federal reclamation law. Davis also charged project officials to investigate the cost of extending Tornillo Canal, but he made no commitment to encumber government funds to do so. He further cautioned Acting Director F. E. Weymouth that any renewal of the surplus water contracts must contain "proper provision protecting the Government against adverse diversion, and against initiating a right to permanent water supply. However, as Rio Grande project manager L.M. Lawson recalled afterwards, Davis was of the opinion that "surplus waters recovered at the end of the project" would probably "take care of lands now under cultivation."[189]

Hudspeth-area landowners acted quickly following their meeting with Davis. In August, they organized their own water district, Hudspeth County Conservation and Reclamation District No. 1 (HCCRD #1). That same month, the district's new president W.T. Young addressed petitions to both the secretary of the interior and EP #1 seeking to join the project through consolidation with the El Paso district.[190]
